As an example of an augmentation of power producing an opposite result from that which was intended, Mr. Mills mentioned two vessels called the "*Tartar*" and the "*Rover*," built by him and his (then) partner, Mr. Charles Wood. They were each of about two hundred and twenty tons register, built from the same draught, and in every respect as similar as possible—except that the engines, which were by the same maker, were respectively of one hundred and seventy, and one hundred and thirty horses power; yet whenever they worked together, the one with the smaller power proved herself the faster vessel, either in a calm, with the wind, or even against it. The "*Achilles*," Liverpool steamer, which lately had an addition of thirty feet to her length, and eighteen inches to her breadth, augmenting the tonnage about one-fifth, had improved her speed upwards of one mile per hour, although she carried a much heavier cargo than before.

He had built a vessel of five hundred and sixty tons register, with engines of one hundred and thirty horses power on board—a proportion of power to tonnage of one to four; the stowage for cargo was ample; the accommodations for passengers excellent. She drew little water, and her speed was much greater than vessels of double her power. Yet in spite of all this, the vessel could not find a purchaser, because the power was not nominally large.

It would be asked—why, with these and so many similar instances, such a system was continued? It was not likely that the engineers would complain of having orders for large engines; and there were certain dimensions prescribed for the vessel, to which the ship-builder was under the necessity of conforming.

The chief cause of mischief, however, was the fiat of the public. It was believed that a great power would remedy want of speed and all other evils, and it was found indispensable for ensuring the confidence of travellers. Hence, the shipowners, who depend upon the public for support, were obliged, against the conviction of their experience, to keep up the errors occasioned by ignorance.

The President observed, that the condemnation of large power should not be carried too far, as experience alone had produced the increase of weight, strength, and power, of the present engines, compared with those of the early steamers which were built, instancing the *Halifax Packets* (Cunard's), which, with their great power in proportion to tonnage, had performed their duties satisfactorily.

Mr. Mills explained that the Halifax Packets were built for the especial purpose of carrying the mails only, to perform the voyage in a given time,—about twelve days. The engines were built by Mr. Robert Napier, after the model of those of the "Great Western," which used their steam expansively; similar provisions had been made in the Halifax Packets, but the expansion valves were seldom used.

Mr. Field agreed with the principal part of Mr. Seaward's paper, but he would prevent an erroneous conception of the term *overpowering* a steamer. A vessel could not have too much power, provided that power could be advantageously applied, without causing too deep an immersion. A good result could be produced only by keeping a proper proportion between the machinery, the vessel, and the paddle wheels, and immersing the hull of the steamer only as deep as the true lines of draught.

Mr. Vignoles observed, that in this country the reputation of engineers depended upon the commercial success of the works they engaged in. An erroneous public opinion might have influence at present; but if the engineer and ship-builder would determine to break these trammels, and produce such vessels as should force conviction upon the public mind by the speed attained, and show the proprietors the consequent commercial advantage, the present system would soon be abandoned.

Mr. Parkes eulogized Mr. Seaward's candour in describing the errors in the first construction of the engine on board the Vernon; more was frequently to be learned from failures than from successful efforts, and no communications to the Institution would be so useful as those which gave accounts of defective design or construction, with the details of the methods adopted for remedying the defects. He directed attention to the performances of the "Great Western" steam ship, which at least equalled those of the Halifax Packets, without the disadvantages of being unable to carry cargo, or of shipping so much sea, when the weather was foul. The important feature of economy of fuel on board the "Great Western" might be in part attributed to the use of steam expansively. It was very desirable that the Institution should possess very full drawings and a description of the "Great Western," so as to be enabled to compare them with those of the Halifax Packets, which had been promised by Mr. George Mills. He would impress upon manufacturers of marine engines the necessity of adopting a correct and uniform nomenclature of the power placed on board steam vessels. The nominal sailing power did not accord with any calculation.

Mr. Field believed the Table of Velocities calculated by Mr. Seaward to be very nearly accurate. The speed of the "Great Western," when loaded to her proper draught, has been as high as $13\frac{8}{10}$th miles through still water. There was an error in the alleged speed of Cunard's vessels; they reached Halifax in ten days, Boston in three days more, and then had still one day's voyage to New York. The average duration of the voyages of the "Great Western," was about fourteen days and a half. If two hundred tons were deducted from the tonnage of the "Great Western" for cargo and the accommodation for the passengers, she would then be similar to the Halifax Packets. The engines of the "Great Western" were nominally estimated at four hundred horses power, and the average consumption of fuel was twenty-six tons every twenty-four hours.

During the discussion, Mr. Cubitt had calculated the following Table, showing the rates of velocity which would be attained by substituting engine power, with its consequent weight of one ton per horse power, for cargo, so as to preserve the draught of water the same in all cases.

Mr. Seaward remarked, that his Table of power and velocities was corroborated by Mr. Cubitt's—the practical results verified both. The great difference between the "Great Western" and the Halifax Packets consisted in the better adaptation of weight and power to tonnage, and the more economical consumption of fuel of the former over the latter—the one carrying cargo and passengers, the other only the engines and fuel, yet the "Great Western" travelled farther with the same quantity of fuel.

Table showing the power required to obtain various rates of speed in a steam vessel, where the total weight of cargo and engines remains in all cases the same, and in which, with a power of 30 horses, a speed of 5 miles per hour is obtained; the total weight carried being in all cases 1000 tons, and the engines weighing 1 ton per horse power.

Weight of Cargo.	Weight and Power in Tons and Horse Power.	Relative speed.	Speed in miles per hour.

In answer to a question relative to American steam boats, he believed that the build of the river steamers was very peculiar: some of them had engines of 600 horses power on board, yet they drew only four feet of water, whereas a sea-going steamer with that power would draw at least 16 feet. As far as he could ascertain, the actual well-authenticated speed did not exceed 14½ geographical miles per hour through still water. The fuel consumed could not be ascertained, as it was chiefly wood, taken on board at the places of stoppage; there was a great consumption of steam at a very high pressure. Their machinery was not heavy, and was specially adapted to the vessels. Daily improvements were making in the form of vessels in England, and when high pressure steam and light engines were applied to vessels of a different form from those at present constructed, the speed must be increased. Some vessels were now building on the Thames of an extremely light construction, with tubular boilers, and the weight of the machinery would be only eleven cwt. per horse power.

February 16.—The President in the Chair.

The following were balloted for and elected: William Radford, Henry Alexander, John Gandell, William Bagnall, Thomas Bagnall, and James Bagnall, as Associates.

"*Practical Observations on the management of a Locomotive Engine.*" By Charles Hutton Gregory, Grad. Inst. C.E.

The working of a railway involves a number of practical details with which it is of great importance that the young engineer should make himself thoroughly acquainted. Of these, one of the most important is the management of a locomotive engine.

The communication consists of practical remarks on this subject from the author's individual experience; it is divided into three sections:—1st. The management of an engine in the Station. 2nd. On the Road. 3rd. In cases of accident.

Section 1st—contains instructions as to the state in which an engine should be kept in the station, and a detailed account of the examination to which it should be subjected previously to its starting with a train. The principal working parts are mentioned, with the particular attention due to each; and the proper supplies of oil, coke, and water, enumerated. The section concludes with a list of the articles necessary to be carried on the tender.

Section 2nd—enters fully into the leading points of engine driving. After attending to the precautions to be taken in starting, the author points out the proper position of the engineman, and the attention which he should give to the state of the rails, the safety of the train, and the working of the engine. Instructions are then given for the production and maintenance of a sufficiency of steam, by the judicious management of *water* and *fuel*. The proper height of the water in the boiler is described both under general and particular circumstances, and the times at which it should be supplied: with observations on priming, on the action of the pumps, and their irregularities.

This is followed by remarks on the proper manner of supplying coke, the extent and periods of that supply, the proper height of the coke in the fire box, &c.

Instructions are given for economizing and rendering the steam most efficient; the mode of treatment to be adopted in case of extraordinary deficiency or excess; rules for stopping and starting at the stations; general hints in case of the wheels slipping, and of the heating of the axles; precautionary measures to be adopted on curves, steep inclines, dangerous parts of the road, &c.; the care necessary for an engine at the end of each journey, and when finishing its work for the day.

Section 3rd—describes those accidents to which engines are most liable when running, and the steps to be taken under the circumstances: viz.—The bursting of a tube, the lagging of the boiler catching fire, the failing of the feed pumps, the breaking of an axle, of a spring, or of the connecting rod, the disconnexion of the piston, of the eccentrics, or any of the slide valve gear, the fracture of the strap of the slide valve, and the engine running off the rails.

"*Observations on the effect of wind on the suspension bridge over the Menai Strait, more especially with reference to the injuries which its roadways sustained during the storm of January* 1839." By W. A. Provis, M. Inst. C.E.

In the month of December 1825, when the original construction of the bridge was nearly completed, several severe gales occurred, and considerable motion was observed, both in the main chains and in the platform of the carriage ways. It appeared that the chains were not acted upon simultaneously, nor with equal intensity; it was believed, therefore, that if they were attached to each other, and retained in parallel plains, the total amount of movement would be diminished.

On the 30th of January, and on the 6th of February, 1826, some heavy gales again caused considerable motion of the chains and roadway, breaking several of the vertical suspending rods, and of the iron bearers of the platform.

These bearers were constructed of wrought iron bars, overlapping each other, and bolted together, with the ends of the suspending rods between them, for the purpose of giving stiffness to the structure. The flooring planks were bolted to the bearers, and notched to fit closely round the suspending rods, which were thereby held almost immoveably in the platform.

It was observed, that the character of the motion of the platform was not that of simple undulation, as had been anticipated, but the movement of the undulatory wave was oblique, both with respect to the lines of the bearers, and to the general direction of the bridge. It appeared, that when the summit of the wave was at a given point on the windward side, it was not collateral with it on the leeward side, but, in relation to the flow of the wave, considerably behind it, and forming a diagonal line of wave across the platform.

The tendency of this undulation was, therefore, to bend the bearers into a form produced by the oblique intersection of a vertical plane with the surface of the moving wave. The bearers were not calculated to resist a strain of this nature: they therefore were fractured generally through the eyes on each side of the centre foot-path, at the point of junction with the suspending rods, which being bent backward and forwards where they were held fast at the surface of the roadway, were in many instances wrenched asunder also.

The means adopted for repairing these injuries, and for preventing the recurrence of them, were, placing a stirrup, with a broad sole, beneath each of the fractured bearers, attaching it by an eye to the suspending rod, cutting away the planking for an inch around the rods, and at the same time bolting, transversely, to the underside of the roadway, an oak plank, fifteen feet long, between each two bearers, for the purpose of giving to the platform a greater degree of stiffness, combined with elasticity, than it previously possessed. The four lines of main chains were also connected by wrought iron bolts passing through the joint plates, and traversing hollow cast iron distance pieces, placed horizontally between the chains.

The effects of these alterations were so beneficial, that little or no injury occurred for nearly ten years. On the 23rd of January, 1836, a more than usually severe gale caused violent undulation of the platform, and broke several rods. There can be little doubt that ten years' constant friction, combined with the shrinking of the timber, had relaxed the stiffness of the platform, and permitted an increased degree of undulation. The gate-keeper described the extreme amount of rise and fall of the roadway in a heavy gale to be not less than sixteen feet; the greatest amount of motion being about half way between the pyramids and the centre of the bridge.

In consequence of the injuries sustained during this gale, the author and Mr. Rhodes were instructed to give in a report upon the state of the bridge, and on any repairs or additions which might appear desirable.

The result of the examination was satisfactory; the whole of the masonry, the main chains, their attachments to the rock, the rollers and iron work upon the pyramids, and all the principal parts of the bridge, were as perfect as when first constructed; it was, however, recommended, that "a greater degree of rigidity should be given to the roadways, so that they should not bend so easily under vertical pressure."

The bridge remained in the same state until the hurricane of the 6th and 7th of January, 1839; during the night of the 6th, all approach to the bridge was impracticable; the bridge-keeper, however, ascertained that the roadways were partially destroyed; and he in consequence traversed the strait in a boat in time to prevent the down mail from London driving on to the bridge.

When the day broke, it was found that the centre foot-path alone remained entire, while both the carriage ways were fractured in several places. The suspending rods appeared to have suffered the greatest amount of injury; out of the total number of 444, rather more than one-third were torn asunder; one piece, 175 feet long, of the N.E. carriage way, was hanging down and flapping in the wind; much of the parapet railing was broken away; the ties and distance pieces between the main chains were destroyed; the chains had resisted well in spite of the violent oscillation they had been subjected to, to such an extent, as to beat them together and strike the heads off bolts of three inches diameter.

Means were immediately adopted for restoring the roadways; and so rapidly was this effected, that in five days carriages and horses passed over, while foot passengers were not at any time prevented from crossing.

The account of the restoration of the bridge, communicated by Mr. Maude to the Institution, is then alluded to.

The substance of the report of the author to the Commissioners of Her Majesty's Woods is then given, and a review of the proposals made by Mr. Comms, Colonel Pasley, and others, relative to the restoration.

The opinion of Colonel Pasley, "that all the injuries which have occurred to the roadways of Suspension Bridges must have been caused by the violent action of the wind from below," is then examined, and reasons given for the author's dissent from that opinion.

The action of the wind upon the Conway and Hammersmith Bridges, is next examined; and from the amount of oscillation observed in all suspension bridges, the conclusion is arrived at, that winds act strongly and prejudicially on the fronts as well as on the horizontal surfaces of the platforms of suspension bridges, and that the effect of winds is modified and varied by the nature of the country, and the local circumstances connected with each individual bridge. Although differing in opinion with Colonel Pasley as to the general cause of injury to suspension bridges, the author agrees with him in the propriety of giving increased longitudinal rigidity to their platforms, to prevent or to restrict undulation. He advised its adoption in 1836, and applied his plan of stiffening by beams, in 1839. He preferred beams to trussed framing, on account of the facility with which the former could be increased in number, to obtain any requisite degree of stiffness, and because he feared that trussed frames could not always be kept firmly in their true vertical positions.

A drawing showing the injuries sustained by the platform during the hurricane of 1839, accompanied the communication.

Mr. Cowper was of opinion, that the real cause of injury to suspension bridges was the vibration of the chains and roadway. The whole suspended part, when acted upon by the wind, became in some measure a pendulum, and if the gusts of wind were to recur at measured intervals, according either with the vibration of the pendulum, or with any multiplies of it, such an amount of oscillation would ensue as must destroy the structure. He illustrated this proposition by a model with chains of different curves, and at the same time pointed out the efficiency of slight brace chains in checking the vibration.

Mr. Brunel agreed with Mr. Cowper in his opinion of the cause of injury to bridges, and with the propriety of applying brace chains, for preventing the vibration. He then alluded to the introduction of lateral braces in the bridge designed by Mr. Brunel, senior, for the Isle of Bourbon. He had been at the Menai Bridge during a severe storm, and had particularly noticed the vibration of the chains with the accompanying undulation of the platform. The force of the wind was not apparently from beneath; it appeared to act altogether laterally. The chains were too high above the roadway; their vibration commenced before the platform moved: the unequal lengths of the suspension rods then caused the undulating motion. His attention had latterly been much given to the subject on account of the Clifton Suspension Bridge, now erecting under his direction. The span would be seven hundred feet, and the height above the water about two hundred feet. He intended to apply the system of brace chains at a small angle to check vibration. To two fixed points in the face of one pyramid would be attached two chains, each describing a curve horizontally beneath the platform, touching respectively the opposite sides of the centre of the bridge, and thence extending to similar points on the other pyramid: there they were attached to two levers, the ends of which were connected with a counter balance of about four tons weight appended to each: these weights would hold the chains sufficiently extended to enable them to resist the lateral action of the strongest winds without their being so rigid as to endanger any part of the structure. By this contrivance the platform would be kept firm, which was the chief point to be attained.

In all suspension bridges the roadways had been made too flexible, and the slightest force was sufficient to cause vibration and undulation. The platform of the Clifton Bridge would have beneath it a complete system of trough-shaped triangular bracing, which would render it quite stiff. He was an advocate for bringing the main chains down to the platform, as at the Hammersmith Bridge, and for attaching the bearings to the chains at two points only; when they were suspended by four rods, it not unfrequently happened that the whole weight of a passing load was thrown upon the centre suspension rods, and the extremities of the bearers were lifted up and relieved from all pressure. The extent of the expansion and contraction of the chains was a point of importance. In the Menai Bridge the main chains on a summer day would be as much as sixteen inches longer than in a winter's night. At the Clifton Bridge the difference under similar circumstances would be about twenty inches. The whole expansion of the back chain beyond the pyramids must be thrown into the suspended part. He would prefer having only one chain on each side of the bridge, and that chain much stronger than is usually adopted, but in deference to public opinion he had put two; he believed that they rarely expanded equally, and hence an unequal distribution of the weight of the roadways upon the suspension rods occurred. A rigid platform would in some degree prevent this, but he had endeavoured to lessen the effects of unequal expansion by arranging a stirrup at the top of each suspending rod, so as to hold equally at all times upon both the chains, and thus cause each to sustain its proportion of the load.

Mr. Seaward had never seen the force of wind exerted at regular intervals, as Mr. Cowper had supposed; if the gusts were repeated at such intervals, no suspension bridge, nor any elevated shaft or chimney in masonry, could resist them.

Mr. Rendel believed that the errors committed in the construction of suspension bridges had principally arisen from engineers theorizing too much on the properties of the catenary curve, without attending sufficiently to the practical effects of wind in the peculiar localities in which the bridges were placed. He could not agree with Mr. Cowper in his view of the intermittent action of the wind, or the vibrating of the chains. Observation had led him to conclude that, in the positions in which suspension bridges were usually placed, the action of the wind was not uniform; for instance, it would act at the same moment on the upper side of one end of the roadway, and on the lower side at the other end. In this case, unless the platform possessed a certain degree of rigidity, undulation was induced and oscillation ensued. Braces and stays would not counteract this—nothing but a construction of platform, which made it in itself rigid by some mode of trussing, could withstand this kind of action. He agreed with Mr. Brunel in his idea of reducing the number of the suspending chains. At the Montrose Bridge, which was 432 feet span, he had endeavoured to avoid all complexity of contrivances by adopting a complete system of vertical diagonal trussing, which was ten feet deep—five feet above, and five feet below the platform—so as to insure rigidity, and to produce that solidity which was essential for preventing undulation and oscillation.

Mr. Cowper reverted to the motion which he had found to be so easily produced by repeatedly exerting a small force at measured intervals against the main chains of the Hammersmith Bridge. He conceived that if the chain oscillated, the roadway must oscillate also.

Mr. Rendel contended that the motion produced by the impulses communicated by Mr. Cowper to the chain resolved itself into undulation, and not oscillation. He could not understand the advantages of the trussing adopted at the Hammersmith Bridge: it appeared to him that its tendency was, on the passage of a heavy weight, to relieve four out of five of the suspending rods from their due proportion of the load, and to throw it upon the fifth rod. His object in the construction of the framing of such platforms had always been to spread the load quite equally, and rendering it rigid by means of vertical trussed framing, to prevent the undulation which was the primary cause of oscillation. He would distinguish clearly between the two motions, and say, that undulation was a motion in the direct line of the platform, and that oscillation was a motion at right angles with it. Vibration was identical with undulatory action.

Mr. Donkin conceived that a good system of trussed framing could alone prevent undulation or oscillation; if the framing were placed vertically, its tendency would be to prevent undulation; if placed horizontally, to prevent oscillation: now, as Mr. Rendel had given it as his opinion, that the latter action resulted from the former, the system of trussing adopted by him at the Montrose Bridge would appear calculated to obtain the desired end. A slight exertion of force would produce a perceptible undulation, and a certain degree of vibration would result from the natural elasticity of the materials.

Mr. Seaward remarked, that the degree of oscillation would appear to depend in some measure upon the distance at which the platform was suspended beneath the chains, and upon the distance between the points of suspension of the main chains; if the platform were rigidly held at the extremities, the motion would be vibratory, and not amounting to undulation.

The railway tickets on the Manchester and Leeds line, invented by Mr. Edmondson, are printed by a machine which gives each a progressive number, and arranges them in order. Two boys lately printed 10,000 tickets in four hours.

THE PRESIDENT'S CONVERSAZIONE.

The general conversazioné of Mr. Walker, the President of the Institution of Civil Engineers, took place on Wednesday evening, 12th ult., and was distinguished by the same features of interest which always render this one of the most remarkable reunions of the season. The suite of rooms was embellished by works of art of almost every class, extending from the production of the golden age of art, down to those of the aspirants of the present day. Amongst other objects of this description, which were scattered in profusion through the spacious though crowded area, we particularly noticed several admirable busts by Park, Belines, and Smith, together with one of the host himself, modelled in clay by Mr. J. E. Jones, an amateur whose talents, if he had not already chosen a profession in life, would certainly entitle him to shine in this department of art. The portfolios of drawings by Varley, Hering, Tomkins, Fripp, and Kendrick, and the paintings by Scanlan and John Wood, excited great attention, and elicited corresponding praise. A new etching by Thomas Landseer, the first proof of his brother Edwin's picture of Count d'Orsay's dog "laying down the law," was displayed amongst these objects of art. Nor ought the unrivalled vases and bronze figures, the work of the eccentric Florentine artist of the 15th century, of Clodion and others of later date, to be passed over in silence. There were also some of Goddard's fine Daguerréotypes, some electrotypes, as also some specimens of Cheverton's beautiful mechanical sculpture. The most striking of the useful novelties were samples of coloured glass from Mr. Apsley Pellatt's manufactory, some ornamented slabs, &c., of slate from Magnus's Pimlico works. Atkinson's patent ornamental wood mouldings, which are equal to carved work; Pole's new hygrometer. The principal feature, however, of Mr. Walker's soirée was the exhibition of models of machines, &c., which were, throughout the evening, the chief focus of attraction. It is impossible, within the limits of an ordinary notice, to afford any thing like an adequate epitome of the various ingenious and highly useful, as well as valuable, novelties which attracted the attention of the guests on all sides. The model of the lighthouse erected on the Maplin sands at the mouth of the Thames, by Mr. Walker himself, obtained very great attention, a description of which appeared in the last number of the Journal. Mr. Hicks' radial drilling machine, his compound hydraulic press, and new governor, &c. Messrs. Seawards' beautiful models of marine steam-engines, the slide-valves, the disconnecting apparatus for paddle-wheels, and the brine detector, Barnes' paddle-wheel, and the model of the Castor steamer. Mr. Dent's electric and central percussive clocks, Mr. Gossage's disc steam engine, Messrs. Whitworth's (of Manchester) street cleansing machine, cutting tools, &c., Messrs. Ransome & May's railway chairs, Dr. Schaffhaeutl's new universal photometer, a sectional drawing of the Thames Tunnel by Sir Isambart Brunel, and a vast assemblage of other beautiful adaptations of the chemical, electrical, and mechanical branches of science to the purposes of utility and ornament, excited the admiration and occupied the untired attention of the stream of visitors for several successive hours. The conversazioné was attended by most of the distinguished amateurs and professors of science and art, and notwithstanding the eventful debate in the House of Commons, which was proceeding at the same time, and which occupied all the peers and members of Parliament, and the Literary Fund dinner, which detained many of the usual visitors, the numbers who availed themselves of this opportunity of testifying their love of science and esteem for the distinguished President, was very great.

Among the company we noticed, besides the council and a large number of the members of the Institution, the chief members of almost all the scientific societies of the metropolis:—The Marquis of Chandos, Lord Hennecker. Admiral Adam, Barons Schleinitz and Bulow, Colonels Pasley, Maclean, Lieut. Colonels Blanshard, R.E., Hutchinson, Major Anderson, Sirs J. J. Guest, M.P., Frederick Pollock, M.P., Wm. Symons, John M'Neil, Isambart Brunel, George Murray, Walter Riddell, Henry Parnell, M.P. Edward Knatchbull, M.P., Chas. Price, Harry Verney, M.P., John Scott Lillie, Chevalier Benkhausen, Captains Laird, Ivanetskey, Locke, Willis, Scanlan, Pringle, R. Wellbank, L. Price, Kincaid, Smith, G. Smith, R.N., Evans, R.N., R. Drew, Drs. Paris, Schaffhaeutl, Elliot, Field, Pollock, Arnott, Walker, Billing, Roget, Bowring, Rigbey, Reid, Professor Willis, Messrs. E. R. Rice, M.P., Pryme, M.P. F. Hodgson, M.P., Ormsby Gore, M.P., G. F. Young, M.P., Emerson Tennent, M.P., Mr. Justice Haggerman, of Canada, Messrs. T. Landseer, F. P. Stephanoff, Belmes, Tomkins, J. Varley, E. H. Bailey, F. Stone, G. Rennie, Fripp, Rivers, Jun., Hakewell, R. Scanlan, Sargey, A. Cunningham, Oliver, Page, S. Howell, W. Boxall, C. Landseer, Macready, Barry, Sydney Smirke, Tite, Donaldson, Hopper, and Poynter.

ROYAL INSTITUTE OF BRITISH ARCHITECTS.

Monday, May 3.

The annual general meeting of the Institute was held for the purpose of electing the council and officers for the ensuing year. Earl de Grey in the chair.

The report of the council and the annual balance were presented, and exhibited a highly favourable view of the progress of the Society.

Monday, May 17.

A paper was read by Mr. G. F. Richardson, of the British Museum, on the subject of geology as connected with architecture. After a prefatory sketch of the general stratification of rocks, Mr. Richardson adverted more especially to the stratum and quality of those in most general use as building materials. The lecture was illustrated by the exhibition of various objects connected with the subject in the oxy-hydrogen microscope.

Messrs. Pontifex and Co. exhibited a new construction of a self-acting water closet.

ROME AT THE SURREY ZOOLOGICAL GARDENS.

The mimic volcanic flames of Hecla, Etna, and Vesuvius, are now extinct at the Surrey Zoological Gardens, and we have another giant wonder from the burning climes of the South. When we heard that Rome was to be portrayed to the gaze of the successor of its greatness, we were naturally anxious to ascertain whether it had a fitting representative; Mr. Cross has succeeded very well in housing lions and tigers and elephants, but where he was to pitch down the Eternal City we could not readily conceive. He has, however, by placing it near the lake found means to appropriate to it a space of five acres, a space large enough to hold a modern town, and to do justice to the object of this representation. We have here a pictorial model, covering a surface of more than a quarter of a million of square feet, and presenting, as has been well stated, "a stupendous panoramic view, and the largest picture or model ever produced." The lake now stands for the Tiber, and across it we have the bridge of St. Angelo, with its statues of angels on the walls. Beyond are seen on the left the Tordinona Theatre, the Palazzo Tortonia, and other well known edifices. On the right the Mole of Hadrian, now the Castle of St. Angelo, raising its giant bulk. Farther behind, rising over every thing, is St. Peter's, upwards of a hundred feet in height, and appearing as magnificently as its great original. The façades of the Vatican, the Papal Palace, the Ospitale di Spirito Santo, and many other structures well known to fame are strikingly represented. To be properly appreciated this exhibition must be seen; the apparent solidity and verisimility of the structures, the extreme range of distant view, are features which tend to impress us with a sense of the reality of the objects before us. The painting is good, free from glare and exaggeration, and subdued so as to give that sobriety and real life, which augments the impression on the spectator; we think however that the effect might have been increased by a few figures of men and animals being appropriately introduced. The artist is Mr. Danson, and in naming him we do quite enough to show that full justice has been done to the subject, for his reputation in this department of art is a guarantee of the extent of his exertions. We may indeed assure our friends that those among them well acquainted with the Eternal City will be gratified in renewing their recollections of it, and those who have the pilgrimage yet to make, cannot have a better introduction than by a visit to this, its prototype.

NEW INVENTIONS AND IMPROVEMENTS.

IMPROVEMENTS IN STEAM ENGINES.

George Henry Fourdrinier and Edward Newman Fourdrinier, of Hanley, Stafford, paper makers, for certain improvements in steam engines for actuating machinery, and in apparatus for propelling ships and other vessels on water.—Rolls Chapel Office, March 17, 1841.—These improvements are, as the title explains, divided into two parts; the improvements in steam engines consist in applying and working two pistons in one cylinder, which are simultaneously actuated by the expansive force of the same volume of steam. A long cylinder is supported vertically on pivots, in the middle of which it vibrates; two pistons are attached to piston rods which pass out through stuffing boxes at either end of the cylinder. On steam being admitted through suitable slide valves to the middle of the cylinder, the two pistons are forced apart towards the opposite ends of the cylinder, the valves are then shifted, and the steam admitted at the two ends of the cylinder, which drives the piston back again to the centre, the spent steam passing off to a condenser or into the atmosphere, and so on continually. The lower piston rod is attached to a crank in the middle of the shaft, while the upper piston rod carries a cross head from which connecting rods pass down to two cranks placed on the same shaft, but opposite to the former, so that as the one is descending the other is ascending, in conformity with the opposite motion of the pistons. In another arrangement, the cylinder is divided into two parts by a partition in the middle, and the pistons do not expand simultaneously as in the former case, but the one piston begins to move when the other is at the quarter stroke, the valves being so adjusted as to effect this movement; for the purpose of overcoming the dead points, when one piston is at the dead point the other is exerting its full force. The apparatus for propelling ships and other vessels consists of certain arrangements of mechanism by which a volume of air may be forced against the water at the bottom of the vessel, in the direction of its stern, for the purpose of impelling the vessel in an opposite direction. The air being compressed by an air pump, "to the same density as the water under the ship's bottom," is admitted through a valve into a tube, down which it flows into the water. The bottom of the vessel has two guards of wood or other material, parallel to its keel; as the air enters the water beneath the vessel it is guided by the guards, which prevent it from escaping at the sides, and by its pressure against the water, in the direction of the stern, impels the vessel head foremost. The direction of the air, backward or forward, is regulated by a tumbling valve, worked by a quadrant rack or sector, and an endless screw; by altering the position of this valve the direction of the air, and, consequently of the vessel, may be reversed at pleasure. When the vessel rolls about in a heavy sea, it is considered desirable to force the air under the most depressed side of the vessel only; to effect which the air plugs are connected to a pendulum which opens the valves on the one side or the other, according to the position of the vessel. In another arrangement for reversing the motion of the vessel, two sets of sliding tubes descend from the air chambers, opening fore and aft; if the vessel is to be propelled head first, the two hinder tubes are depressed and the air passes off towards the stern; but if the vessel is to be backed astern, the foremost tubes are depressed and the air projected towards the head of the vessel. The claim is—1. To the application of two pistons working in one cylinder, as shown.—2. For propelling vessels, by forcing a volume of air against the water beneath the bottom of the vessel, in the manner shown and described.—*Mechanics' Magazine.*

MOVEABLE OBSERVATORY AND SCAFFOLD.

Alexander Horatio Simpson, of New Palace-yard, Westminster, Middlesex, gentleman, for a machine or apparatus to be used as a moveable observatory or telegraph, and as a moveable platform in erecting, repairing, painting, or cleaning the interior or exterior of buildings, and also as a fire escape. Enrolled May 5.—Claim first. The use of a shaft or spar as herein described, with a gallery or platform suspended or attached so as to be capable of being raised or lowered on the shaft by a power, either manual or otherwise, exerted within the platform.

This machine consists of a shaft or spar, mounted in a step, in which it is capable of turning (the step being fixed to a foot or pediment), and supported laterally by stays, jointed at their upper ends to a collar, which slides on the shaft, but is retained in any required position by a pin. The lower ends of the stays fit into holes in the foot or pediment, so as to admit of the stays altering their position or angle, in relation to the shaft, and thereby supporting it in different positions. The shaft is constructed of wrought iron plates, rivetted together, and one side of it is formed by a rack sunk flush with the surface of the shaft, which rack may be of cast iron; but one of the lantern form is preferable, the teeth of which is formed by long bolts or rivets, running across in the same position as the teeth of the cast iron rack. On the shaft is a sliding frame, to which is attached a gallery for the reception of workmen, tools, &c., and this sliding frame is fitted with a pinion, whch working in the rack of the shaft raises or lowers the gallery or platform, according to the direction in which it is turned.

This machine may be used as a telegraph, by having the usual apparatus attached to the top of the shaft, or it may be used as a moveable observatory.

Claim second.—The use of a horizontal suspension rail, supported by shafts or spars, with a platform or gallery suspended therefrom, capable of receiving motion from within the gallery.

Claim third.—The giving motion to the gallery or platform, by the application of a power, either manual or otherwise, from a point not within the gallery or platform.

This part of the invention is an improved construction of scaffolding, and consists of two shafts, placed one on each side of the front of the building, similar to that before described, but without the rack and platform with its appendages. On the top of these shafts is fitted a cross rail, on which is mounted a carriage running on flanged wheels, and to these wheels are fixed two "gallows," suspending a light ladder by a pin or bolt. On the centre of this bolt is a roller or pulley, over which a rope passes, one end of it being fastened to a gallery similar to that before mentioned, and sliding on the ladder, and the other end to a counterpoise weight. On the foot of the ladder there is another roller, that runs on a cross bar, similar to the bar at the top, but which roller supports none of the weight of the ladder, as it rolls nearly horizontally and against the side of the bar, being provided for the purpose of permitting the ladder to travel easily to and fro.

In order to bring the gallery to bear on any portion of the surface of the building that the workman may require, four ropes are provided; two of these are fastened to the bottom of the shafts, and passing over two live pulleys at the foot of the ladder, proceed up to the gallery; the other two are fastened to the top of the shafts, and pass over two live pulleys, on the same axletrees as the wheels of the carriage before mentioned, into the gallery.

Now if the person in the gallery pulls the two top ropes, he raises the gallery, or if he pulls the two bottom ropes, he lowers it; if he pulls either of the two side ropes, namely, those attached to the same shaft, leaving the other two side ropes loose, the gallery and ladder will move horizontally in a lateral direction.—*Ibid.*

DRIVING BELTS AND STRAPS.

James Heywood Whitehead, of the Royal George Mills, near Saddleworth, Yorkshire, manufacturer, for improvements in the manufacture of woollen belts, bands, and driving straps. Enrolled May 2.—This invention consists in applying a composition to a woollen belt to give it firmness and adhesiveness, as a substitute for leather for driving machinery.

The composition consists of linseed oil and resin mixed together, in the proportion of three pounds of linseed oil to two pounds of resin; but these proportions may be varied a little to suit circumstances. The oil is first boiled, and the resin in fine powder added to it while it is in the boiling state, being well stirred till they are thoroughly mixed together.

The belt or strap is passed through the mixture and between two rollers, which are weighted sufficiently to make the composition even, so that it will not run out of the cloth when hung up. The cloth is then well stretched in length and dried, after which it is ready for use.—*Inventors' Advocate.*

RAILWAY CARRIAGE.

James Boydell, jun., of Cheltenham, ironmaster, for improvements in working railway and other carriages, in order to stop them, and also to prevent their running off the rails. Enrolled May 2.—Claim first. The mode of applying apparatus acting by lever pressure on rails, as a means of stopping carriages, as herein described.

Beneath the lower part of the railway carriages a projection is affixed, carrying the axis of a lever, the lower end of which lever is enlarged and embraces the rail, the part which comes against the rail being lined with wood, to enable it to offer greater friction. This part of the lever is, by means of another lever, and connecting links, brought in contact with the rail, whenever it is desired to stop the train.

Claim second.—The mode of applying bars to prevent carriages running off the rails of railways.

Beneath each carriage are two bars, which extend across from opposite corners of the framing of the same, crossing each other beneath the centre of the framing, and from which centre they are suspended by means of a pin passing through a slot formed in the centre of each bar. The ends of the bars are connected by pins to the ends of the bars of the carriages before and behind them, thus forming a continuous bar, which will in most cases prevent the carriages from getting off the rails, and in case one of the carriages should run off the rails will prevent it from running at any considerable angle to the same. The slots in the bars have sufficient play to permit the train to move over curves easily.—*Ibid.*

MR. GRANT'S PATENT FUEL FOR STEAM BOATS.

We learn with great satisfaction, that this important invention is at last to be brought into general use. The Admiralty, after a long series of experiments made under their directions, by Mr. Grant, and followed up by frequent trials of his fuel in her Majesty's steam vessels, instructed him some time ago to take out a patent, chiefly, we suppose, to secure themselves and the public against the interference of any pretenders to the invention.—This point being settled, it became the wish, as it was the obvious duty of government, to extend the benefits of Mr. Grant's labours to the country at large.

Numerous applications having been made to Mr. Grant, by the various steam vessel companies, for permission to make use of his patent, the Admiralty, in a spirit of enlarged policy, have, as we understand, directed that gentleman to refer all persons to them who desire licenses to manufacture his fuel—and we have no doubt that their Lordships sanction will be given accordingly. But, we trust, the terms will be so moderate as to render it the interest of those extensive companies, whose vessels now cover so many seas, to employ this new agent for the production of their steam power.

A word or two on the nature and properties, as well as the practical advantages of Mr. Grant's fuel, will probably not be unacceptable to our readers generally, and may prove useful to such persons as are engaged in steam boat enterprises on the large scale.

It is not our purpose, nor would it be proper, to describe minutely Mr. Grant's process—it will be enough to say, that his fuel is made of coal-dust and other ingredients, mixed together, in certain definite proportions, and then fashioned, by a peculiar process, into the shape and size of common bricks. The advantages of Mr. Grant's patent fuel over even the best coal may be stated to consist—first, in its superior efficacy in generating steam, which may be stated in this way—200 tons of this fuel, will perform the same work as 300 tons of coal, such as is generally used;—secondly, it occupies less space, that is to say, 500 tons of it may be stowed in an area which will contain only 400 tons of coal;—thirdly, it is used with much greater ease by the stokers or firemen than coal is, and it creates little or no dirt, and no dust—considerations of some importance when the delicate machinery of a steam engine is considered;—fourthly, it produces a very small proportion of clinkers, and thus is far less liable to choke and destroy the furnace bars and boilers, than coal is;—fifthly, the ignition is so complete, that comparatively little smoke, and only a small quantity of ashes are produced by it;—sixthly, the cost of the quantity of Mr. Grant's fuel required to generate in a given time a given amount of steam, is so much less than that of the quantity of coal which would be consumed in effecting the same purpose, that, even if the advantages of stowage, cleanliness, and facility of handling, were not to be taken into the account, the patent fuel would still recommend itself to the attention of all steam boat proprietors.—*Hampshire Telegraph.*

[The first part of this statement appears to us rather extraordinary that the Lords of the Admiralty should interfere with the working of a patent in any kind of way, and that parties requiring licenses are to be referred to them; surely there must be some mistake in the statement.—Editor C. E. and A. Journal.]

APPLICATION OF ELECTRO-MAGNETISM TO MACHINERY.

(From the Leipsic Allgemeine Zeitung.)

Leipsic, April 17.

The meeting of our Polytechnic Society was rendered peculiarly interesting by a lecture given by Herr Störer on his experiments in the application of electro-magnetism as a motive power. Herr Storer commenced his experiments several years ago, before Wagner's invention, and has proceeded independent of it. By merely following up and carrying out the ideas of Jacobi, to whom the first merit of the discovery is due, he has succeeded in constructing a small machine, the power of which is as yet limited to the raising of only a moderate weight and putting a turning lathe in motion, but which is nevertheless sufficient to render perfectly evident the whole mechanism of the important invention, and which, as the constructor observed, needs only to be enlarged to produce more practical effects.

The principle of electro-galvanic movement has its source, as is well known in the law of reciprocal attraction and repulsion of two iron bars, surrounded by a galvanic current, alternating with positive and negative electricity, and thereby magnetized. Herr Störer's machine consists at present of only two concentric circles of spiral iron bars, surrounded by conducting wires for the reception of the electric current. Each circle contains 12 single bars, placed at the distance of from 2½ to 3 inches from each other, the bars of the outer circle being about half an inch separated from those of the inner. The outer circle is fixed; the inner forms the periphery of a moveable disc, swinging wheel, or pinion. This mechanism is brought into connexion by two conducting wires with a galvanic battery, in such a manner that in the first place the bars of the one circle with positive electricity surround those of the other with negative electricity; then suddenly, by an arrangement in the conducting apparatus, the current is changed, and thereby electricity of the like name is produced in both circles. The consequence of this is, that the opposite bars, in consequence of the different magnetic power communicated to them, first attract each other, then instantly becoming, by the inversion of their poles, similar magnets with equal force, repel each other. By this regularly repeated alternation of attraction and repulsion, each bar of the internal moveable circle is in succession drawn towards all the bars of the external fixed circle, and then driven as it were back on the next, whereby the whole disc is brought into a state of uniform motion.

The inventor makes a very moderate estimate of the cost of the machine. The expense consists chiefly in the wear of the zinc in the galvanic battery, by the action of the acid; but as to the outlay for this article, it will be almost entirely counterbalanced by the precipitate which in consequence of the operation is formed in the acid, and which yields a somewhat valuable chemical product. With regard to the power of the machine, and the possibility of reinforcing it so as to produce greater practical effects, Herr Störer submits the following considerations:—The present machine, though only double the size of the one he first constructed, which had only six pair of bars, acts with a sixfold increase of force. Each galvanic element consists of a copper cylinder, a zinc cylinder within it, and a chemical mixture by which they are connected. Now, as respects the effect of the number of elements employed, Herr Störer makes the following observations, the accuracy of which he has proved by experiments:—"In the connexion with a single element the machine raises, with moderate velocity, 3 lb.; with two elements, 13 lb.; with three, 25 lb.; with four, 40 lb. This is approximatively an ascending gradation of power in the ratio of 1, 4, 8, 12, whence it certainly would appear that the force might not be found to augment exactly in the relation of a progressive increase of the elements." According to Herr Störer's calculations, the connexion of a battery of 50 elements, with a machine in cubical contents 26 times greater than the one exhibited, would produce an effect equivalent to 50 horse power.

Still, however, after all these data and calculations, there remain several doubts as to the practicability of the application of this invention to machinery on an extensive scale. On the other hand, the results obtained by the experiments hitherto made are of sufficient importance to encourage a spirited prosecution of the discovery, which is in itself so ingenious, that it ought to be joyfully hailed by all who take an interest in the progress of civilization, as a new triumph of the human mind over inanimate matter. At all events, we Germans have just reason to be proud of an invention the first idea of which came from a German, and all the improvements yet made in which are the offspring of German intellect and German perseverance.

CONTINENTAL MODE OF BORING, BY APPLICATION OF THE ROPE.

When I was lately residing on the Continent, I occasionally observed notices in the foreign papers of this mode of boring, with flattering accounts of its advantages. I was anxious to obtain information about it, but I did not succeed in doing so until I perused the official report of M. Jobard on the Paris exhibition of 1840. His account is, indeed, in some degree, defective, as it does not furnish diagrams of the instruments; nevertheless, it gives a general view of the method, which seems to be attended with the surprising benefit, that the expense of the bore per fathom does not increase in any considerable degree with the depth of the bore. Having both observed and experienced the cost, danger, and tardiness of the bore with boring rods, when a great depth is reached, I have found M. Jobard's report interesting and instructive; and, therefore, as the subject may be new to some of your readers, I venture to send you the substance of it, in case you think it worth insertion in your valuable Journal.

There are in all three instruments, or tools, used in the method alluded to—the *mouton, emporte pièce*, and *alèzoir*. The *mouton* is a cylinder of cast-iron, of about eight inches in diameter and thirty-nine inches in height—weight from one to three cwt. This cylinder has exterior flutings, 1-10ths of an inch in depth and 6-5ths of an inch in breadth; the upper part contains an empty cone, whose base is reversed, which gives it the form of a bucket with thick sides. There are two handles to the cylinder, one above the other—if the first should break, the second retains the rope. The lower part of the tool is prepared to receive a number of steel chisels, which are fixed by a transversal key. The tool should be composed of as few pieces as possible, for, however well they are fixed, the percussion tends to detach them, and to leave them at the bottom of the hole. The best way of procuring good moutons of percussion, for hard strata, is to make them all of one piece of case-hardened cast iron, with handles of malleable iron hooked into the cast iron. These handles should be high up, in order to facilitate the extraction of the powdered stone, which accumulates in the empty part of the mouton. The head, or top, of the tool should exhibit a number of pyramidal points, projecting about an inch, diamond-pointed, the better to cut into the stone. The case-hardening gives them the hardness of tempered steel, and makes them last a long time. A mouton of three cwt. costs only 50f. (2*l.*); when it is worn, the old metal serves for the casting of others. The rock is cut daily to the depth of at least 39 inches. The rope is worked by a long plank placed obliquely, the upper end being about 12 or 15 feet above the hole. The mouton is suspended about 15 or 20 inches from the bottom of the hole. Motion is given to this plank by the hands or the feet, or by several men pulling together by ropes attached to the plank. There are also several other ways of working the main rope.

In boring with boring rods, four or five hours are required to draw them and lower them again; but all this is done (when the bore by means of the rope is used) in eight or ten minutes. In this latter, then, the progress of the work is always nearly the same—at 3000 as at 100 feet. The same number of men, too, is sufficient to work it, let the depth be what it may. What takes place, is as follows.—The mouton, falling 25 or 30 times a minute, from a height of two or three feet, readily breaks and pounds the rock. The dust or powder which results from this would soon deaden the blow, if there were no water in the bore hole, but there is almost always some—if not, it should be thrown in. The water and the dust form a magma—a mortar or mud, which spouts up by the flutings carved around the mouton. This mud falls back necessarily on the head of the mouton, and, as this is hollow, the mud enters a little at every blow. This powdered stone heaps up in the interior of the cone, by the work, to such a degree, that force is often necessary to get out the stony sugar-loaf which is there concreted after some hours striking. The contents of the instrument are known; it is sufficient, then, to put a mark on the rope, at such a height, to know that, when the rope has lowered a certain distance, a certain number of inches of matter have passed from below to above the tool. Before retiring the mouton it should be left at rest one or two minutes, to allow the heavier particles of the mud, which are in suspension at the bottom of the bore hole, to deposit themselves on the bucket—but not longer, for so it might get it incrusted.

The mouton alone suffices to the Chinese to bore to the depth of 1800 feet. Their strata are hard and solid enough not to require tubing, but it would not do for clay, sand, or pebbles—in that case the *emporte pièce* is requisite. It is a cylinder, which has at its base two valves, turning on a hinge in the diameter, in the form of the wings of a butterfly. This cylinder is lowered to the bottom of the hole, and is caused to penetrate the strata by the intermediate percussion of a mouton, of the weight of 65 lbs., which is made on purpose for the emporte pièce. The mouton, having an aperture in the centre, slides for some feet along a metallic rod, which is fixed to the emporte pièce. When the mouton is raised, it gets as far as a bolt, which stops it; it then falls on the emporte pièce, which latter sinks at every blow, and its valves open to let the mud pass. When it is thought the instrument has sunk far enough, it is drawn up, and it arrives with a cake of mud, &c.; but care should be taken not to allow it to sink too far into plastic clay—it might then be difficult to draw it out. For strata which require tubing, there is, besides, the *alèzoir*. The following is the simple artifice employed to enlarge the bore hole when it is tubed (or, to resolve the problem, to form with an instrument, which is obliged to pass through a tube, a hole larger than the exterior of this tube):—The tube is supported by straps, at about two lengths of the mouton from the bottom of the hole. The mouton used in this case has a square, and not a round, handle at its upper part. It is easily conceived that, if the rope is fastened to the middle point of the handle, which corresponds to the centre of gravity and to the centre of figure, the mouton would strike straight, and would only form a hole equal to the diameter of the instrument or the interior diameter of the tube; but if the point to which the rope is fastened is borne away one or two inches from the middle point of the handle, the centre of gravity becomes displaced, and the lower part of the mouton inclines to the right or left—a position which causes it to rob and wear away the sides of the hole with its crown, at the same time that it attacks the bottom with its steel teeth. When this instrument, which is slightly conical, is drawn up, it sets itself straight again, and rises up in the tube, exercising a feeble friction on the sides of the tube. This mouton, like that for the strata, which require no tubing, has a receptacle for the mud. In using either mouton, a movement of torsion must be impressed on the rope. This is effected by fixing the rope into the extremity of a wooden bar, of about two feet long, which gives a workman sufficient leverage to turn or twist the cord a little at every blow, or to regulate its untwisting. In this way the hole cannot fail to be circular and quite perpendicular. By this means, at the well of the Military School, they have got down a single tube of iron plates, rivetted, of 11 inches diameter, to the depth of 650 feet. The tube moves freely—one man can turn it round. The wire rope would answer well for this mode of boring. The moutons are not difficult to make; a village blacksmith may construct or repair them; he should fasten the steel chisels in such a way that they can be occasionally taken out to be sharpened. The method of boring by means of the rope is much used in Saxony.—*Mining Journal.*

BUILDERS' BENEVOLENT INSTITUTION.

In another part of the Journal, it will be seen that we have requested the attention of our engineering readers to the merits of an institution for the relief of engineering workmen, and now we have to make a similar request of our architectural readers. They will see that a meeting has been held for the purpose of establishing a Builder's Benevolent Institution, and we hope that they will readily lend their aid for the promotion of an object so laudable. We need scarcely say that it has our very best wishes for its success. The meeting to establish an asylum and pension fund, and for the general relief of the decayed and suffering members of the builders' trade, was held on the 24th ult. at the Crown and Anchor, Strand; Mr. Burnard, surveyor, in the chair. The advertisement convening the meeting having been read by Mr. Barber, the secretary, the chairman, in a brief but neat speech, detailed the objects of the institution, remarking that there were no less than 20 trades connected with the building business—as architects, surveyors, painters, engineers, bricklayers, slaters, sawyers, &c.; yet the builders had neither an institution like that which they were assembled to establish, nor an asylum, nor any benefit society to apply to in poverty or old age. The objects for which the institution was about to be formed were highly praiseworthy and beneficial, and he was glad to say, that the committee had been promised support in all cases in which they had applied, and he hoped soon to see the builder's asylum rise second to none even in this great metropolis. The secretary then read letters from the Marquis of Westminster, the Earl of Cadogan, Sir R. Peel, Mr. Barry, the architect, Mr. Philip Hardwicke, Mr. D. Burton, Mr. Thomas Cubitt, Alderman John Johnson, and many other gentlemen of standing and respectability, all concurring in the objects of the meeting. The report of the committee was then read. It contained a well-written narrative of the steps the committee had taken, the reception they had met with from those to whom applications had been made to assist them in their praiseworthy endeavours to found the Builders' Asylum, and concluded with a very flattering account of the success that had attended their efforts. The report being adopted, a series of resolutions was put and passed in the usual manner. A subscription was entered into before the members left the room, for carrying out the purposes of the institution, and was liberally responded to.

REPAIRING AND MAINTAINING OF PUBLIC WORKS.

The following important judgment in the case of *The Queen* v. *The Bristol Dock Company*, was delivered in the Court of Queen's Bench, Westminster May 25, at the sittings *in Banco*. The defendants in this case have been incorporated under the 43rd George III., c. 140, for the purpose of making, completing, and maintaining a new watercourse in connexion with the river Avon, and this purpose they had effected. Some part of the works of the new watercourse, however, became subsequently out of repair; and upon a former occasion a rule had been obtained calling upon them to show cause why a *mandamus* should not issue commanding them to repair that portion of the banks of the new watercourse which had become dilapidated, and which, in its present condition, caused an obstruction to the navigation. The rule was made absolute, and the writ having issued, the defendants returned that they were not bound, according to the general law of the land, or to the provisions of the particular act above mentioned, to repair the portions of the watercourse which formed the subject of the discussion.

Lord Denman now delivered the judgment of the court upon the case, which was, that in the circumstances of the transaction the defendants were bound to make the repairs which the writ commanded them to make. His lordship laid it down in the course of the judgment, that where parties obtained an act of parliament for the construction and maintenance of great public works, they were bound in law to fulfil all the incidental duties of which the performance was necessary for the discharge of their duties in respect to the principal subject. His lordship also stated, that if public bodies omitted the performance of such incidental duties, they would be compelled to do so by the direct interposition of this court. It had been argued upon the part of the defendants, that as the injury consequent upon their neglect to repair the bank was of a public nature, and one for which they were liable to an indictment, that particular proceeding ought to be adopted, and there was therefore no necessity and no ground for a *mandamus*. The court, however, dissented from this position, and declared that where a company were obliged to do a particular work, and where the consequence of their not doing it was to produce a public nuisance, that circumstance, although it rendered them liable to an indictment, did not release them from the necessity of a specific performance of their duty upon the subject, in obedience to the mandate of this court. In this case, therefore, a peremptory *mandamus* would be awarded.

S. L. IN REPLY TO CANDIDUS.

Sir—I am surprised that Candidus should have thought it necessary to combat an imaginary assertion by such very trite observations. But he is evidently affected with the usual mania of critics, viz., that of putting an arbitrary interpretation on the object of their criticism, and then attacking the author for entertaining an idea which is but the fruit of their own fertile imagination. For instance, where Candidus can find that I have said any thing to discourage the roughest handling of public men, if kept within the bounds of truth and reason, I cannot possibly conceive; nor can I find any thing which can justify his supposition, that I may probably greatly prefer Buckingham Palace to Windsor Castle, &c.

With regard to mullioned windows, I confess I cannot see the propriety of substituting any thing which would have the effect of an open screen, for a glazed window; and though we may make infinitely greater departure from the genius of Grecian architecture. Candidus may remember that pure Grecian was not the style advocated; the architect must go to Rome and Pompeii for his materials, as well as to Athens.

When I spoke of the difficulty of persuading persons to adopt Gothic, who are not possessed of antiquarian taste, I said nothing about "soi-disant" or "hole-in-the-wall" Gothic; every one is aware of the great facility afforded for the adoption of that style—I mean by Gothic such as would do credit to an architect; but most persons find this to interfere too much with their comfort for them to "allow it to be properly treated."

With respect to what Candidus is pleased to call my very bold assertion, I would beg him to observe that I stated that the *object* of the architect, when he employed the Grecian or Roman style, was invention, not that originality was always the *result* of his efforts. I shall, however, be glad if he will refer me to a modern Gothic building possessing half as much originality as St. Stephens, Walbrook, or the spire of Bow church.

I quite agree with Candidus that it is well to avoid "squeamishness and affected delicacy in architectural criticism," but it would also be well if he would pay some respect to decency in the choice of his expressions, and not make use of those of which a gentleman would be ashamed, and which diminish, rather than increase, the force of his observations.

I remain, &c.,

S. L.

STEAM NAVIGATION.

THE MONGIBELLO STEAM SHIP.

This fine vessel belonging to the Neapolitan Steam Navigation Company at Naples, is fitted with a pair of Messrs. Maudslay, Sons and Field's patent double cylinder engines, of the nominal power of 200 horses; their general principle is described in the last volume of the Journal, page 73.

The improvements realized in this description of engine are *first*, that the power is applied more directly to the cranks than in any other construction, having only two working joints through which the power is conveyed, viz. the lower and upper ends of the connecting rod, the stroke being of the usual length, and the connecting rod of the usual proportions; the force of the engine is also so completely confined within its own framing, that no strain is thrown upon the vessel. The *second* advantage is that the space occupied by the engine, is not greater than in an engine of half the power, on the side beam construction, and when combined with their improved boilers, (as is the case on board the Mongibello), the total length occupied by the machinery is reduced to 40 feet, whereas the ordinary construction requires 60 feet, thus effecting a saving of one-third, on this most important head. The *third* advantage arises from the reduction in weight, which in the Mongibello, and including water in the boilers, was 150 tons, being 13½ cwt. per horse power, instead of one ton per horse power, which is the weight in beam engines, and even this is often much exceeded.

These advantages, which bear so strictly upon the profitable employment of steam vessels, are fully realized in the one in question, which is of 509 tons burthen, being 156 feet long, and 26 feet beam; besides the saving in space referred to above, the machinery of the Mongibello is about 70 tons lighter than ordinary beam engines, and in addition to the increased tonnage derived from the saving in space. She thus possesses 70 tons additional buoyancy for cargo, or coal, for a more extended voyage. Another consideration, which ought not to be overlooked, is that in building a vessel to carry a certain number of passengers, or quantity of cargo, the first cost of the vessel may be much reduced; the same space for passengers and tonnage for goods, may be obtained by a vessel of 70 tons less measurement, and the saving under this head cannot be estimated at less than 1400*l.* in a vessel of the size of the Mongibello, and it would be greater as the size increased.

These engines work with great steadiness and effect, making 25 strokes per minute, and performing from $11\frac{1}{2}$ to 12 miles per hour. They are fitted with expansion gear, brine pumps, &c. In short the vessel is replete with every requisite for a sea-going ship.

RENNIE'S TRAPEZIUM PADDLE WHEEL.

In our number for March last, we enumerated some of the advantages which were likely to be derived from the adoption of the above invention in steam navigation; we have now the satisfaction to lay before our readers the results of a series of experiments which have been made on the efficacy of the Trapezium Paddle Wheels in comparison with the common Rectangular Paddle Wheels. The Lords of the Admiralty having decided that the trial should be made upon a vessel of known qualities, fixed upon the African, an old gun brig which had been converted into a steamer, by two engines of 45 horse power put into her, as best calculated to give a comparative result. Accordingly the old paddles were removed, and a pair of trapezium wheels fixed in on the same shaft, which formerly served for the old wheels, so that with the exception of a slight alteration in the paddle boxes, no further additions were required. On the 14th of April last the whole being ready, the engines were set to work, and the vessel proceeded down the river to the measured mile in Long Reach.

The dimensions of the African are—length, 109 ft. 10 in. midship section; breadth, 24 ft. 10 in. semi-elliptical, bluff at the bows; depth, 12 feet full at the quarters. She is a good sea boat, but not calculated for high velocities, as compared with steam vessels of modern times.

The power of the engines is two of 45 horse power each, the number of strokes 29 to 30.

The velocity of the vessel at a load draught of 9 ft. 5 in. is nine miles per hour through still water

According to a series of experiments made with the African by Mr. Kingston, Admiralty engineer, the diameter of the old wheel was 14 ft. 7 in., the width 7 feet, the area of the floats immersed was about 62 feet super., the mean draught of the vessel was 9 ft. $4\frac{1}{2}$ in., and with the barometer at $26\frac{3}{4}$ inches, and the engines making from 29 to 30 strokes per minute, the maximum mean velocity opposite the measured mile was 9·174 miles per hour.

	miles per hour.
On the 14th of April last, the engines making from 22 to $23\frac{1}{2}$ strokes	8·29 to 8·75
On the 26th April, 23 strokes	8·4 to 8·6
On the 1st of May, 25 to $28\frac{1}{2}$ strokes	8·8 to 9·032
On the 8th of May, 25 strokes	8·6 to 8·8
On the 12th of May, 26 to $27\frac{1}{2}$	8·5 to 9·136

The last results were obtained with from $2\frac{1}{2}$ strokes of the engines less than formerly, and with a reduced diameter of wheel of 22 inches, and an immersed surface of 30 square feet. The action of the float in the water was entirely free from shocks or vibration; thus establishing on a greater scale than hitherto, the properties of the trapezium wheel as promulgated in the prospectus, namely, that it combines all the advantages of the common paddle wheel, and does away with all its defects, arising as before stated, from the great weight, width, and indirect action of the former, and combining all and even greater simplicity of the latter.

The Steam Frigate "Styx"—On the 6th of May an experimental trip was made with this vessel down the river as far as Gravesend. There was present a numerous party of naval and scientific gentlemen, among whom were Lord Prudhoe, Admiral Sir Philip Durham, Sir W. Symonds, Chevalier Benkhausen, the Russian Consul General, Mr. Routh, &c. She is what is termed a second class government steam frigate, and the third vessel of that class fitted within the last six months. Altogether there will be five vessels, viz., The "Driver," "Vixen," "Styx," "Growler," and "Geiser," the two latter are not yet finished; they are all built to one mould, under the direction of Sir William Symonds, and to be fitted with engines by Messrs. J. & S. Seaward & Capel. The dimensions of the "Styx" are, length 210 feet over all, or 185 feet between perpendiculars, 36 feet breadth of beam, and 21 feet depth of hold; she draws 13 feet aft and 12 feet forward, and when laden with her full complement of guns, stores, &c., 15 feet aft and 14 ft. 6 in. forward. She is to carry four 8 inch guns, for 64 lb. hollow shot, and two 10 inch guns on swivels and slide beds for 96 lb. hollow shot. The two engines are of the collective power of 560 horse power; the cylinders are 62 inches diameter, and 5 ft. 3 in. stroke, performing 17 strokes per minute; the paddle-wheel is 26 feet external diameter, breadth of float boards 8 ft 3 in, divided into two, each being 11 inches wide. The engines are upon Messrs. Seaward's patent principle, the action being applied direct from the piston rod to the crank of the paddle shaft, as adopted on board the "Cyclops." Drawings and a description of these engines will be found in the Journal for February last. Mr. Samuel Seaward has also applied his patent for disconnecting the paddle wheels, which is extremely simple and efficacious; it only required 3 minutes to disconnect one of the wheels, and 4 minutes to reconnect it, and we have no doubt if the men had had a little more experience, they could have been connected and disconnected in half that time. The engines worked very beautifully, and free from the slightest vibration; the speed through still water was at the rate of about $10\frac{1}{2}$ miles per hour. During the excursion the company were entertained with a sumptuous collation.

Blackwall Steamers.—The Blackwall Railway Company have had three iron steamers built by Messrs. Ditchburn and Mair, to run from the Brunswick Pier to Gravesend, viz. the "Brunswick," "Railway," and "Blackwall," all of one mould. Their length is 146 feet and 19 ft. beam. The mould is beautiful, the bows being remarkably sharp, and throwing but little, if any, wave in front; the cabins are tastefully finished, and do credit to the builders. Each vessel is fitted with engines of 90 horse power collectively, and all have tubular boilers. The *Brunswick* has a pair of oscillating engines by Messrs. J. & S. Seaward & Capel, and the same description of engines are on board the *Railway* fitted by Messrs. John Penn & Son. We were present at an experimental trip of this boat on Saturday the 8th ult., when her speed exceeded that of any other boat on the river; indeed her average is about 16 miles per hour. Her performance gave great satisfaction to the Directors of the Railway who were on board, and to the company generally. The whole of the machinery including the boilers is only $45\frac{3}{4}$ tons in weight, very little more than one half the usual weight of engines of so large a power. The other vessel, the "*Blackwall,*" has a single steeple engine of 90 horse power fitted with tubular boilers by Messrs. Miller, Ravenhill & Co. We understand that the speed of this vessel is nearly equal to that of the "*Railway.*"

The Elberfelt.—This splendid vessel built of iron by Messrs. Ditchburn and Mair, for navigating the Rhine, performed an experiment trip on the Thames on the 8th instant. Her dimensions are, length 176 feet, beam 21 feet, depth 11 ft. 6 in., and draws only 2 ft. 8 in. of water. her cabins are fitted up with great taste, particularly the ladies cabin, and the saloon which is decorated with views on the Thames,—throughout the vessel every attention has been paid to the comforts of the traveller. She is propelled by a pair of oscillating engines of 55 horse power each, by Messrs. Miller, Ravenhill and Co., her speed in still water is calculated at 13 miles per hour; the boilers are tubular, of Mr. Spiller's patent.

Steam Frigates.—The town of Greenock exhibits at present a scene of no common interest. Six large steam frigates are now being constructed in the town or its vicinity, each of these of about 1,500 tons capacity, and carrying engines of 500 horse power, being part of the fleet of 14 armed frigates destined in time of peace to carry out and distribute the mails among our West Indian colonies. Four of these are to be supplied by a single firm in Greenock, who deliver the ships, engines, and equipments complete, and ready for sea. We announced a short time ago the successful launch of the first of these four, the Clyde, which was constructed by the late Mr. Duncan. The second of these ships, the Tweed, was launched from the yard of Messrs. Thompson and Spiers on Saturday last, and we hope soon to announce the completion of the series of these four sister ships, in the launch of the Tay and the Teviot, which are rapidly progressing on the stocks. In general appearance and construction this ship resembles closely her precursor, the Clyde, being slightly fuller forward, and finer abaft. To the eye she also seems larger than the Clyde, but this may arise from the latter being a foot or two deeper in the water, having already her whole engines and boilers fitted up on board, although it is only about two months since her launch. The dimensions of the Tweed are as follow:—Length, over all, 240 feet; keel and forerake, 215; beam, 37; depth, 30.—*Greenock paper.*

Thames Steamers.—The competition among the steamers has become so great, and their numbers have so much increased of late, that 17 vessels are daily engaged in conveying passengers between Gravesend and London. Some of them charge 2*s.* in the after cabin, and 1*s.* 6*d.* in the fore part of the steamer, for each passenger; others 1*s.* 6*d.* and 1*s.*, and a few 1*s.* only all over the vessel; while the steamers from Blackwall to Gravesend convey passengers for 8*d.* each. Fourteen steam vessels are engaged in carrying passengers between London and Greenwich, and a majority of them have lately reduced their fares to 6*d.* each; but the pier dues swallow up one-third of the fare, and it is doubtful whether the steam boat companies will be able to continue the reduced fares for any length of time. Eight steamers are constantly running to and from Woolwich, and they will receive a great accession in a few days by the fast and elegant boats of the Watermens' Steam-packet Company. There are 16 small vessels belonging to different companies steaming away from morn till night above bridge, and on Sunday last they carried upwards of 55,000 passengers, at 4*d.* per head, between the numerous piers from London-bridge to Chelsea.—*Times.*

Improvement in the Construction of Steam Ships.—A Correspondent of the *Times* suggests that safety bulkheads, by which a vessel is divided into three or four water-tight compartments, should be introduced into ocean steamers in future. The suggestion is an excellent one, but it ought to be enforced by legislative authority, and applied to all steamers. Many lives and much valuable property would have been saved if such a regulation had been in force since steam navigation has been so largely extended. The loss of the Phœnix, which was struck before the paddle-box by another large steamer at sea, affords one instance; and the Albion, on her voyage from Dublin to Bristol, touched a sunken rock on the Welch coast, and immediately went down in comparatively smooth water, and on a beautiful day, in consequence of the leak produced in her bow. The distressing loss of the Killarney, on the coast of Cork, would, no doubt, have been averted, had not the fires in the engine-room been extinguished by a leak, which it was impossible to keep down. Many other cases might be cited; and we shall place in juxtaposition with the preceding an accident which happened to the Royal William a celebrated steamer belonging to the City of Dublin Company, on one of her voyages from London to Dublin. This vessel, we must premise, like several others belonging to the same spirited company, is divided into water-tight compartments by bulkheads. One dark stormy night, when off the Isle of Wight, she suddenly came into violent collision with a three-masted ship, which exhibited no lights; and a large hole was made in her bow, which must, had she been built like ordinary steamers, have involved her almost instantly in the same fate as the Albion. The bulkhead, however, near her bow, prevented the leak from spreading—nay, so little inconvenience did this alarming collision occasion, that she proceeded on her voyage to Plymouth, scarcely depressed in the slightest degree, to use nautical language, "by the head." This is a striking anecdote; and we only wonder that steam-boat proprietors have not long ago seen the importance, even for their own interest, of adopting the mode of construction which saved the Royal William. We repeat that that they ought to be compelled to do so; and we trust that some member of Parliament will bring the subject forward without delay. We are not able to say whether some such safeguard might or might not be adopted in ships; but the recent frightful loss of life occasioned by the sinking of the Governor Fenner, owing to a collision with a steamer, ought at all events to draw attention to the subject. In the Thames 1,000 or 1,200 persons often trust themselves in a single steamer of comparatively slight construction.—*Glocestershire Chronicle.*

Launch of a Steam Frigate.—The West India Royal Mail Steam-packet Company's magnificent and powerful steam ship the Forth was launched from the building-yard of Messrs. Robert Menzies and Sons, Leith, on Saturday last. She glided into the Forth, the estuary after which she has been called, in a most majestic manner, and in presence, it is reported, of not fewer than 80,000 spectators. So gay a scene had not been witnessed in Leith since the visit of his late Majesty George IV., in August, 1822. The following are the dimensions of the Forth:—Length of keel, 215 feet; on the spar deck, 229 feet; over all, 245 feet; breadth over paddle-boxes, 60 feet; depth of hold, 30 feet 3 inches; tonnage, 1,940. She is to be propelled by two engines now fitting at Liverpool by Mr. Bury, of 220 horse-power each. The Forth is the third steam frigate already launched for the West India Royal Mail Steam-packet Company. The two first were built on the banks of the Clyde.

Steam-ship Building in Derry.—In Mr. Coppin's yard there has been laid the keel of a vessel intended for foreign trade, which, in point of dimensions, will come very little short of the largest steamers ever built, the proprietors of her being partly Englishmen. She is to be impelled by the Archimedean screw, to have a horse-power of between 500 and 600, and to be of 1,500 tons register. Her keel is 221 feet, only a few feet inferior to that of the greatest steamer launched, and her length over all will be 230 feet.—*Derry Journal.*

MISCELLANEA.

Westminster Bridge is again opened to traffic, after having, during the short period of four weeks, been subjected to extensive repairs. The well-known hollow arch has been removed, and spandrel walls with longitudinal arches in brickwork have been substituted, so as not only to strengthen the pier, but to remove a serious cause of danger, threatened by the pressure of the hollow arch on the haunches of the adjoining main arches. A rather unusual circumstance has been the removal and restoration of a whole course of stone throughout one arch. Great satisfaction has been given by the prompt and energetic manner in which the alterations have been effected by Mr. Cubitt, under the directions of the engineers, Messrs. Walker & Burgess.

Preston and Wyre Railway, Harbour and Dock Company.—Extract from a report to the directors by Captain Denham, at the last half-yearly meeting of the proprietors.—"The new channel through the 'Knot-spit,' and over the 'Little Ford,' has been so deepened as now to afford 13 feet of water at half tide through the straight course thus produced upon the line of lights direct from sea into the harbour. The present period is occupied in dredging up the shelving bottom between the landing wharf and 'Canshe-hole' anchorage, so as to produce a continuous depth of 12 feet at low water spring tides, an object we hope to attain by June next, during which the upper layer of shelving shore now interrupting the north or early approach to the wharf, will be excavated, leaving the under or lower shelf to be dredged down to 12 feet over the whole space across to 'Canshe-hole.' The dredge's service this year will thus be wholly dedicated to the wharf frontage and approaches. The new Channel to Sea will, however, be improved by excavating and carrying away at low water the remainder of the 'Knot-spit,' and trimming down the surface and marginal projections of the new cut or channel, the marl arising from which will be appropriated to the 'neckings' half tide wier about to be constructed on the opposite side of the channel. This latter work will also be prosecuted this year, and additional pontoons and stone flats are preparing for it. This tide wier will have the effect of concentrating the whole volume of back water, the scouring force of which has already been so essentially increased by the completion of the 'Knot-gulph' embankment."

Florence and Leghorn Railway.—A supplement to the *Florence Gazette* of the 27th April, contains the decree of H. I. and R. Highness, the Grand Duke of Tuscany, granting for the term of 100 years (to be reckoned from the time when it will be completed and opened to the public), the railway from Florence to Leghorn, to the Company announced by the Manifest of Fenzi and Senn of the 24th April, 1838, to be executed according to the report of the celebrated English engineer, Robert Stephenson, Esq. His Imperial and Royal Highness graciously allows said railway to bear his royal name of "Leopold," and grants numerous advantages and privileges, among others *the importation duty free, of all the iron works, machinery, locomotives, and every other article required for its construction, and completely placing it in active operation.* The exemption from the register stamp due on all the deeds of the company during the construction of the railway, the option of converting into perpetual leaseholds the amount of such lands as will be occupied by the company, and which may belong to the state, or to religious corporations, and which from its nature should be subject to re-investment. The right of expropriation fixed on a liberal basis, with the right of immediate occupation, and a low tariff for the transport of persons and goods.

Copper Mine.—The copper mine recently discovered in Jamaica is situate in Mount Vernon, a huge mountain six miles to the East of Kingston. The lodes run from east to west, with a dip to the north. The veins of ore are found in the neighbourhood of Lucky Valley estate, in the parish of Port Royal, and at the base of the mountain. The richest ore is a sulphurte, yielding 40 per cent. of metal. This ore is obtained in immense quantities from a shaft which opens on a small stream sufficient to carry away the debris. Several hundredweights have been sent to London and Swansea for smelting, great difficulty having been experienced in performing this operation perfectly in Jamaica, from the want of reverberatory furnaces. There is also a carbonate which yields 11 per cent. of metal by the humid process. This is a very beautiful ore, and occurs in what is called abon rock. The matrix consists principally of lime-stone, argillaceous sand-stone, slate, schist, and a fine black sand-stone. The black sulphuret, which is abundant, is obtained in masses resembling wet and rotten coals, soft when extracted from the mine, but hardens in the sun, and is full of pyrites. When dry it is perfectly friable. The situation of the mine is convenient, being only three miles and a half from the sea, and the road is a gradual descent to the harbour, Bull Bay, where there is good anchorage for vessels. It may be added that the mine is in full operation, a company having been formed, and all the shares bought up. When the packet left Jamaica, Senor Don Rennaldo, the captain of the Cuban mines, had been applied to for assistance and advice, and was daily expected there.

Consumption of Smoke.—We have great pleasure in directing public attention to the efficacy of Hall's apparatus for the consumption of smoke from steam engine chimnies. Mr. Hall has just completed one at the manufactory of Messrs. Boden and Morley, in Castle-street, in this Borough, which from its efficacy, if generally adopted, will leave no cause of complaint from what has hitherto been a source of annoyance to the inhabitants of the borough. The furnace is supplied by a current of air heated by the furnace itself, which, when in full operation, completely consumes the volume of dense smoke, which is frequently sent forth from the chimney of a steam-engine. Of course this cannot be done till the fire is got up in the morning, and whenever the furnace door is opened for feeding, the apparatus ceases to act; but half a minute suffices to clear the chimney, when the furnace door is shut, and then, however thick and dark the smoke was previously, the quantity is immediately greatly reduced and its density gives place to a silvery hue. We believe the apparatus saves something considerable in fuel, and we are sure its adoption will be hailed with general approbation by the inhabitants of this borough.—*Derby Reporter.*—A short time ago, our columns contained a notice of the perfect consumption of smoke by apparatus applied to the steam engine of Messrs. Benjamin Cort and Co., of this town; it has also been used with equal success as applied to other steam engines, both here and at Derby. We are highly gratified at being informed that this invention answers equally well with locomotive engines. A trial was made of it, as attached to the "Wizard," a few days ago, on the Midland Counties Railway, in the presence of some of the directors of the company, and of several other gentlemen; of the former were William Hannay, Esq., and Henry Youle, Esq., and of the latter were Francis Wright, Esq., of Lenton Hall, H. B. Campbell, Esq., &c., who all expressed their high approbation of its satisfactory operation. The above apparatus for which a patent was taken out in January last, is the invention of Mr. Samuel Hall, the inventor of the condensers (known under his name), for supplying pure distilled water instead of salt or otherwise impure water to the boilers of marine and other steam engines, as well as the inventor of the reefing paddle wheel for steam vessels. The importance to railway companies of being able to use coal instead of the costly article of coke to locomotive engines, can scarcely be estimated, so greatly must it reduce the expense of the transit of passengers and goods, and consequently increase the profits of the shareholders.—*Nottingham Review.*

Dorsetshire—The body of the church of St. Mary's, Wareham, Dorset, is now being pulled down for the purpose of being rebuilt. This part has evidently been already once before pulled down and rebuilt, the nave being divided from the side aisles by square massive piers of rough rubble construction, with impost and archivolt mouldings of a Roman character. This alteration was possibly done towards the latter end of the 17th, or beginning of the 18th century. The workmen have found in the walls some fragments of stone with curious carvings and inscriptions. There is a fine tower and spacious chancel of decorated Gothic which will not be touched, and attached is a small sepulchral chapel with tombs of cross legged knights in chain armour. The new church provides accommodation for 1000 persons. The contract has been taken by Messrs. Cornick and Son, of Bridport, Dorset, and the works are to be completed by Michaelmas 1842, under the superintendence of Mr. T. L. Donaldson, architect, by whom also a new Scotch Church is to be erected at Woolwich, in the Norman style, with accommodation for 1000 persons, half of whom will be soldiers of the garrison. The plot of ground for the church and schools, which are to be erected in connexion, has been given by the Government, in consideration of the sittings, which will be provided for the troops of the Kirk communion.

Mr. Stephenson's Lime Works at Amber Gate.—Mr. Stephenson has now commenced burning lime at these works, and is sending it to the different places adjacent to the North Midland Railway. In the course of a short time it will be conveyed to most of the principal towns in England. The kilns are built in a handsome and substantial form, standing from 30 to 40 feet above the surface of the ground. The limestone is procured from the village of Crich, about two or three miles distant from the kilns, on a tramway formed for that purpose. A short distance from Crich, the tramway passes through a tunnel between 50 and 60 yards in length; a little further on is an inclined plane, worked by a wheel, which lets down six wagons full of limestone, and draws up the same number of empty wagons. Nearly adjoining this is another inclined plane, which is uncommonly steep, rising at the rapid rate of one yard in three and a half, and is worked by a large drum, round which passes a wire-rope; a lever is attached to the drum, by which one man alone is able to regulate the speed of the wagons at pleasure, or stop them altogether. Two full wagons are let down and two empty ones are drawn up at the same time. The full wagons pass over the Cromford canal by a wooden bridge (elevated several feet above the surface of the water) to the top of the kilns. These stupendous works, when finished, will be of the most extensive character in England, or we may say in the whole world. They will, when complete, be able to turn out upwards of 200 tons of lime per day.—*Sheffield Patriot.*

Victoria Park Bill.—The Bill authorising the Woods and Forest to form a Park in the eastern part of the metropolis, has already past the House of Commons.

The bronze statue of Rubens is at length completed, and has been sent from Liege to Antwerp, the place of its destination.

Parisian Bitumen.—The terraces at the Slough station of the Great Western Railway are being lined with this material. its use has of late been considerably on the increase; it has been introduced in several parts of the metropolis.

LITERARY NOTICES.

Mr. Dollman has given the public two faithful representations of the restorations of the Vicar's Close at Wells, the details of which are given in Mr. Walker's book. The chimneys we think felicitous, but the sentry-box porches might, we conceive, without injury have been omitted by the architect; fidelity of this kind savours too much of the ingenuousness of the Chinese tailor, who treated the patches in the pattern coat as an essential part of the workmanship.

Mr. E. Clifford, a teacher of mathematics, has brought out a small treatise styled *Arithmetic Considerations on Marquoi's Parallel Scales, and the Protractor,* which contains a number of useful calculations and directions.

LIST OF NEW PATENTS.

GRANTED IN ENGLAND FROM 29TH APRIL, TO 27TH MAY, 1841.

Six Months allowed for Enrolment.

JAMES SIMS, of Redruth, Cornwall, civil engineer, for "*certain improvements in steam engines.*"—April 29.

ALFRED JEFFERY, of Prospect-place, New Hampton, Middlesex, gentleman, for "*a new method of defending the sheathing of ships and of protecting their sides and bottoms.*"—April 29.

GEORGE TOWNSHEND, of Sorpcote-fields, Leicester, Esquire, for "*improvements in machinery or apparatus for cutting certain vegetable substances.*"—April 29.

JOSEPH GIBBS, of Kennington, civil engineer, for "*a new combinaiion of materials for making bricks, tiles, pottery, and other useful articles, and a machine or machinery for making the same, and also a new mode or process of burning the same, which machine or machinery and mode or process of burning are also applicable to the making and burning of other descriptions of bricks, tiles, and pottery.*"—April 29.

MILES BERRY, of Chancery-lane, for "*certain improvements in machinery or apparatus for making or manufacturing nails and brads.*" (A communication.)—May 4.

FRANCIS JOSEPH MASSEY, of Chadwell-street, Middleton-square, watch manufacturer, for "*improvements in the method of winding up watches and other time keepers.*"—May 4.

EDWARD NEWTON, of Leicester, manufacturer, and THOMAS ARCHBOLD, of the same place, machinist, for "*improvements in producing ornamentai or tambour work in the manufacture of gloves.*"—May 4.

CHARLES THOMAS HOLCOMBE, of Bankside, Southwark, iron merchant, for "*certain lubricating or preserving matters for wheels and axles, applicable also to the bearings, journals, or other parts of machinery.*"—May 4.

HUGH GRAHAM, of Bridport-place, Hoxton, artisan, for "*an improved manufacture of that kind of carpeting, usually denominated Kidderminster carpetting.*"—May 6.

MOSES POOLE, of Lincoln's Inn, Esquire, for "*improvements in the manufacture of fabrics by felting.*" (A communication.)—May 6.

PHILEMON AUGUSTINE MORLEY, of Birmingham, manufacturer, for "*certain improvements in the manufacture of sugar moulds, dish covers, and other articles of similar manufacture.*"—May 6.

JAMES HANCOCK, of Sidney-square, Mile End, civil engineer, for "*certain improvements in the manufacture of locks, keys, latches, and other fastenings, part of which improvements are applicable to taps and cocks for drawing off fluids.*"—May 6.

JOHN PAULY, jun., of Preston, Lancashire, manufacturer, for "*certain improvements in looms for weaving.*"—May 10.

HOOTON DEVERILL, of Nottingham, lace manufacturer, for "*certain improvements in machinery for making and ornamenting lace, commonly called bobbin net lace.*"—May 10.

ANDREW MC NAB, of Paisley, North Britain, engineer, for "*certain improvements in the manufacture of bricks.*"—May 11.

EDMUND TAYLOR, of King William-street, gentleman, for "*certain improvements in the construction of carriages used on railroads.*" (A communication.)—May 11.

HENRY PINKUS, of Maddox-street, Hanover-square, for "*an improved method or methods of applying electrical currents or electricity, either fractional, atmospheric, voltaic, or electro magnetic.*"—May 14.

JAMES GREGORY, coal master, and WILLIAM GREEN, turner, both of West Bromwich, Stafford, for "*certain improvements in the manufacture of iron and steel.*"—May 14.

PIERRE JOURNET, of Dean-street, Soho, engineer, for "*improvements in fire-escapes, which improvements are applicable to other useful purposes.*"—May 19.

JOHN CARR, junior, of Paddington, engineer, for "*improvements in apparatus for retarding and stopping railway-carriages.*"—May 20.

CHARLES PHILLIPS, of Chipping Norton, Oxford, engineer, for "*improvements in reaping and cutting vegetable substances as food for cattle.*"—May 20.

JOSEPH WOODS, of Lawn-place, Lambeth, Surrey, civil engineer, for "*certain improvements in locomotive engines, and also for certain inavrovements in the machinery for the production of rotatory motion for obtaining mechanical power, which improvements in machinery are also applicable for raising or impelling fluids.*"—May 22.

WILLIAM GALL, of Beresford-terrace, Surrey, for "*certain improvements in the construction of inkstands.*" (A communication.)—May 22.

JOHN AINSLIE, farmer, Redheugh, North Britain, for "*a new and improved mode of making or moulding tiles, bricks, retorts, and such like work from clay, and other plastic substances.*"—May 22; four months.

CHRISTOPHER DUMONT, of Mark-lane, London, for "*improvements in the manufacture of metallic letters, figures, and other devices.*" (A communication.)—May 22.

JOHN WINTERBORN, of Clarence-place, Hackney-road, surgeon, for "*improvements in machinery to facilitate the removal of persons and properly from premises, in cases of fire; which improvements are applicable to raising and lowering weights generally, to assist servants cleaning windows, and as a substitute for scaffolding.*"—May 22.

WILLIAM LEWIS RHAM, of Winkfield, Berks, clerk, for "*certain improvements in machinery or apparatus for preparing land, and sowing or depositing grain, seeds, and manure.*"—May 22.

JOHN WHITEHOUSE, of Deptford, engineer, for "*an improved method of making boilers, to be used in marine steam engines.*"—May 22.

WILLIAM JOEST, of Ludgate-hill, merchant, for "*improvements in propelling vessels.*" (A communication.)—May 26.

GEORGE HULME, of Saint John-street, Smithfield, cock founder, for "*improvements in water closets.*"—May 27.

JOSEPH BETTRIDGE, of Birmingham, wood turner, for "*an improved method of manufacturing papier mache, pearl, china, ivory, horn, wood, and composition, into pillars and stands for table and other lamps, and other articles of domestic furniture.*"—May 27.

JAMES SHANKS, of Saint Helen's, Lancashire, chemist, for "*improvements in the manufacture of carbonate of soda.*"—May 27.

TO CORRESPONDENTS.

Communications from M R., Daniel Clark, &c., *received too late will appear next month.*

We have received a proposition for forming "An Association of Architectural and Engineering Draughtsmen," which we have deferred for consideration until next month.

Communications are requested to be addressed to "The Editor of the Civil Engineer, and Architect's Journal," *No.* 11, *Parliament Street, Westminster.*

Books for Review must be sent early in the month, communications on or before the 20th (if with drawings, earlier), and advertisements on or before the 25th instant.

Vols. I, II, and III, may be had, bound in cloth, price £1 each Volume.

ERRATA.

In last month's Journal, p. 173, for *Harry* Austin read *Henry* Austin.

P. 129, for Mr. Edward Hall (late of *Birmingham*) read late of *Manchester.*

The type of pages 151 and 152, after it was made up, got disarranged; we have consequently reprinted them, which are given with the present number. We have to request our readers to cancel these pages, and substitute those given herewith.

the level of the engineman's eyes; and that the point where the centre of the beam would intersect the horizon, A C, of his vision at E, should be about 700 feet from the lens. The impulse of the light would be most advantageously received at some point as near the lens as is consistent with a full effect from a flame placed in its principal focus. A more remote observer would receive the rays diluted by distance: while a nearer approach of the eye to the lens would render it necessary to adopt an ex-focal arrangement, so as to cause convergence of the rays. By the latter arrangement their divergence would be decreased, and the space covered by the light would be lessened not only in proportion to the decrease of divergence, but also to that of the cosine of the beam's inclination to the horizon. Both these circumstances would therefore combine to curtail the duration of the impression on the eye.

It may naturally be expected that I should say something regarding the duration of the impulse of the light on the eye; and upon this topic I shall, in absence of actual experiment, content myself with stating briefly the result of my calculations. If we suppose that an effective divergence of only 2° were to be obtained (and this is just one third of what is obtained from Fresnel's lens with the great lamp), I find that the light would spread itself along the horizon of the observer's eye between B and C to the distance of about 1000 yards, which, at the speed of 40 miles an hour, would be passed over in about 50 seconds, but at the ordinary railway speed of 25 miles an hour, about 80 seconds or 1⅓ minute would be required. Such a flash of light falling upon the polished parts of the engine, and upon the observer's face, would undoubtedly act as a most effective signal. If, however, it should be thought advisable to increase the duration of the impression by spreading it over a greater length of the line, this effect could be easily produced by a slight alteration of the inclination of the lens, so as to cause the line of railway to cut the refracted beam more obliquely; but I by no means expect that any such modification would be found necessary in practice. The nearness of the eye to the lens, and the brilliancy of the flash, would, I am inclined to think, more than compensate for the shortness of the impression.

I must add a few words regarding the expense of these signals, which would be made up of the cost of erecting the scaffold of carpentry, the price of the lens, and the maintenance of the light. The price of the stage I shall pass over as a matter which may vary according to the circumstances of the situation and the taste of individuals; but the cost of the great annular lens does not exceed 40*l*.; and if a smaller sized lens, which I think would be found quite sufficient for the purpose, were employed, the expense would not be more than 10*l*. The annual maintenance would consist of little more than the supply of a gas or an oil burner. The consideration of the expense, therefore, of maintaining such a system of signals at the necessary intervals on railways, is not for a moment to be set against the most remote risk of the least of all the numerous accidents, the records of which fill the public prints.

OBSERVATIONS ON THE MOTIONS OF SHINGLE BEACHES.

By Henry R. Palmer, Esq., F.R.S.*

From the Philosophical Transactions of the Royal Society:—read April 10, 1834.

The extraordinary prevalence of tempestuous weather during the last autumn having occasioned numerous disasters on our coast, the public attention was directed in an unusual degree to the imperfections of many of the harbours, and more particularly to those which are encumbered with accumulations of shingle. The access to harbours thus circumstanced is generally uncertain, and in tempestuous weather is frequently dangerous, or even impossible.

The action of the sea, which gives motion to the shingles and produces the evils complained of, has long been a subject of speculation; but I have not found that it has been systematically investigated. Indeed, the contrariety of opinions advanced upon the subject, sufficiently indicates an entire absence of that satisfactory mode of inquiry which is essential to the foundation of a safe and practical deduction.

Very little has been written upon the subject; and such facts as have been mentioned have only been referred to incidentally, or with a view to geological science. My present object is exclusively practical in its nature, and my observations have been limited to such facts as would assist in establishing certain and fixed rules for controlling the motions of the beach, so far as to enable us to preserve a clear channel through it in all seasons, and in every variety of weather: and to accumulate and preserve the shingles, where it is needful to do so.

The subject at first sight appears greatly complicated; and were it necessary to discuss minutely all the modifications arising from the variety of forms and local circumstances, it would perhaps be too much so for general description. I have, however, limited my investig atin to those simple and unvarying laws to which nature always adheres; and therefore the following observations must be considered as restricted only to certain general principles, subject to a variety of modifications.

The principles which I propose to illustrate will (under similar circumstances) at all times exhibit the same phenomena, but for the sake of perspicuity I shall now only refer to the coasts of Kent and Sussex.

Section 1.

That the pebbles which compose the shingle beaches on these coasts are kept in continual motion by the action of the sea, and that their ultimate progress is in an easterly direction, are facts long known and commonly observed. The following observations are chiefly directed to the particular manner in which the motions are produced.

From a general view of the effects that I have noticed, it appears that the actions of the sea upon the loose pebbles are of three kinds: the first heaps up, or accumulates the pebbles against the shore; the second disturbs, or breaks down the accumulations previously made; and the third removes, or carries forward the pebbles in a horizontal direction.

For convenience I propose to distinguish these by the following terms, viz. the first, the accumulative action; the second, the destructive action; the third, the progressive action.

All the consequences resulting from these various actions are exclusively referrible to two causes. The one is to the current, or the motion of the general body of the water in the ebbing and flowing of the tides; the other to the waves, or that undulating motion given to the water by the action of the winds upon it; and it is of considerable importance to the present inquiry that the effects resulting from each specific cause be separately considered.

The motion of the shingles along the shore is commonly attributed to the currents, the action of the waves being considered only as a disturbing foace. That such a notion is erroneous will, I apprehend, presently appear; although I have to regret that I have not had the opportunity of obtaining such satisfactory information relating to the velocities of the currents in the channel, as would have enabled me to include every form of argument upon the subject. The absence of such information has also prevented me from deciding satisfactorily as to the sources from whence the whole body of shingle is derived, which, although not necessary for the practical purposes I have in view, would have given more interest to the subject, and would have rendered the elucidation more complete. I must, therefore, for the present, be content to pursue the motions of the beach after it is found lying along or near the shore; observing only that the materials of which it is composed are those of the various strata in the vicinity of the coasts, together with the ordinary sea sand, and such small particles as may have been brought to the shore by the floods of the various rivers.

That the current is not the force which moves the pebbles along the coast, will appear from the following reasons;

1st. If it were so, the direction of the motion of the pebbles would be determined by that of the currents: but while the direction of the currents will vary with the changes of the tides, we find that the direction of the pebbles may remain unaltered; and also that the motion of the pebbles is continued where no current exists.

2nd. Although the velocities of the currents may not have been ascertained with precision, yet it is known that the velocities generally along this coast, which can possibly act on the shingles, are not sufficient to give motion to pebbles of every dimension, which are in fact carried forward.

3rd. The motion of a current will not produce that order in which the pebbles are found to lie, which order (as will be hereafter shown) may easily be distinguished as the effect of the motion of the waves only.

The direction of the waves is determined principally by the wind, the prevailing direction of which on the coasts referred to is from the westward. Every breaker is seen to drive before it the loose materials which it meets; these are thrown up the inclined plane on which they rest, and in a direction corresponding generally with that of the breaker. In all cases we observe that the finer particles descend the whole distance with the returning breaker, unless accidentally deposited in some interstices; but we perceive that the larger pebbles return only a part of the distance; and upon further inspection we

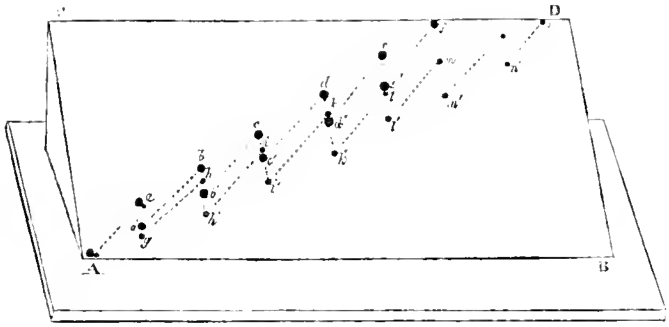
* The construction of harbours, piers, and breakwaters is likely to become of considerable importance to the engineering profession; we therefore propose to collect for publication in the Journal, such papers as have been written on the subject.

find that the distance to which each pebble returns bears some relation to its dimensions. This process is an indication of the accumulative action.

But under some circumstances, depending on the wind, it is found that pebbles of every dimension return with the breakers that forced them up the plane, and that these are accompanied also by others, which had been previously deposited, but which are in such cases disturbed by the waves; and by a continual repetition of the breakers acting in this manner, the whole of the shingle previously accumulated is immersed below the surface of the water. This process is an indication of the destructive action.

The particulars of the accumulative action, *combined with that of progression*, are explained as follows. (Fig. 1.)

Fig. 1.



Let A B C D be an inclined plane, representing that on which the loose pebbles move. Suppose the wind to blow in such a direction as to cause a wave to strike a pebble at A, in the direction of Aa, and to the distance a up the plane, that point being the extent to which the force can reach. Now here the wave breaks partly into spray, and is dispersed in all directions; is partly absorbed, and descends in a shallow form, which rapidly diminishes in its depth, so that the pebble is soon left exposed, and therefore does not return the whole distance with the water, but is left at rest at a' being at a higher level than that from whence its motion commenced.

With the rise of the tide the striking force is also elevated; and by the repetition of the operation described through the different heights in succession, the further motion of the pebble will be represented by a' b' b' b', &c., the distance in each step of its descent being something less than in that of its ascent, until it has reached the summit f, determined by the height of the tide. Now if we suppose a pebble of less dimensions than the former to be struck from the same point, we shall find it raised as before; but because its surface is greater in proportion to its weight, and because from its less bulk it remains longer immersed in the declining wave, it will descend further, and follow the line a g, &c., and will not be left at rest till it has reached o.

If, then, we suppose a pebble whose dimensions are less than either of the former, it will be evident that the point at which that will arrive on the highest level will be more distant still; hence it follows that the distance travelled horizontally by the pebbles during a tide will be in some proportion to their bulk, the specific gravities being the same.

(The pebbles do not in reality move in straight lines, but in a succession of curves; the straight lines are assumed here, and in other parts of this paper, to simplify the description.)

I trust it is only necessary to remark, that if the wind continue to blow in the same direction during the ebbing of the tide as through the flowing of it, the direction in which the waves will strike the shore will be nearly the same, and the progress of the pebbles will be urged by a similar action, and therefore their direction will also be the same.

In this action we observe a constant tendency to heap up and accumulate the shingles; and it is an interesting fact, that when the action has continued equally through a tide, the pebbles are left *in regular order, according to their dimensions*, the largest being uppermost, and the smallest at the bottom of the plane. I do not mean to state that all the largest are at the top, or that all the smallest are at the bottom, for it is evident that some of every size will be found at every level; but that if an equal measure (say half a peck) be taken from the different levels, the average of each specimen will exhibit in regular order the various dimensions.

The order in which the pebbles are thus found is, then, that by which the effect of the waves is distinguished from that of a current, the effect of the latter consisting only in its influence on the direction of the impinging and recoiling motions of the waves, by which the motion of the beach may in a small degree be accelerated or retarded.

Section 2.

In the illustration of that action of the sea which breaks down and removes an accumulation, I propose referring to my observations in the order in which they were made. My attention was first directed to this part of the subject in the neighbourhood of Sandgate in October last.

The accumulative action had been continued for a considerable time. The numerous groins erected near Folkstone to impede the progress of the beach, for the protection of the cliffs, had collected a bank of pebbles, which in some parts was five feet in height. The wind had so much abated as to be scarcely perceptible, but the sea had a motion denominated a *ground swell.*

The waves approached the shore nearly at right angles with it; but although in rapid succession, their forces were very moderate. These circumstances continued through five tides, by which time nearly the whole of the loose shingle had disappeared, including all that had been collected by the groins at Folkstone. The water being particularly clear, I was enabled to perceive distinctly the action upon the pebbles, and their motion downwards. I observed, that although every wave became broken and dispersed as usual, yet they followed in such rapid succession, that each wave rode over its predecessor while on its return, and thus produced a continual downward current, which carried with it the pebbles that were disturbed. That the pebbles were not removed far from the line of low water, would appear from the fact, that on the subsiding of the swell, it being succeeded by a light breeze of wind from the westward, the accumulation immediately commenced, and was restored to its former quantity by the action of four tides. I have subsequently had some favourable opportunities for making other observations on the effects produced by different rates of succession of the waves, and particularly at Dover, during the late gales, where the same actions were noticed. There I watched for an opportunity of witnessing that rate of succession which exhibited the destructive and accumulative actions in their smallest degrees; and I observed, that when ten breakers arrived in one minute, the destructive action was but just evinced; and that when only eight breakers arrived in the same period, the pebbles began to accumulate; which facts harmonized with my observations made at Sandgate and Folkstone, viz. *that the difference between the two actions was determined by the rapidity in succession of the waves upon the shores.*

In the description of the accumulative action, I have assumed the forces to be directed obliquely with the line of coast, and have therefore necessarily included the progressive motion; but it remains to be explained in what manner the shingles are carried forward while the destructive action is going on.

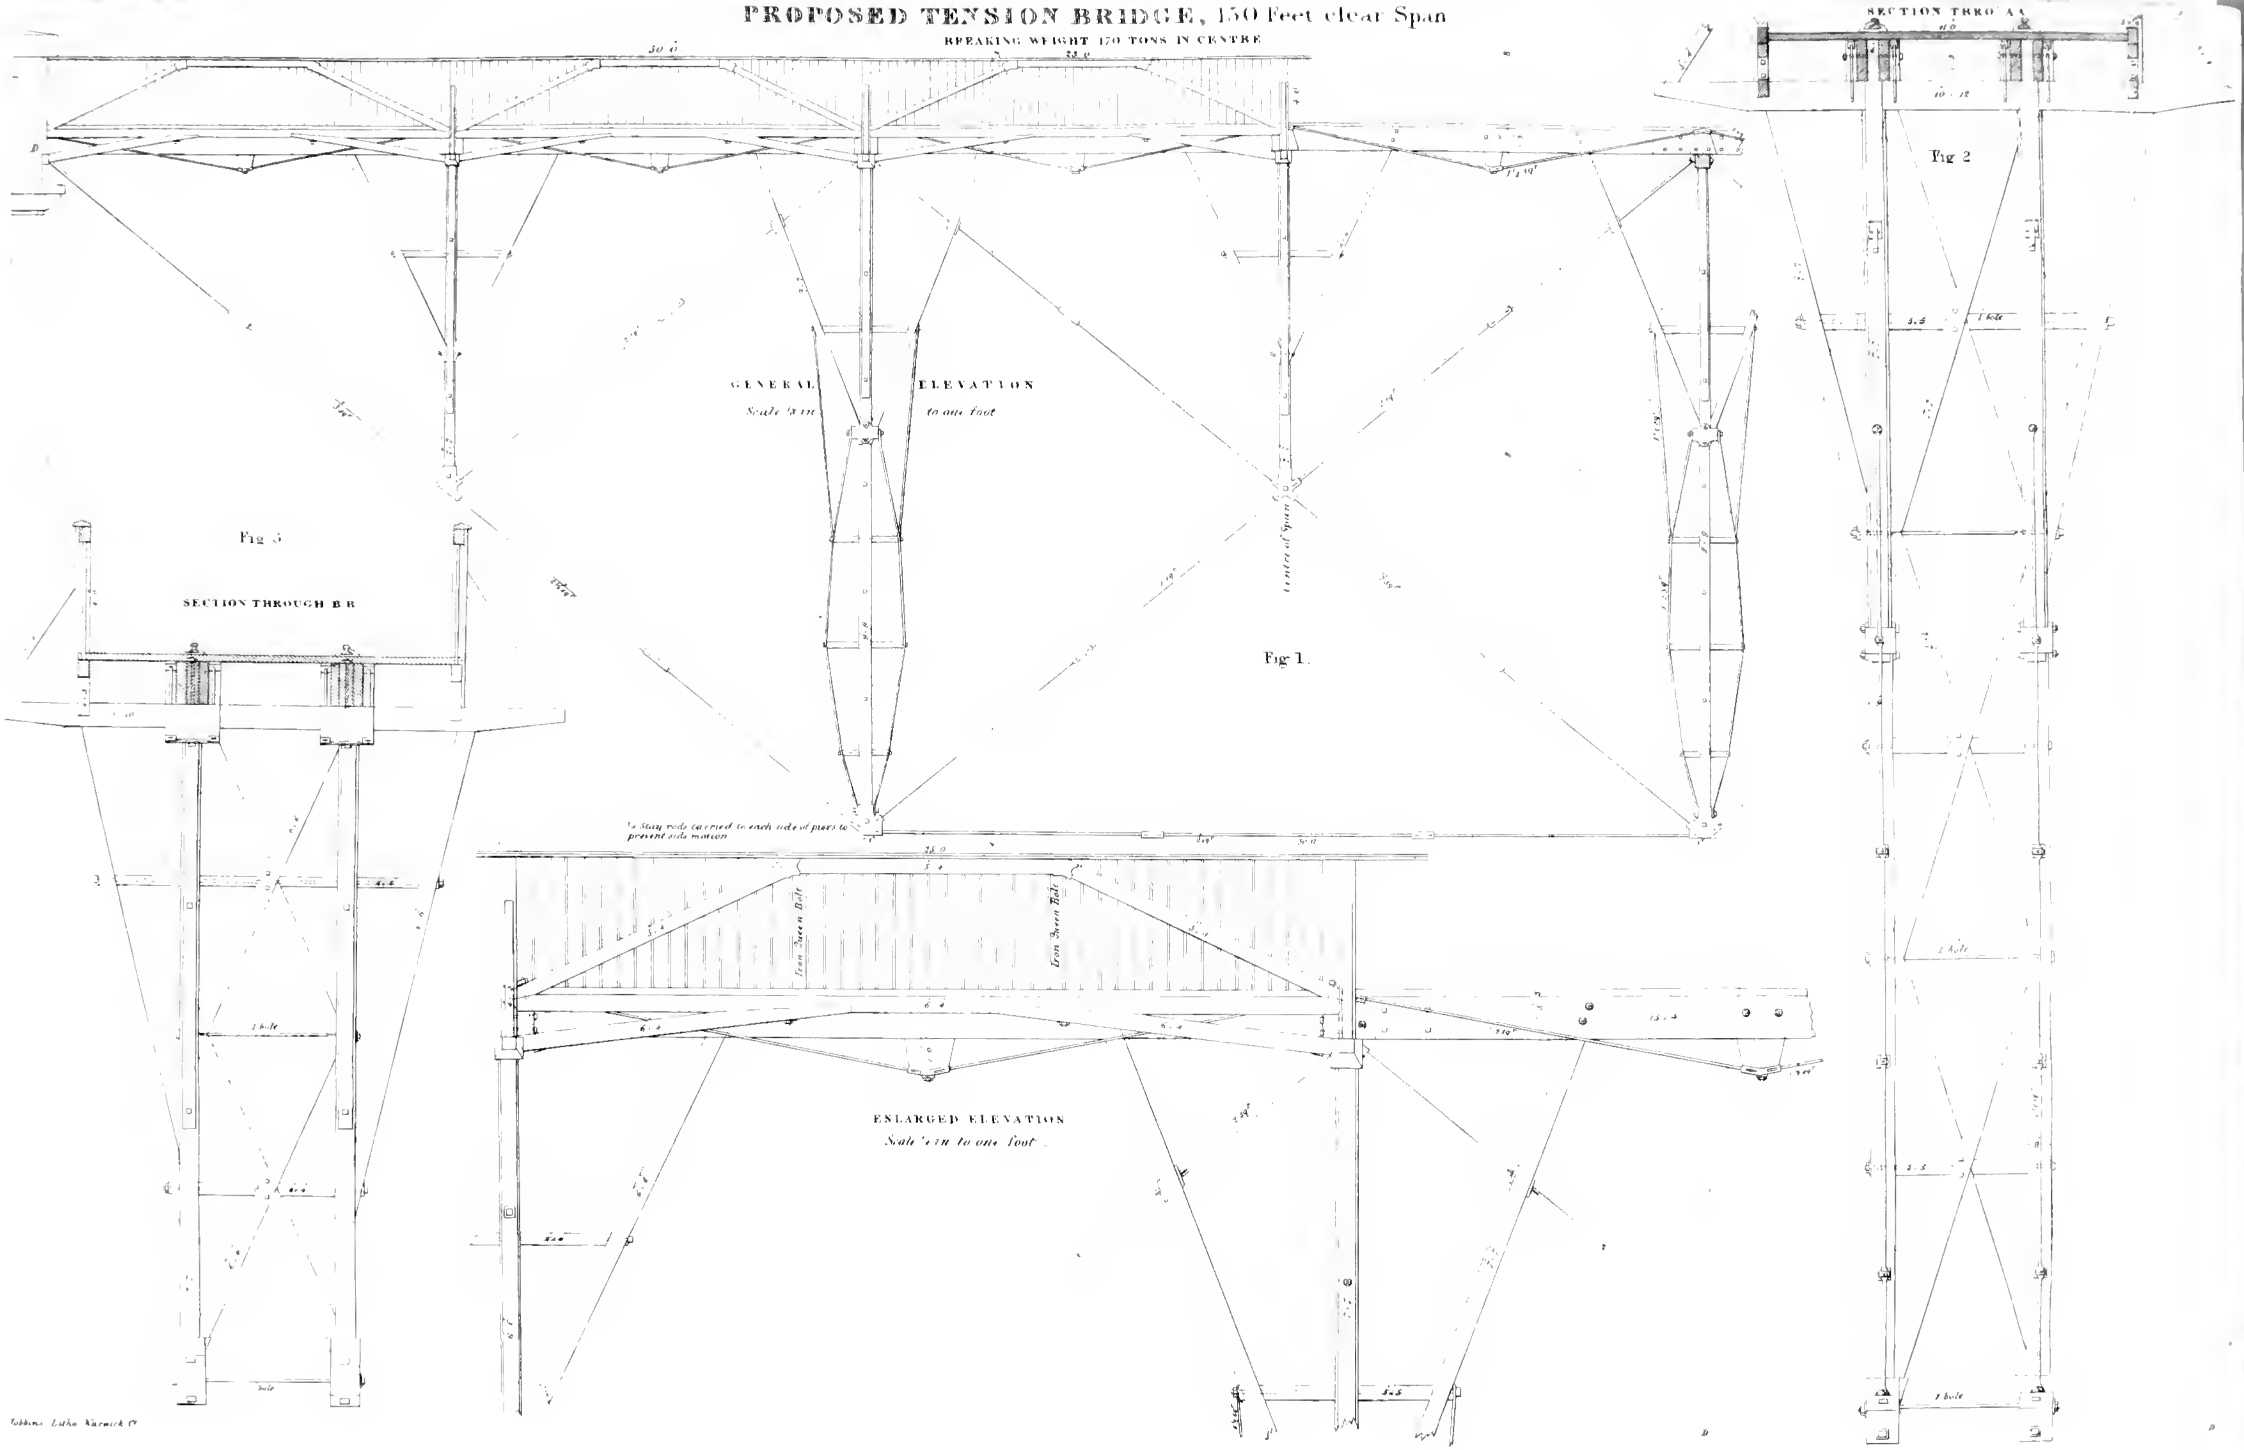
It is known that the action and re-action of the waves give to the whole body of the water, within a certain distance from the shore, an undulating motion. The direction of this motion, when approaching the shore, will, to a certain degree, correspond with that of the waves upon the surface, and the direction of the recoil will also be affected in like manner; therefore the pebbles that have been carried down by the destructive action are moved forward through an angular course *beneath the water*, until, by the excess of the impinging forces over those of the recoil, they are again raised by the action of the water, and deposited where the destructive action has ceased, or where, from local circumstances, it cannot occur. The circumstances which are most unfavourable to the destructive action are those which least admit of the constant downward under-current—an inlet, or narrow arm of the sea, for example. If we suppose a wave rolling through the mouth of an inlet, carrying with it a charge of shingles, it does not break as upon an inclined plane, but is dispersed in the general body of the water, which is comparatively quiescent; and there being no returning force, the shingle becomes deposited, and a bank is formed: and although the destructive process would act upon that bank if it could attain a certain height, yet the attainment of that height is prevented by the waves passing over it, and carrying with them, in succession, the shingles with which they are charged.

Section 3.

In Fig. 2 is represented a section of the beach formed along the outside of Folkstone Harbour. This section was taken with great accuracy, after the ground swell before referred to had removed most of the loose pebbles from it; so that the section may be considered as representing the plane upon which the progressive motion of the pebbles is carried on. Its slope is in the proportion of 1 to 9, nearly, and (with the exception of that part near the summit where there remained

PROPOSED TENSION BRIDGE, 150 Feet clear Span

BREAKING WEIGHT 170 TONS IN CENTRE

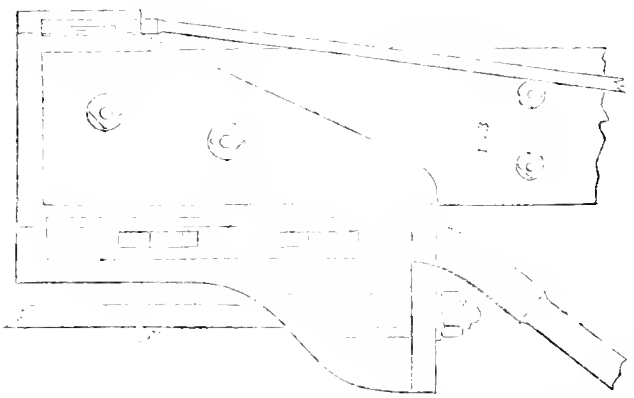


NEW FORM OF VIADUCT.

(With an Engraving, Plate VII.)

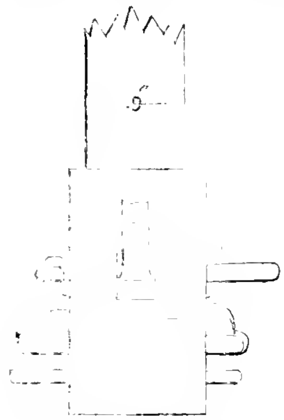
The accompanying drawings show a new species of viaduct that has been made use of as a general design, in the parliamentary estimate of a recently surveyed Railway.

Fig. 4—Side view of the Clutch Box D.



The principle in its simple form, is not new to the engineering world, having been put into execution in the "Foot bridge over the Whitadder, at Abbey St. Bathans," (see Theory, Practice, and Architecture of Bridges, part four,) and being commonly used in temporary erections, scaffolding, &c., and frequently applied in strengthening various kinds of vehicles. The novelty consists in carrying out the idea to the magnitude of the present case.

Fig. 5—End view of the Clutch Box C.

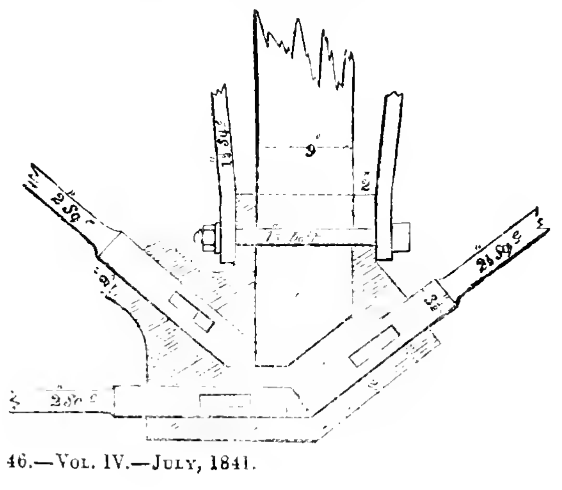


It will be seen that the system is applicable on a great scale, in those cases only where there is a large amount of headway to spare, as the efficiency of the arrangement is so completely dependant on the inclination of the tension bars. The estimation of the strength in the original form, is a matter of great ease, involving only a simple case of resolution of forces.

This design is made for a single line of rails only, but it would appear that it might be much more advantageously and economically applied to a double line.

A reference to the drawing will preclude the necessity of any detailed description, and it will be necessary merely to draw attention to the more important points. It will be seen that the application of the tension bars is not confined to the resistance to vertical deflection, but that it is made use of in given lateral strength to the main supports, (inverted tressels would perhaps be the most descriptive term), their bending being prevented in one direction by the transverse studs and tie-bolts, and in the other by the tension of the iron rods.

Fig. 6—Section of the Clutch Box C.



A weight entering upon the bridge will be perceived to immediately distribute its effects over the whole structure, by means of the ascending intermediate bars; these bars will effectually prevent any partial deflection that might be expected to occur upon an unequal distribution of the load.

It will be observed that rods are dotted in, and noted as being carried to the sides of the piers, to prevent any lateral oscillation: little fear of this however need be entertained, as the surface exposed to the wind would be so slight; nevertheless if there were any apprehension of such an effect, it might be further guarded against, by a divergence, of the sides of the supports, as shown by the dotted lines at D', D', on the transverse section; and this would be done with very little diminution of strength. In a double line there would be no need of such precaution.

The estimated cost, including scaffolding, &c., and exclusive of piers, is 5*l.* per lineal foot; the quantities I took out myself, and can bear testimony to their fulness; the prices were given by another, and were high in consequence of the difficulty of the localities: in short I believe that the above price is rather more than would be the cost in average cases. With regard to the strength, I think it will be found by any one who will be at the trouble to calculate it, that it is if any thing greater than what is stated.

To those with whom appearance is the main point in railway works, the design will probably afford some amusement; but every one will I think perceive that elegance of effect is not attempted, an economical and durable structure being the only object in view.

Herbert Spencer.

Derby, May 1[illegible], 1841.

Reference to Drawings.

Fig. 1. Plate VII. is a side view of the bridge, part of the span is omitted in order that the remainder might be kept to as large a scale as the size of the Journal would admit. Fig. 2. is a transverse section of one of the suspensions or the cross trusses; and fig. 3. a transverse section of the centre suspension or cross truss. Fig. 4. enlarged view of the clutch box D, secured to the piers. Fig. 5. end view of the clutch box C; and fig. 6. a section of the same. The three last figures are drawn to a scale of [illegible] of an inch to a foot.

CONDUCT OF THE GOVERNMENT TOWARDS THE ENGINEERING INTERESTS.

We have, on more than one occasion, thought it our duty to call the attention of our readers to the conduct which has long been pursued by the government and the legislature, as to all measures bearing upon the interests of the engineering profession. We are well aware that many of these measures, although weighing most strongly upon the engineers were directed against other interests, and cannot therefore be considered as purposely levelled against the profession: but, nevertheless, when we observe the tendency of measures more direct, and the uniform tenor of these proceedings, we are obliged to admit that either the policy or the inclination of the governing body is constantly directed to our injury. In whatever way we examine the measures affecting us we are impressed with this feeling, and now that we are enabled to look back and class together isolated events, we find an accumulation of evil in the highest degree threatening the profession. On the one hand our employment is proposed to be taken from us, and on the other we are to be placed under the government direction and control: so that both our moral and physical interests are equally concerned. It is perhaps fortunate that circumstances have intervened to prevent every attempt from being effective, but still a sufficient amount of mischief has been perpetrated to call for the serious attention of every one to the position in which he is placed. It might have been well at a former period for the civil engineer to say, that affects the marine engineer or the capitalist and not me, or for the practical engineer to say that has nothing to do with me, but now when we come to review the whole of these proceedings we find something which affects each individual branch, while there no longer remains a doubt that the whole body is in danger. What engineer when he considers the several government measures of the last four years can now flatter himself that he is safe, and that the attack on his neighbour is imminent of no danger to himself? Let him look at the Ten Per Cent. Deposit Clause, the Irish Railway Scheme, the Steam Navigation Bill and the Railways Bill; let him read the speeches of ministers, the reports of committees and commissioners, and the suggestions of commissioners, let him reflect on what has been attempted and then say if he dare to assign any limit to their future aggressions. We feel that the period has now arisen when it becomes the profession in a collective capacity to do in all its power for resisting present attempts, preventing future invasions, and remedying past evils, and unless these things be done and be done quickly too, we very much fear that an amount of distress and inconvenience will be inflicted on every individual, such as to make him bitterly regret his inactivity.

The Standing Order of the House of Commons requiring the payment of a deposit into the Bank of England of ten per cent. on the proposed capital of all public works, is a regulation the evils of which we have long deprecated. Many have shut their eyes under the delusion that either the order would be repealed from a conviction of its inefficiency, or such a change would take place in the money market as would enable it to be complied with. We were never so insane, for we considered that the same ignorance, which could lead to such an enactment in the teeth of reason and experience, would blind its partisans to any defect in its operations, and that whether the money market were either in a sound or unsound state, the impediment would be equally serious. The evils which have arisen to the profession from the stagnation of affairs have been quite enough without any aggravation, but now whatever may be the means or disposition of the monied interest, three years have passed over without a single act having passed for any public work of importance. After the present year we really cannot see where employment for a large part of the profession is to be obtained, for there will be neither railways, canals, docks, harbours, bridges, gas nor water works to be constructed, and no prospect, with means however abundant, of obtaining acts of parliament, except after the long period required by the standing orders. We foresaw what the result would be, and we gave warning of it, if therefore every one has remained lukewarm it has been from no default or neglect on our part, and those who will suffer will have themselves to blame for the event. The engineers must petition and obtain petitions from other parties for the redress of the grievances caused by the Ten Per Cent. Clause, for they may readily see that unless they put their shoulders to the wheel and sturdily too, no relief will they obtain. When an honourable member rose the last session to move for a reduction in the amount of the deposit, how was he supported, and what was the language of the President of the Board of Trade, the mouthpiece of that department in which all our evils have originated? He actually declared that no diminution in the number of acts had taken place, that no mischief was caused by the Standing Order, and finished by referring triumphantly to the number of notices then before the House of application for acts. Had he but enquired how many of these applications were rejected for non-compliance with this very regulation, and if he had enquired at the end of the session how many acts had passed, he would find that the account was merely a blank.

The Irish Railway Report, and the new Irish Railway scheme, are further developments of the same system; the progress of railways in Ireland has been checked, and the management of such as may be made is proposed to be entrusted to the government, the most inefficient body for the purpose which could possibly be selected, and which has already filled Ireland with monuments of jobbery and mismanagement. This new scheme must also be opposed as an emanation from the same stock, and as calculated by acting as a precedent to be productive of more immediate evil. The Steam Navigation bill exhibited, in all its deformity, the grasping ambition of the Board of Trade; the genius of our engineers was to be controlled, their plans revised, and their workshops taken from under their own management, and placed under the inquisitorial power of the government. The marine engineers were aroused, and the evil was warded off, but it must not be thought that an end is put to the existence of this monster, 'the snake is not killed but scotched,' and the spirit which animates it is too visible in the Railways Bill to allow us to doubt of its revival. These Railways Bills are too serious warnings of the danger of allowing the least tampering with our interests, to let us pass them by without calling the attention of our readers to the evils which are threatened by them. Discretionary powers are asked for, the future operation of which we are too well able to trace in those "shadows of coming events," the "Reports and Papers relating to Railways," presented to Parliament. Here we see military ignoramuses interfering with every part of the construction of railways and locomotives, putting the designs of the engineers under supervision, and suggesting that the workshop of the manufacturer of locomotives should be subjected to an inquisition. In fact, if our space permitted us, we might, on this subject alone, draw a fearful picture of the mischief which is threatened to every branch of the profession. Enough has now been said to call for an interference, and we have only to say further, that experience has shown that even the slightest opposition has been sufficient to check the Board of Trade in its mid-career, and if a sturdy opposition be organized, we are not without hopes of having all the grievances redressed. We again recommend the engineers to lose no time, or the profession will be stripped of its independence, and their offices of all appearance of business.

Neither are the evils confined to the engineers, but equally threaten other and more numerous classes. It is acknowledged that it is to the railways and other public works that we, in a great degree, owe the employment of the working classes, and diminution of the poor rates, and any sudden cessation of employment must be productive of the most disastrous consequences. The contractors, also and subcontractors employed, and the several classes of tradesmen and labourers connected with them, are exposed to consequences equally ruinous; not only will they be put out of work, but their plant, tools and materiel becoming useless, must be sold at ruinous prices. A large amount of capital, also, which was directly employed in promoting the progress of the nation, has been, during the suspension, diverted, being either hoarded or rendered comparatively idle. Considered, indeed, in every possible way, whether on the broadest grounds or the narrowest, the measures of the government equally refuse the test, the interests of the nation being sacrificed through narrow-mindedness, or a love of jobbery.

PLAN FOR A NEW ASSOCIATION OF ARCHITECTURAL AND ENGINEERING DRAUGHTSMEN.

Among the various means which may be adopted in order to attain any desirable object, the association of numerous individuals who have a common interest in it, is one which has often proved successful in cases where isolated energy would have been unavailing. This may be observed in various instances, whether in pursuits of public utility, of pleasure, of charity, or of a private advantage.

It is now intended to suggest to the consideration of these concerned, whether this principle of association, so largely applied at the present day to objects of great public concern, might not be made useful to those engaged in one department of the arts of design with which it has hitherto had perhaps but little connection.

That class of artists is here alluded to, who are employed in a subordinate capacity in preparing the necessary drawings required previously to the execution of any great work either of architecture or engineering, to furnish the necessary illustration for the artificers who are to carry it into practice, and for the proprietor who is to possess it when completed.

It may be true that the different societies already formed both of architects and engineers, may have the effect of adding to the general stock of information, of increasing the means of knowledge, and maintaining the character of each profession with the public; but the union now advocated, is intended to be of a more humble kind of utility, less exalted in its objects, less interesting to the imagination, but it is conceived, not less adapted to meet the wishes and supply the wants of a considerable number of individuals.

However it may be that the young student of architecture (by which perhaps he merely means the drawing of architectural decoration), flatters himself that he is pursuing a "fine art," including all the grand and elevating, and beautiful attributes that may be connected with the term, he will probably find sooner or later, (circumstanced as the art is in these utilitarian days), that he cannot pursue it professionally without making it a different sort of business: a pursuit in which the physical qualities of objects shall be more considered than the æsthetical, in which the combination of the various talents of others shall be preferred to the concentration of a single isolated mind upon a single visionary object, in which the useful shall triumph over the beautiful, and the matter of fact over the imaginative.

These observations are put forward as prefatory to the main object of this paper, which is to suggest the formation of an Association of Architectural and Engineering Draughtsmen, for the purpose of enabling them more readily to communicate with each other, and with those at whose hands they expect employment; and of affording to the latter class, the means of readily obtaining that assistance of which they may stand in need, on terms the most equitable to both parties.

To obtain these ends, the means now proposed are, the collecting together at a given place for public exhibition, a number of specimens of the abilities of members of the associated body, whether applied in the different ways which are found practically useful in business, or exerted to produce results more attractive to the eye at first sight. For there should not merely be a display of the heaven-ward aspirations of unfettered fancy, exerted upon castles in the air, bridges over chaos, temples for which even if already erected it would be difficult o contrive any useful destination, and palaces adapted to pursuits of pleasure, unsuitable to our tastes, our habits, and to the climate of the country we inhabit; but places should also be assigned to those working drawings of common houses, and modern economical churches, those practical details of machinery, and surveys of parishes, and plans of estates, which would perhaps attract still more scrutiny from some of the frequenters of the proposed exhibition.

In reducing this plan to practice, several reasons might be alleged why the draughtsmen themselves ought to be the managers. They might make it one of their rules to be allowed respectively space for their drawings proportionable to the sums they subscribe to defray the necessary expenses. On the other hand contributions might also be levied from those whose curiosity led them to visit the collection, by the sale of catalogues, the possession of which might give a right of admission for a certain period.

The writer of these observations would be glad if they should have any effect in inducing others of the parties interested to join and carry his proposal into effect. Of course he would not be backward in lending his share of assistance so far as was within his limited means, and he should expect to be joined in doing so by some other of the younger members of the profession, who have expressed their concurrence in the views here expressed.

G. M.

ENGINEERING WORKS OF THE ANCIENTS, No. 6.

In our last we gave an account from Xenophon of the Athenian silver mines, which, by some inadvertence, was detached from this series of papers, and now we proceed to give what Diodorus Siculus says as to the gold mines of Ethiopia (Book 3.)

EGYPTIAN OR ETHIOPIAN GOLD MINES.

In the confines of Egypt and the neighbouring countries of Arabia and Ethiopia there is a place full of rich gold mines, out of which with much cost and pains of many labourers, gold is dug. The soil here naturally is black, but in the body of the earth, run many white veins, shining with white marble, (query quartz), and glistering with all sorts of other bright metals; out of which, laborious miners, those appointed overseers, cause the gold to be dug up by the labour of a vast multitude of people. For the kings of Egypt condemn to these mines notorious criminals, captives taken in war, persons sometimes falsely accused, or such against whom the king is incensed; and that not only they themselves, but sometimes all their kindred, and relations with them, are sent to work here, both to punish them, and by their labour to advance the profit and gain of the king. There are infinite numbers upon these accounts thrust down into these mines, all bound in fetters, where they work continually, without being permitted any rest day or night, and so strictly guarded, that there is no possibility or way left to make an escape. For they set over them barbarians, soldiers of various and strange languages, so that it is not possible to corrupt any of the guard, by discoursing one with another, or by gaining opportunities of familiar converse.

The earth which is hardest and full of gold, they soften by putting fire under it, and then work it out with their hands; the rocks thus softened, and made more pliant and yielding, several thousands of profligate wretches break it in pieces with hammers and pickaxes. There is one workman who is the overseer of the whole work, who marks out the stone, and shows the labourers the way and manner how he would have it done. Those that are the strongest amongst them, that are appointed to this slavery, provided with sharp iron pickaxes, cleave the marble shining rock by mere force and strength, and not by art of sleight of hand. They undermine not the rock in a direct line, but follow the bright shining vein of the mine. They carry lamps fastened to their foreheads to give them light, being otherwise in perfect darkness in the various windings and turnings wrought in the mine; and having their bodies appearing sometimes of one colour and sometimes of another (according to the nature of the mine where they work). They throw the lumps and pieces of the stone cut out of the rock upon the floor. And thus they are employed continually without intermission, at the very nod of the overseer or taskmaster, who lashes them severely besides. And there are little boys that attend upon the labourers in the mines, and with great labour and toil gather up the lumps and pieces hewn out of the rock as they are cast upon the ground, and carry them forth and lay them upon the bank. Those that are about thirty years of age take a piece of the rock of such a certain quantity, and pound it in a stone mortar with iron pestles till it be as small as a pea, then those little stones so pounded are taken from them by the women and older men who cast them into mills that stand together near at hand there in a long row, and two or three of them being employed at one mill, they grind it so long till it be as small as fine meal, according to the pattern given them. No care at all is taken of the bodies of these poor creatures, so that they have not a rag so much as to cover their nakedness, and no man that sees them can choose but must commiserate their sad and deplorable condition. For though they are sick, maimed or lamed, no rest nor intermission in the least is allowed them, neither the weakness of old age nor the infirmities of women are any plea to excuse them; but all are driven to their work with blows and cudgelling, till at length overborne with the intolerable weight of their misery, they drop down dead in the midst of their insufferable labours; so that these miserable creatures always expect worse to come than that which they at present endure, and therefore long for death as far more desirable than life.

At length the masters of the work take stone thus ground to powder, and carry it away in order to the perfecting of it. They spread the mineral so ground upon a broad board somewhat hollow and lying shelving, and pouring water upon it, rub it and cleanse it, and so all the earthy and drossy parts being separated from the rest by the water, it runs off the board, and the gold by reason of its weight remains behind. Then washing it several times again, they first rub it lightly with their hands, afterwards they draw up the earthy and drossy matter with slender sponges gently applied to the powdered dust, till it be clean pure gold. At last other workmen take it away by weight and measure, and they put it into earthen urns, and according to the quantity of the gold in every urn, they mix it with some lead, grains of salt, a little tin, and barley bran; then covering the pot close, and carefully daubing them with clay, they put them in a furnace where they abide five days and nights together; then after a convenient time that they have stood to cool, nothing of the other matter is to be found in the pots, but only pure refined gold, some little diminished in the weight.

And thus is gold prepared in the borders of Egypt, and perfected and completed with so many and so great toils and vexations. And therefore I cannot but conclude that nature itself teaches us, that as gold is got with labour and toil, so it is kept with difficulty, creates everywhere the greatest cares, and the use of it is mixed both with pleasure and sorrow. Yet the invention of those metals is very ancient, being found out, and made use of by the ancient kings

Assyrian Engineering.

Keeping Diodorus Siculus as our guide, we now come to such notes as he has left of Assyrian engineering. (Book Second.)

WALLS OF NINEVEH.

Ninus (1950 B.C.) is styled the builder of Nineveh, having provided money and treasure and other things necessary for the purpose, he built a city near the river Euphrates, very famous for its walls and fortifications, of a long form; for on both sides it ran out in length above a hundred and fifty furlongs; but the two lesser angles were only ninety furlongs a piece; so that the circumference of the whole was four hundred and fourscore furlongs. And the founder was not herein deceived, for none ever built the like, either as to the largeness of its circumference, or the stateliness of its walls; for the wall was a hundred feet in height, and so broad that three chariots might be driven together upon it abreast. There were fifteen hundred turrets upon the walls each of them two hundred feet high.

BABYLON.

Semiramis, the wife of Ninus, was the founder of Babylon. To this end having provided architects, artists, and all other necessaries for the work, she got together two millions of men out of all parts of the empire to be employed in the building of the city. It was so built that the river Euphrates ran through the middle of it, and she compassed it round with a wall of three hundred and sixty furlongs in circuit, and adorned with many stately turrets; and such was the state and grandeur of the work, that the walls were of that breadth that six chariots abreast might be driven together upon them. Their height was such as exceeded all men's belief that heard of it (as Ctesias Cnidius relates). But Clitarchus, and those who afterwards went over with Alexander into Asia, have written that the walls were in circuit three hundred and sixty-five furlongs; the queen making them of that compass, to the end that the furlongs should be as many in number as the days of the year. The walls were of brick cemented with asphalte; in height, as Ctesias says, fifty fathoms; but as some of the later writers report, but fifty cubits only, and that the breadth was but little more than what would allow two chariots to be driven afront. There were two hundred and fifty turrets in height and thickness proportionable to the largeness of the wall. It is not to be wondered at that there were so few towers upon a wall of so great circuit, seeing that in many places round the city, there were deep morasses; so that it [illegible] year's [illegible] progression, she [illegible] over the [illegible] piers of the river five furlongs in [illegible] the supports [illegible] of the arches with great art [illegible] in the bottom of the water twelve feet distance from each other. That the stones might be the more firmly joined, they were bound together with hooks of iron, and the joints filled up with molten lead. And before the pillars she made defences sterlings with sharp pointed angles, to receive the water before it beat upon the flat sides of the pillars, which caused the course of the water to run round by degrees gently and moderately as far as to the broad sides of the pillars, so that the sharp points of the angles cut the stream, and gave a check to its violence, and the roundness of them by little and little giving way, abated the force of the current. This bridge was floored with great joists and planks of cedar, cypress and palm trees, and was thirty feet in breadth, and for art and curiosity yielded to none of the works of Semiramis. On either side of the river she raised a bank, as broad as the wall, and with great cost drew it out in length a hundred furlongs. Semiramis built likewise two palaces at each end of the bridge, upon the bank of the river, whence she might have a prospect over the whole city, and make her passages as by keys to the most convenient places in it as she had occasion. And whereas Euphrates runs through the middle of Babylon, making its course to the south, the palaces lie the one on the east, and the other on the west side of the river, both built at exceeding cost and expense. For that on the west had a high and stately wall, made of burnt brick, sixty furlongs in compass; within this was drawn another of a round form, upon which were pourtrayed in the bricks, before they were burned, all sorts of living creatures, as if it were to the life, laid with great art in curious colours. Our author goes on further to describe the ornaments of the palaces, which as less connected with our object we omit. He also describes the formation of a vaulted passage between the two palaces under the Euphrates, made by diverting the river. He says that the walls of this vault were twenty bricks in thickness, and twelve feet high, beside and above the arches; and the breadth was fifteen feet. The arches were of firm and strong brick, and plastered all over on both sides with bitumen four cubits thick. This piece of work being finished in two hundred and sixty days, the river was turned into its ancient channel again.

SEMIRAMIS'S WAY.

In a march towards Ecbatana, Semiramis arrived at the mountain Larcheum, which being many furlongs in extent, and full of steep precipices and craggy rocks, there was no passing but by long and tedious windings and turnings. To leave therefore behind her an eternal monument of her name, and to make a short cut for her passage, she caused the rocks to be hewn down, and the valleys to be filled up with earth, and so in a short time at a vast expense laid the way open and plain, which to this day is called Semiramis's way.

AQUEDUCT AT ECBATANA.

Besides this road, when she came to Ecbatana, which is situated in a low and even plain, she built there a stately palace, and bestowed more of her care and pains than she had done at any other place. For the city wanting water, (there being no spring near) she plentifully supplied it with good and wholesome water, brought thither with a great deal of toil and expense after this manner. There is a mountain called Orontes, twelve furlongs distant from the city, exceedingly high and steep for the space of five and twenty furlongs (query) up to the top; on the other side of this mountain there is a great lake which empties itself into the river. At the foot of this mountain she dug a canal fifteen feet in breadth and forty in depth, through which she conveyed water in great abundance into the city.

BRIDGE OF BOATS.

In her expedition into India, Diodorus relates that to cross the river, she carried with her boats, and made a bridge of boats by which she crossed.

SEMIRAMIS DEIFIED.

After her death or disappearance, Semiramis was adored by the Assyrians in the form of a dove, it being believed that she was enthroned among the gods.

MEMNON'S CAUSEWAY.

Of this work Diodorus gives the following account. Memnon, the [illegible] Persians [illegible] which is called Memnon's [illegible] Egypt question this, and say that Memnon was [illegible] and show several ancient palaces, which (they say) retain his name to this day, being called Memnon's palaces.

We shall now cull from the Fifth Book of Diodorus a number of desultory notes on different subjects, and first as to the

IRON MINES OF ETHALIA.

This island (Elba) abounds with iron stone, which they dig and cut out of the ground to melt, in order for the making of iron: much of which metal is in this sort of stone. The workmen employed first, cut the stones in pieces, and then melt them in furnaces, built and prepared for the purpose. In these furnaces, the stones by the violent heat of the fire, are melted into several pieces, in form like to great sponges, which the merchants buy by truck and exchange of other wares, and transport them to Dicearchia, and other mart towns.

TIN MINES OF BRITAIN.

Now we shall speak something of the tin which is dug and gotten here. They who inhabit the British promontory of Belerium, by reason of their converse with merchants, are more civilized and courteous to strangers than the rest are. These are the people that make the tin, which with a great deal of care and labour they dig out of the ground: and that being rocky, the metal is mixed with some veins of earth, out of which they melt the metal, and then refine it. Then they beat it into four square pieces like to a die, and carry it to a British Isle near at hand, called Ictis (Wight).*

GOLD MINES OF GAUL—ARMS.

In Gaul there are no silver mines, but much gold, with which the nature of the place supplies the inhabitants, without the labour or toil of digging in the mines. For the winding course of the river washing with its streams the foot of the mountain, carries away great pieces of golden earth: and when it is so done, they cleanse them from the gross earthy part, by washing them in water, and then melt them in a furnace: and thus get together a vast heap of gold, with which not only the women, but the men deck and adorn themselves.

As the arms used by the Gauls are calculated to show the progress made by them in the working of other metals, we copy the following descriptions. Some carry on their shields the shapes of beasts in brass, artificially wrought, as well for defence as ornament. Upon their heads they wear helmets of brass, with large pieces of work raised upon them for ostentation sake, to be admired by the beholders; for they have either horns of the same metal joined to them, or the shape of birds and beasts carved upon them. Some of them wear iron breastplates, and hooked; but others, content with what arms nature affords them, fight naked. For swords they use a long and broad weapon called *spatha*, which they hang across their right thigh by iron or brazen chains. Some gird themselves over their coats, with belts, ornamented with gold or silver. For darts they cast those they call lances, the iron shafts of which are a cubit or more in length, and almost two hands in breadth.

CELTIBERIAN MODE OF PREPARING IRON.

They carry two edged swords exactly tempered with steel, and have daggers beside of a span long, which they make use of in close fights. They make weapons and darts in an admirable manner, for they bury plates of iron so long under ground, till the rust hath consumed the greater part, and so the rest becomes more strong and firm: of this they make their swords and other warlike weapons, and with these arms thus tempered, they so cut through every thing in their way, that neither shield, helmet, nor bone can withstand them.

SILVER MINES OF SPAIN.

Having related what concerns the Iberians, we conceive it not impertinent to say something of their silver mines; for almost all this country is full of such mines, whence is dug very good and pure silver; from which those who deal in that metal gain exceeding great profit. The Pyrenean mountains are the highest and greatest of all others, and being full of woods, and thick of trees, it is reported that in ancient time this mountainous tract was set on fire by some shepherds, and continuing burning for many days together, (whence the mountains were called Pyrenean or fiery), the parched superficies of the earth sweated abundance of silver, and the ore being melted, the metal flowed down in streams of pure silver, like a river; the use whereof

* Valso, Spain.

being unknown to the inhabitants, the Phenician merchants bought it for trifles given for it in exchange, and by transporting it into Greece, Asia and all other countries, greatly enriched themselves: and such was their covetousness, that when they had fully laden their ships, and had much more silver to bring aboard, they cut off the lead from their anchors, and made use of silver instead of the other. The Phenicians for a long time using this trade, and so growing more and more wealthy, sent many colonies into Sicily and the neighbouring islands, and at length into Africa and Sardinia: but a long time after the Iberians coming to understand the nature of the metal, sunk many large mines, whence they dug an infinite quantity of pure silver, (as never was the like almost in any other place of the world), whereby they gained exceeding great wealth and revenues. The manner of working in these mines, and ordering the metal among the Iberians is thus: there being extraordinary rich mines in this country of gold, as well as of silver and brass, the labourers in the brass take a fourth part of the pure brass dug up, to their own use, and the common labourers in silver have a Euboick talent for their labour in three days time: for the whole soil is full of solid and shining ore, so that both the nature of the ground, and the industry of the workmen is admirable. At the first every common person might dig for this metal, and in regard that the silver ore was easily got, ordinary men grew very rich; but after Iberia came into the hands of the Romans, the mines were managed by a throng of Italians, whose covetousness loaded them with abundance of riches, for they bought a great number of slaves, and delivered them to the task masters and overseers of the mines. These slaves open the mouths of the mine in many places, where digging deep into the ground, are found massy clods of earth, full of gold and silver: and in sinking both in length and depth, they carry on their works in undermining the earth many furlongs distance, the workmen every way here and there making galleries under ground, and bringing up all the massy pieces of ore, (whence the profit and gain is to be had), even out of the lowest bowels of the earth. There is a great difference between these mines and those in Attica; for besides the labour, they that search there are at great cost and charge; and besides are often frustrated of their hopes, and sometimes lose what they had found, so that they seem to be unfortunate to a proverb. But those in Iberia who deal in mines, according to their expectations, are greatly enriched by their labours: for they succeed at the very first sinking, and afterwards by reason of the extraordinary richness of he soil, they find more and more resplendent veins of ore, full of gold and silver; for the whole soil round about is interlaced on every hand with these metals. Sometimes at a great depth they meet with rivers under ground, but by art give a check to the violence of their current; for by cutting of trenches under ground, they divert the stream: and being sure to gain what they aim at, when they have begun, they never leave till they have finished it; and to admiration they pump out those floods of water with those instruments called Egyptian pumps, invented by Archimedes the Syracusan, when he was in Egypt. By these with constant pumping by turns they throw up the water to the mouth of the pit, and by this means drain the mine dry, and make the place fit for their work. For this engine is so ingeniously contrived, that a vast quantity of water is strangely with little labour cast out, and the whole flux is thrown up from the very bottom to the surface of the earth. The ingenuity of the artist is justly to be admired, not only in these pumps, but in many other far greater things, for which he is famous all the world over, of which we shall distinctly give an exact enumeration, when we come to the time wherein he lived. Now though these slaves that continue as so many prisoners in these mines, incredibly enrich their masters by their labour, yet toiling night and day in these golden prisons, many of them by being over wrought, die under ground; for they have no rest or intermission from their labours; but the taskmasters by stripes force them to intolerable hardships, so that at length they die most miserably. Some that through the strength of their bodies, and vigour of their spirits are able to endure it, continue a long time in those miseries, whose calamities are such, that death to them is far more eligible than life. Since these mines afforded such wonderful riches, it may be greatly admired that none appear to have been sunk of later times; but in answer thereunto the covetousness of the Carthaginians, when they were masters of Spain, opened all.

In many places of Spain there is also found tin; but not upon the surface of the ground as some historians report, but they dig it up, and melt it down as they do gold and silver. Above Lusitania there is much of this tin metal that is in the islands lying in the ocean over against Iberia, which are therefore called Cassiterides; and much of it is likewise tranported out of Britain into Gaul, the opposite continent.

(To be continued.)

HISTORICAL SKETCH ON THE USE OF BRONZE IN WORKS OF ART.

By César Daly, Architect.

(Translated for the Civil Engineer and Architect's Journal, from the Revue Générale de l'Architecture.)

Some years ago, many, otherwise remarkable for their learning, would ask in what degree modern civilization differed from that of ancient Greece or Rome: and even in the present day there are some who will ask the same question, even in England, in the heart of London, or of Manchester, or of Birmingham, with a thick cloud of coal smoke from a hundred factories rolling in volumes over their heads. To these a feature so extraordinary, unknown to the ancients, tells no tale, though it is one which marks most strongly the character of modern times, superior in its power over physical nature, and the great development it has given to the efforts of mechanical invention. So generally, indeed, is the industrial character of modern times unnoticed, that we have scarcely any accounts of the various branches of manufactures, or of the subject generally, although this practical history is one which has the greatest interest in relation to the human race. This history in all its ramifications, whether as to the tools employed or the materials upon which they are exercised, would open a wide field of research, capable of ample gratification, notwithstanding the manner in which the records are dispersed. Among the metals and their alloys known at an early period, none has been devoted to such important uses as bronze, to which we shall devote the present essay.

Had the art of metallurgy been better known in distant periods, and the use of iron and steel more prevalent at a former epoch, or even had copper been more extensively used, we should have remained ignorant of much of the material history of antiquity, for both of the former metals disappear under the influence of rust, and copper is also a sufferer from the action of damp. Thus, while in the Portici Museum the bronze articles are well preserved, those of copper have been more or less affected, and those of iron are scarcely recognizable.

Copper was known in the earliest times, and is mentioned by Moses; but the difficulty of working it with the hammer, and the high degree of heat requisite to melt it, greatly limited its use. It was fortunately not long before the properties of a mixture of copper and tin were discovered, a mixture with greater tenacity and resistance than copper alone, fusible at a lower temperature, and denser than the mean of its components. By this mixture was obtained a metal which readily flowed into every part of the mould, so as to take a correct impress of the pattern, while it was hard enough to wear well, was not brittle, and so far from being injured by oxidation, which only affected it slightly, it was preserved by it from the action of the atmosphere, taking the beautiful colour which is so much admired. The providential discovery of these properties doubtless gave a great impulse to the infant civilization of the early stages of society, affording at the same time a greater facility for manufacture united with greater durability. Thus it came to be employed for arms and edge tools by all the nations of antiquity, whether Indians, Chinese, Egyptians and Hebrews, Greeks, Etruscans, Romans or Celts. In connexion with them, indeed, it might be well said that for many long ages bronze was the iron of the ancients. The fine arts were not long in making use of it, and we find it ministering to the decoration of many of the most ancient monuments of Egypt. In Scripture we find that the Philistines, after the capture of Sampson, loaded him with chains of brass, and Josephus relates that Solomon employed Hiram of Tyre to make two columns of bronze richly decorated, eighteen cubits high, twelve cubits in circumference, and four inches in thickness, or four times as thick as that on the Column of July. The columns were placed at the entrance of the porch of the Temple at Jerusalem. From these works we may judge that working in copper and brass was already of old date at this distant period.

We are quite in the dark as to the processes of melting and forms of the furnaces used by the ancients; but we can readily judge, from the interest, in these days of the progress of science, still attached to the casting of bronze on a large scale, of the difficulties to which workmen must have been subjected in the rude state of chemistry and metallurgy. In Greece the use of bronze was very common; the Chalciæcos, at Lacedemon, was a temple of bronze, dedicated to Minerva, and executed about 750 years before the Christian era by the celebrated Gitiadas, poet, sculptor, and architect. Every part of this building, from the top to the bases of the columns, was entirely covered with plates of bronze decorated with mythological sculptures. Pausanias (B. 10, ch. 5,) relates that when the temple of Apollo at Delphi was rebuilt for the third time, it was constructed of copper, which is not surprising, adds he, as Aerisius had a bronze room made for his daughter, and as there is still to be seen at Sparta the temple of Minerva Chalciaecus. He goes on further to say, "at Rome, the place in which justice is administered excites surprise by its grandeur and magnificence: but what is most admired is a bronze ceiling, which extends from one side to the other. The same author, who attributes to Theodosius and Racos of Samos the discovery of founding statues in bronze, informs us that it was about the year [illegible] before our era that this art was first practised. This, like all the other arts, made great progress in the time of Pericles, but did not reach its full height until the age of Alexander, when each of the principal cities of Greece possessed several thousand figures of bronze, among which were some enormous colossi. This is what Pliny says in his 24th book, sec. 18, "There are numberless instances of boldness in this art, for we see that enormous colossal masses have been executed as large as towers. Such is the Apollo of the Capitol, brought from Apollonia, a city of Pontus, by M. Lucullus; this is thirty cubits high, and cost fifty talents. Such is the Jupiter of the Campus Martius, consecrated by the Emperor Claudius, and called Pompeian, because it is near Pompey's Theatre; such is that of Tarentum, executed by Lysippus, and which is forty cubits in height. What is most remarkable as to this figure is, that it is so well balanced that it may be moved by the hand, although it could not be upset by a whirlwind. The most admired of these colossi was that of the Sun at Rhodes, made by Chares of Lindus, a pupil of Lysippus. This figure was seventy cubits high, was overturned 56 years after its completion by an earthquake; but cast down as it is, it still excites admiration. Very few men can put their arms round the thumb, the fingers are bigger than most statues, and the hollows in the broken limbs are like the yawning mouths of caves: inside are seen stones of large size, which were used to settle it on its base. It is said to have been finished in twelve years, and to have cost three hundred talents, a sum produced by the warlike engines of King Demetrius, when he raised the siege of Rhodes. In the city are a hundred other smaller colossi, each of which would be worthy of bestowing distinction on the town in which it might be placed; besides these are five colossi of gods by Bryaxis. Italy has also produced colossi, for we see in the library of the temple of Augustus, the Tuscan Apollo, which is fifty feet high from the toe, and in which it is difficult to tell which to admire most, the bronze or the beauty of the workmanship. Spurius Carvilius had a Jupiter made for the Capitol out of the helmets, cuirasses and greaves of the conquered Samnites. The size of this statue is such that it may be seen from the place in which is the Latial Jupiter. But in our times, Zenodorus has surpassed all the figures of this kind in height, in the Mercury which he made for a city of the Gauls in Auvergne. This was ten years in execution, and cost four hundred thousand sisterces."

It is probable that these colossi were formed of a number of pieces secured with nails, like so much brazier's work, for it is thus that the ancients made their metal statues before they had acquired the art of founding. At Lillebonne in Normandy, a few years ago, in the course of the excavations for uncovering the Roman theatre, a bronze Mercury was found made in this manner. In reading the travels of Pausanias in Greece, we cannot but feel surprised at the immense number of bronze works in sculpture which he meets with at every step, particularly when we recollect that this country has been in the possession of the Romans for three centuries, and that they had already, on several occasions, carried away thousands of bronze figures. Of 33 colossi described by the tourist, 30 were of bronze, the three others of wood; he also describes 32 equestrian statues of bronze and 24 chariots, at least of natural size, sometimes with two, and oftener with four horses, and holding one or two figures. Some were accompanied by runners or grouped with men on foot who led them; in fine, he mentions more than [illegible] animals of considerable size, also of bronze. And yet Pausanias only visited a part of Greece. It was of bronze that the Athenians, after the death of Pisistratus, formed the first quadriga, in memory of their fellow countrymen who died while fighting for their native land. Of bronze also is constructed, in our days, the Monument of July. Bronze is, in truth, the symbol of strength, and it is interesting to observe how the same metal has been chosen, at two periods so remote, to consecrate the remembrance of facts having so much resemblance.

The Romans, as we have seen from extracts before given, made frequent use of bronze, and like the Greeks, employed it in the form of candelabræ, lamps, furniture, triclinia, altars, tripods, tools, fastenings, letters for monumental inscriptions, window fastenings, &c. The doors were sometimes plated with bronze, secured with nails of the same metal; such as those of the Pantheon. Pliny (B. 34, § 7,) says that the ancients were accustomed to make the threshold and gates of temples of bronze. Ancient gates entirely formed of bronze are still to be seen in the church of St. Cosmo and St. Damian in the Forum at Rome, formerly the temple of Romulus and Remus, and this luxury was not exclusively confined to temples, for, 380 years before our era, the ornaments were of bronze on the doors of the house of Camillus. By means of cramps large masses of bronze ornaments and carvings were fastened on monuments by way of decoration. On bronze tablets were engraved laws, treaties of peace, and public acts intended to be made known to posterity. Three thousand of these tablets were destroyed in the fire of the Capitol, in the time of Vespasian. Capitals were also made of bronze, which were secured on cores of stone. Pliny relates that "C. Octavius, who conquered Perseus in a naval action, erected, in honour of his triumph, a double portico, which was called Corinthian because the capitals of the columns were of bronze; this portico was near the Flaminian Circus; the capitals of the Pantheon, placed there by Agrippa, are of the same metal." The Romans further applied bronze in the execution of works on a large scale; the framing of the Pantheon was constructed of bronze, and, according to Serlio, who had examined it in its place, the different pieces were hollow; they were put together in the same way as woodwork. The caissons of the vault of this monument were also of bronze, and the circle which frames the opening by which the Rotunda is lighted still remains. In the baths of Caracalla the ceiling of the immense hall known as the Cella Solearis was formed of a net-work of bronze; a fact of which M. Blouet did not seem to be aware when he published his restoration of that monument. The ancients also constructed roofing of bronze, for at Rome, 212 years before the Christian era, the temple of Vesta, at Rome, was covered with tiles of bronze, and so, at a later period, was the Pantheon. As to bronze statues, there was at Rome a number truly prodigious, brought from all the great cities of Etruria, Greece, Sicily, and Asia Minor. Scaurus having erected a temporary theatre at Rome, towards the end of the republic, decorated it with three thousand of these statues.

The art of the founder naturally underwent all the vicissitudes of the other arts; in the time of Nero the decadence had already commenced, it not being possible to cast the colossal statue of that emperor, modelled by Zenodorus, and which was to have been 110 feet high,* although a century afterwards the beautiful equestrian statue of Marcus Aurelius was cast. Falconnet, in comparing these two facts, endeavours to make out a case for an attack on Pliny; but it seems to us that the circumstances may be reconciled by supposing that casting in bronze had been momentarily neglected before the time of Zenodorus, and that they had been more successfully cultivated in the time of Marcus Aurelius, for a similar circumstance happened in our own days. The brothers Keller, under Louis XIV., carried the art of casting in bronze to a high degree of perfection; but under Louis XV. the founders were not so good; and in the early part of the empire, great difficulties were met with in executing works of this kind, whilst now the art of casting in bronze has made greater progress than ever. Besides, it may be said that whenever a process is not carried on scientifically, while the reason of the different phenomena has not been discovered, and the artist consequently is reduced to take the bare results of experience for his guide, the neglect of the art for some time is enough to cause the facts to be forgotten, and the guides are consequently lost. This, however, cannot happen when the theory of an art is firmly based on scientific principles, and the reason of the phenomena is consequently understood; drawing our conclusions, from which we may say that the art of casting in bronze will henceforward never be lost, even should it be neglected for centuries; a few trials would be enough to bring it back to the point at which it had been left.

In the Middle Ages.

During the Lower Empire, nothing remarkable was executed except some bronze gates, and the process of casting seems to have been quite lost at Constantinople. The gates of the Basilica of St. Paul, at Rome, were cast in the 11th century by Staurachios Tychitos of the isle of Chios. In the 11th century were cast those of the basilica of St. Zeno, at Verona, on which are represented passages of the Old Testament and the miracles of the saint. The bronze gates of St. Mark, at Venice, were also brought from Constantinople in the 13th century.

Germany possesses some bronze gates of the 11th century, such as those of Mentz and Augsburg. In 1330, Andrea Ugolino executed two panels for gates in bronze, from the designs of Giotto, for the Baptistry of Florence. Ghiberti finished his chef d'œuvre in 1424. In the 15th and 16th centuries several gates of bronze were cast at Venice, Padua, Bologna, Florence, Pisa, Loretto, &c.; but these works were not sufficient to prevent the art of casting in bronze from falling

[illegible] B. 8. ch. 11. B. [illegible] B. 10. also Pliny B. 24. ch. 6.

* Pliny. B. 34. § 7. Suetonius says 120 feet.

into complete oblivion, and during almost the whole of the middle ages this art was wholly limited to casting bells.

In Modern Times.

At the Revival appeared several bronze works of art, in which Italian artists, and particularly those of the famous school of Florence, in the beginning of the 16th century, distinguished themselves most, and contributed most efficaciously in diffusing a taste for it in different European countries. The sculptor Torrigiani passed several years in England, where Henry VIII. gave him several commissions for bronze works. Primaticcio also executed, at Fontainebleau, several bronze statues from antique models which he had brought from Rome. At this time there were several French artists who were employed in brass founding; but their modes of proceeding seem to have been very imperfect, for Benvenuto Cellino relates in his memoirs that during his stay in France, he wished to cast a bronze statue of Jupiter about six feet high, which had been ordered of him by Francis I.; "but never having been engaged in this kind of work," said he, "I consulted some of the old masters of Paris, and explained to them how we managed in Italy. They replied that their manner was different, and that if I would leave it to them, they were sure to make my model in bronze such as it was in clay. I made my bargain with them; I promised them the price they asked, and even something over. I put my hand to work, but I could see well enough that they were not trying the right way. I wanted also to try myself upon a head of Julius Cæsar, larger than life, made after the model of a small head designed from a beautiful antique which I had brought from Rome. I added to it a head of the same size which I modelled from that of a beautiful girl in my service, and whom I called Fontainebleau, from the name of His Majesty's favourite palace. When I saw my furnaces finished, and our models baked, I said to my master founders, I fear that the Jupiter will not come out well, because you have not left draught enough for the air; but they replied that, if they did not succeed, they would give me my money back again, and that I should find less chance of success in the Italian method. This took place before some gentlemen whom the king often sent to see how I was getting on. Before casting the melted metal for the Jupiter, the founders wanted also to place my two heads to cast them at the same time, feeling persuaded that their mode would not succeed, and that it would be a pity to lose such fine works; but the king, who learnt it, sent to them to tell them that they must think of learning from their master, and not of teaching him. Then, smiling, they put their Jupiter in the pit, and I also arranged my two heads at the sides, and when the metal was ready, we left a free passage for it. Our moulds were quite filled, and we were all happy, I, with having succeeded in my way, and they in theirs. They asked me for something to drink, and I gave them plenty of refreshments; they then asked me to pay the sum I had promised them. You smile, said I to them, then, but I very much fear that you will cry soon; for I saw that more metal ran into the Jupiter than was wanted, and that is the reason that I shall not pay you until it is all right. These poor men felt that I was in the right, and went away without saying anything. They returned the next day very quietly to empty their pit, and began with the two heads, which were perfect; they then came to the Jupiter, which caused them to cry out, as I thought, for joy, and which made me run, but I found their faces like those of the soldiers who watched the tomb of Christ. You see, said I, what has happened to you from not believing me; you would have reaped more profit and I more honour. Learn, then, to work, and not to laugh at what is said to you. They acknowledged their error, but they regretted their time and expenses, on account of their families, whom they had to keep, and for which they should be obliged to run into debt. Never mind that, said I, I will pay you as soon as the treasurer pays me; for I pitied them, because they had worked with a good heart." Further on, telling the story about his statue of Perseus, which was also cast in bronze, he says, "The model of the Medusa, made of clay, and well-secured with iron, had already passed through the fire; I had already covered it with wax, and the bronze only was wanting. I had my furnace built directly; I took such good care, and the figure came out so clean, that my friends thought it was all done, like the French and German founders, who never finish their bronzes after they come out of the fire, being doubtless ignorant of the practice of the ancients, and many of the moderns, who finish off with a hammer and chisel." This remark of Benvenuto would lead us into the belief that the French and German bronzes contained a good deal of tin; for when the bronze contains a good deal of copper, its fusion requires a very high temperature, which vitrifies part of the sand of the mould, which, becoming attached to the figure in cooling, requires to be removed; on the other hand, a larger proportion of tin making the metal more fusible, this result was less to be feared. Benvenuto, not contented with having executed so many admirable works, left also a treatise on casting in bronze, which was long the best manual on the subject.

(To be continued.)

ON THE POWER OF THE SCREW.

Sir—There is an article by Mr. Cussen on the above subject in your number for May, on which allow me to make the following remarks.

His first objection to Mr. Bridge's formula seems to arise from a want of acquaintance with the style of mechanical language. Surely Mr. B. just meant by d, the pitch, or distance between the centres of the threads, or, in general, the distance between the threads, just as we talk of the length of an engine beam, when we mean its length between the end centres. Why did we not get an example from Bridges, to test his meaning of the ambiguous d?

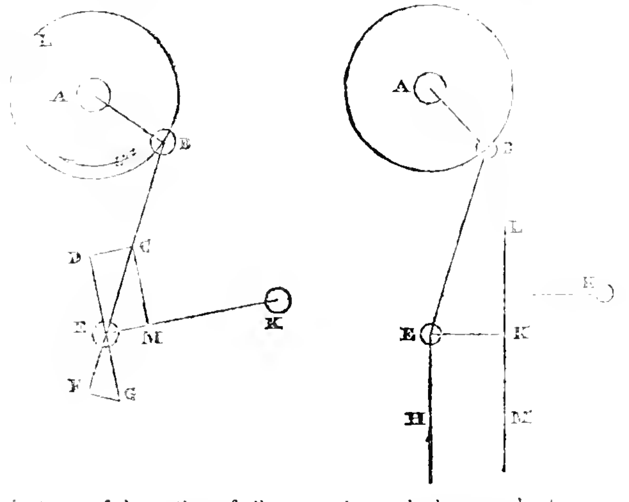
As to his second objection, he denies that the diameter of the cylinder is of no importance. One of 12 inches diameter, he says, will sustain six times the weight with the same power that one of 2 inches will do. Now this is not the point at issue. We are not talking about mere pressure, but of moving power. Let him consider that when the machine is set in motion, the velocity of the weight up the inclined plane increases as the diameter of the cylinder. Thus his advantage is neutralized by necessitating a greater velocity. But again, it is evident that with the same power at the same leverage, whatever be the diameter of cylinder, the weight that can be raised through the *same height* in one revolution must be the same. It is an established law that the momenta of power and weight are equal; therefore the momentum of the power, (viz. the product of its intensity by its velocity) being constant, that of the weight must also be constant; *i. e.* since the velocity of the weight is constant, (as it is raised through the same height each revolution,) therefore the intensity of the weight also is constant, and this inference is quite independent of the size of cylinder.

His third objection demonstrates that he has not thought three times on what he says. He confounds the *moment* of power with its *momentum*; a vital error. The moment of power is its intensity into its leverage, but its momentum is its intensity into its velocity. Now the relative velocities of the power and weight are the spaces passed through by each in one revolution; therefore the velocity of the latter is the pitch of the screw, and that of the former just the circumference of the circle described by its leverage. Therefore this element is chosen correctly in Bridge's formula.

ON LONG AND SHORT CONNECTING RODS.

Observing that there exists a controversy respecting long and short connecting rods, allow me to present the following demonstration of

Fig. 1. Fig. 2.



the justness of the action of all connecting rods, long or short.

Let $k\,e$ fig. 1, be the crank end of a side lever of a marine engine, $e\,b$ the connecting rod, and $a\,b$ the crank moving as per arrow in the circle $b\,l$. The resistance at b acts always in the line of the connecting rod; let $e\,c$ represent it in direction and intensity, just when the slightest overplus of power would set the engine in motion. The power acts always in the line $g\,e\,d$ perpendicular to $k\,e$; complete the parallel-equivalent of *ae d* and *be* are equivalent to *e c*, and these three forces are in equilibrium. Therefore, *ec* being the resistance, *be* is the power, and ... *e m*, the pressure on the centre *c*, which, as it never has motion, is of no consequence. Taking any point *f* in *be* produced, draw *fe* perpendicular to it, meeting *eg* in *g*; *ef* and *eg* will express the relative virtual velocities of the resistance and power respectively, and *fg*, the passive *lateral* motion of the line of resistance,—passive, I say, for its direction is at right angles to this, and it is therefore of no consequence. But the triangles *feg*, *dec*, are similar, therefore $de : ec :: fe : eg$, and $de \cdot eg = fe \cdot ec$, that is, the momenta of the power and resistance are equal. The same conclusion is due at every other point in the circle *b l*. An addition to the power will set the engine in motion, which would be uniformly accelerated were it not that the resistance increases with the velocity. However great, then, the power may be, there will ultimately obtain a uniform motion, when the power and resistance will be in equilibrium, their momenta being equal, as before. Therefore in connecting rod motion, force for force is given and received, and there is no loss essential to that motion.

The point *e* of *ke* moves alternately in a circle. The greater limit of this angular vibration is a semicircle, in which case $ke = ab$. The smaller limit is a straight line • an indefinitely small portion of a circle, its radius *ke*, being indefinitely long. This limit is practically exemplified in engines in which the piston rod is at once jointed to the connecting rod, as in the annexed sketch, fig. 2, of this motion, in which *a b*, and *be* are the same as in last figure; *e k* the cross head, bearing perpendicularly on the slide surface *l m*, parallel to the piston rod *he*, evidently in the same way as if bearing round a centre *k*, infinitely distant.

Upon the whole, then, short and long connecting rods on the same length of crank must be equally effective, whatever peculiarities there be.

I am, Sir, your obedient servant,

Daniel Clark.

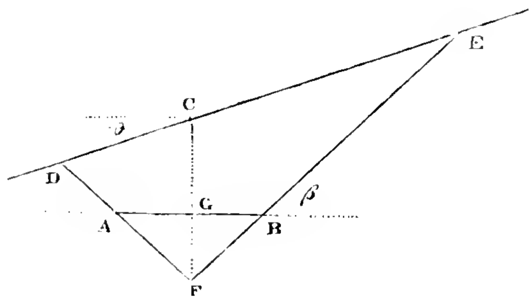
SLOPES IN SIDELONG GROUND.

Sir—The following formula for "setting out slopes in sidelong ground," requiring the distances to be measured along the ground, and not horizontally, has, for that reason (particularly where the ground is very steep), an advantage over the formula in your last number; should you agree with me in this opinion, you will perhaps find a place for it in your next Journal.



Let $2w$ = width of the railway = AB.

$\beta = \angle$ of the slopes.

$\theta = \angle$ of the natural ground.

h = depth of cutting = CG.

Then $(w \tan \beta + F \angle) = CF$.

$$CD = (w \tan \beta + h) \frac{\sin CFD}{\sin CEF} = (w \tan \beta + h) \frac{\cos \beta}{\sin (\beta + \theta)}$$

$$CE = (w \tan \beta + h) \frac{\sin CFD}{\sin CDF} = (w \tan \beta + h) \frac{\cos \beta}{\sin (\beta - \theta)}$$

The slopes remaining constant then $w \tan \beta$ will be constant, and therefore the angle CDF will also be constant.

I am, Sir, your's most obediently,

W. R.

Manchester, June 8, 1841.

THE NELSON COLUMN.

Sir—As the Nelson column rises to view, we become sensible of what appears to be a great mistake in the *position* of it, and which ought to have been in a line drawn from the centre of the portico of the National Gallery through the Statue of Charles I., which appears as it ought to do in the centre of Whitehall; whereas the column seen from the same spot, will appear considerably to the right of the statue, and will be engaged with Drummond's Bank, the Admiralty, &c., instead of appearing to rise in the centre of the street, and thus producing a most awkward effect, whether as seen from the centre of the portico, or in approaching it as you come from Whitehall. This might easily have been avoided by placing the column in a line with the statue, which line, though not *quite* perpendicular to the plane of the portico, would have deviated from it in so very slight a degree as not to be perceptible to the eye, while the present position will produce an effect so glaringly awkward as at once to strike every beholder.—The mistake of the architect consists in having thought it necessary to place the column in a line perpendicular to the plane of the portico, whereas his object should have been to make the column appear to rise in the centre of the street, as seen from the portico which could have been done by the very slight and imperceptible deviation from the perpendicular above mentioned.

I am, Sir, your's,

Æsthetics.

ON THE THEORY OF BARS.

"Lorsque l'homme s'ecarte de la vraie cause d'un objet quelconque, il doit se considerer dans les tenebres, et il est forcé de chercher des arguments absurdes, dans lesque's il se perd, ce qui fait que les sciences deviennent ridicules dans l'opinion du vulgaire."—*Cuvier on marine deposits.*

Sir—Pursuant to the notice I gave in the last number of your valuable Journal, I take leave to send you for insertion the following observations on a "New Theory of Bars, &c., by Mr. Brooks."

The importance of the subject to this great naval and nautical nation, and to the maritime commerce of the world, should admonish us to pursue the investigation of this matter with the most cautious and serious consideration, for as it is well observed in the quotation at the head of Mr. Brooks' treatise, "our errors in this matter are of more importance than in mere objects of taste, luxury, or pleasure, because they will ever result in injury, or in the loss of some previous advantage." Let us also bear in mind Cuvier's reproof quoted above.

It does not appear requisite that I should refer to the many theories quoted by Mr. B., the controversy so prevalent at present, and in past times, in the scientific world on the subject of bars, demonstrates that it has not received that attention and examination which can lead to a right conclusion as to their cause, and what are the most eligible means to obviate the many evils incident to their existence; but I do presume that my subsequent remarks, based on facts and practical observations, will prove, that if the desideratum has not previously been developed, Mr B. has not reflected any new light on a subject hitherto by many supposed to be enveloped in darkness.

It appears apposite to notice that Major Rennel, quoted by Mr. B., p. 1 and 2, states, "that mud and sand suspended in the waters," (*i.e.* the egress waters) "during their motion are deposited when that motion ceases, or rather they are gradually deposited as the current slackens, according to the gravity of the substance suspended;" aod the late Mr. Telford gave a similar exposition. I did not expect in this age of the world, any one would reject such an evident and irrefutable fact, a principle ever in operation during the discharge of the egress tides, or currents; but Mr. B. p. 4, says, "I venture to submit, that it is insufficient," (*i. e.* the Major's thesis) "to account for the formation of bars, because the operation described (the deposit), as producing the latter (the bar), takes place in all rivers, in a greater or lesser degree, and in those which although their waters are abundantly loaded with sand or mud, are nevertheless free from bar." Mr. B. therefore disputes the accuracy of the Major's deduction, because it is the result of a partial, and not of a general law; why, Mr. B. has endeavoured to rest his entire case on local and partial data, and neglected to observe general principles.

That all rivers, harbours, bays, estuaries, &c., where the waters pass with a velocity sufficient to hold matter in suspension, have *beds* of sand, &c., is quite correct; but where the receding waters do not return or run out into the ocean with a force adequate to disturb the deposit that occurred during the quiescent state of the waters, as described by Major Rennel, there certainly *no bar or exterior accumula-*

tion can take place; for matter does not move without an impetus. Mr. B. then *de facto*, leaves the Major's thesis (with which I agree), where he found it, based on the solid and immoveable foundation of truth.

It is quite obvious that the Major has adopted the thesis that I have, viz.

1st. That wherever rivers, sluicing, or backwaters disembogue into the ocean, either under a natural or artificial impetus, and run with sufficient velocity to hold matter in suspension, and cause a conflicting action with the waters into which they pass, there a bar is formed.

2nd. That wherever there is an absence of egress waters, currents, tides or sluicing power, and where no conflicting action ensues, there no bar exists.

3rd. That to these rules there are no exceptions throughout the world, for wherever nature is placed under similar circumstances, she is immutable in her results.

> "Here then we fix the universal cause,
> God acts by general, not by partial laws."

These primordial, universal, and indisputable facts are deduced from an extensive field of observation of many years, and on various harbours, rivers, &c., during which time I have visited the Baltic, Gulf of Finland and Bothnia, Russia, Prussia, Denmark, Sweden, Norway, Jutland, Friesland, Holland, Belgium, France, Spain, Portugal, the Mediterranean, Africa's shores, and many harbours of the united kingdom,—but all this devotion has been dealt with by Mr. Brooks in a most summary way, and to refute my theory he has used the following words, page 5, chap. 6, viz.:—"That the casual direction of the lower reach, or the position of the mouth of the river cannot truly be assigned as the cause of the existence of a bar, is easily proved by observation on rivers subject to great variations at the entrance, the bar being always found to exist independent of the direction of the discharge into the sea, this fact at once refutes the third and fourth theories."—In this extract there seems to be two distinct facts, *i. e.* the casual direction of the lower reach, and the independence of a bar, in the direction of the discharged waters, that is, he means that the deposit or bar, does not occur in the direction or course of the egress waters. With respect to Mr. B.'s assertion of the independence of the bar, of the egress waters, I have much to say, if he be correct, he has indeed "at once refuted my theory," and would prove it to be a mere visionary and hypothetical deduction; but I will proceed to show the converse, and that he has committed, as in other parts of his book, an egregious error. If the reader will turn to the author's theory, subsequently here inserted, where he uses the *wedge* to aid his illustration, and where the battle with the elements occurs at the first quarter flood, he will find it stated, "that in the conflict the sand, or other materials, which it was (*i. e.* the effluent waters), capable of holding in suspension previously to its encountering the conflicting action of the flood tide, yields it to the latter, and when this takes place the *bar is formed;*" now observe, Mr. B. tells us that the material which drops and forms the bar, is brought down into the ocean by the egress or effluent waters, that as it advances onwards, (in its own direction of course), it encounters the flood tide, and where it meets that tide there the bar is formed; so that Mr. B. himself destroys the premises which he had the boldness to adopt for the annihilation of my thesis. The positive and irresistable fact is, that all bars are formed in the direction of the effluent waters, the latter are the impetus to the matter held in suspension, and that matter must fall in the direction of the impelling power, as a shot from a gun, the ball from the foot, or the deposit from the stream of the milldam.

Passing on towards Mr. B.'s theory, I notice in chap. 2, page 19, "pier harbours which though free from bar in their natural state, are well known to become encumbered by them, on the introduction of the scouring power," here I suspect he cast his eye southward on Lowestoft Piers. Scouring power no doubt (this is my principle), causes a bar, no matter whatever way or manner it is conducted to the sea, naturally or artificially, whether there be piers or no piers.

The commencement of chapter 11 is a mere repetition of my second proposition, "That whenever a river or harbour approximates to the condition of a simple inlet for the reception of the tide it would have no bar." I endeavoured some time ago, in a conversation with Mr. B., to illustrate this truism by a reference to various harbours where the water did not pass into the sea, with a sufficient velocity to disturb the bed, there no exterior deposit could take place; no matter whether such a harbour be naturally or artificially constructed. Norway, Scotland, Ireland, Scilly Islands, Minorca, and Malta harbours, are of the first kind; Ramsgate, Margate, Scarboro', Cronstadt, Elsinore, &c., the latter.

In page 13, Mr. B. in noticing the geological features of the Yorkshire coast, says, "That a residence of some years on its shores, and a close observation enables him to state, that those seas that break on the outward platform, (the outer flat) are much heavier than those which break nearer the shore." I bear testimony to the accuracy of this fact, taught me in my boyish days by the boatmen, sailors and fishermen, that on all flat shores, or in different elevated platforms (if they must be so designated), the sea loses its force, where it is first intercepted by the shore, and as it advances and rolls up the inclined plane, so the concave dimension diminishes, till at last it finishes in a mere ripple, or tiny billow.

I have now arrived at our author's theory, and it is *multum in parvo.* "During the period of the first quarter flood, the current, in lieu of being able to take its natural upward course, as in rivers where *no bar exists*, is opposed, or effectually checked, by the effluent backwaters; the declination of the stream in the lowest division of the river presenting a head which ensures a strong downward current, long after the tide would have been able to maintain an upward course, provided the backwater had a free discharge; at this period the flood tide, by reason of its greater specific gravity, occupies the lower stratum of the tide-way, and like a wedge endeavours to force its course up the channel, which it is unable to effect, but merely elevates the lighter effluent water, the lower strata of which, being checked by the opposition of the tidal waters, yields to the latter the sand or other materials which it was capable of holding in suspension, previously to its encountering the conflicting action of the flood tide; where this takes place the bar is formed."

Having shown that Mr. B. has attempted to refute my thesis by the aid of a fallacious assertion, I now proceed to prove that he has based his own on a sandy foundation. He commences this part of his work by stating that the current, in the first quarter flood, is not able to take its natural course upwards, as in rivers where no bar exists—that is, where a bar does exist it is not able—and that this inability is occasioned by the conflicting action of the waters (and which conflicting action only exists where a bar is already formed,) and where this takes place (the conflicting action), there the bar is formed. So that, in order to sustain his "novel theory" on the cause of bars, he first must have a bar to produce the cause of a bar, and thus the effect produces the cause, and with this mode of reasoning, illogical as it is, he has attempted "at once," and with one fell swoop, *nolens volens,* to throw me overboard, and include in his general sweep, all who have attempted by principle or practice, ancient and modern, a development of the cause of bars. Mr. Brooks requires a backwater falling out of a sloping river, and that water to be opposed by a first quarter flood, and a bar itself to produce a bar; he appears not to be aware that in various parts of the world bars have accumulated where there is an entire absence of his causes, and not only at places "which approximate to the condition of a simple inlet," but where the only existing cause, amongst those which he assigns for a bar, is the egress or scouring waters; examples of which we have in the Baltic, the Black, and other seas.

In my examination before a Committee of the House of Commons in 1826-1827, on the proposed Lowestoft Harbour, I then stated "that so soon as the scouring water should be applied as then proposed, a bar would accumulate where no deposit or bar previously existed, and if the sluicing were continued the harbour would be so blocked up that small vessels only could enter at high tide." He need only refer, to prove the accuracy of his prescience, to the present state of the bar at that harbour, and the fact that about £150,000 have been expended thereon, the entire of which has been recently offered for sale by the Loan Commissioners for £17,000, it being completely lost as a harbour of refuge for which it was intended."

It is an incontrovertible fact, that the greater the quantity of egress, or sluicing waters, and the more rapid their course, the greater is the exterior deposit. The Mississippi and other large rivers demonstrate this fact—the entrance to that queen of rivers is most difficult in the spring of the year, when the melting of the snow on the mountains increases the quantity and rapidity of the egress waters, so as to carry with them trees, earth, and other matter, all of which are deposited on the extensive bar, at its outlet, and it does not again decrease until after a long continuous dry season, when the quantity of egress water is reduced.

Mr. B. follows his "new theory" by stating, "that he might easily extend his illustrations," and adds that the "direct tendency of the whole period of the ebb, when unobstructed by the tidal currents, must be to reduce the bar." This is really hypothetical. That the ebb or outgoing waters have a direct tendency, and are the real cause of all exterior deposits or bars, &c., I have asserted for the last 20 years, the accuracy of which I will now attempt to prove. At the Neva, Gulf of Finland, the Narva, Dantzic, the Danube, the Nile, and many other places, the current, without intermission (there being no *flood tide*), is perpetually running out at the rate of six, seven, or eight knots per hour, and yet the old entrances to those rivers have been blocked up by impassable bars, and either new passages have been cut into the ocean, or the egress waters have forced a passage out in a new direction; here we have an absence of quarter flood, sloping, and of the difference in the gravity of the two waters, no salt water being in the vicinity of the disemboguing site of the above rivers.

I must now take leave to make an observation on Mr. B.'s proposition to take away the shoals or deposits in the Thames, at Woolwich by scouring, and not by dredging, the result of such an operation (if it were accomplished) would be, that the matter moved could only be impelled onward while the impetus was retained, but so soon as that ceased, a re-deposit would occur which would occupy the same extent of the bed of the river, which it had previously done—he seems not to be informed of the effect produced on Barking Shelf, removed by dredging although an immense accumulation of sand and shingle, the base of which appeared at low water—but I will not further interfere with the interior part of his subject, that is all plain sailing, no insurmountable difficulty occurs in attempts to improve inland navigation, there we have no impinging billow, or any material effect produced by the winds or tides.

Before I conclude, allow me to give some farther proofs of the accuracy of my two first propositions—New Zealand, "The entrance to the bay at Wangarver is 11 miles broad, perfectly safe, and without a bar; the bay is studded with rocks, (so are the harbours I have previously referred to as being free from bar). The water is deep close to the shore. The bays of Plenby and Port Nicholson are similarly formed and are free of bar, although no back waters. The harbour of Hokianga with an extensive interior river, where the waters run out at every ebb tide, there a bar exists. In the West Indies, at St. Lucia and the Havannah, both splendid harbours, but have neither rivers, back waters, nor bars.

I remain, Sir, your obedient servant,

Henry Barrett.

CANDIDUS'S NOTE-BOOK.

FASCICULUS XXVIII.

"I must have liberty
Withal, as large a charter as the winds,
To blow on whom I please."

I. The absurd trifling, the stupid pedantry, the puerile discussions that at one time engaged the attention of architects, almost surpass belief, and are to be paralleled only by the quibblings of the schoolmen and divines of the dark ages, when theology was reduced to idle disputation, and religion to the practice of the grossest superstition. Were it not so authentically recorded, that it is impossible to doubt the fact, hardly would it be now believed that the problem proposed by Sansovino as to the mode of obtaining the *exact half* of a metope at the angle of a Doric entablature—the *semimetopia* of Vitruvius—made a noise throughout Italy, and excited the attention of all the architectural geniusses of the time! Had Sansovino and his contemporaries been equally scrupulous and precise in all other matters, we might excuse their overniceness in regard to such *difficiles nugæ;* instead of which they were most latitudinarian, even shamefully so in many respects. Like those people who make no difficulty of jumping over mountains, yet break their shins against straws, who can swallow millstones whole, yet are choked by a pound of butter, they were not at all shocked at some of the grossest violations of architectural propriety. In some of Sanmicheli's plans, for instance, the rooms are so frightfully out of square, that no two sides are parallel to each other. Symmetry, too, in respect to the position of doors and windows within buildings, is totally disregarded, as if it were perfectly indifferent whether it were attended to or not. The designs of Il Divino Palladio, as he has sometimes been called, abound with scandalous defects of this kind. I suspect that his "*divinity*" must have been somewhat of a piece with that of Il Divino Aretino, a monster who ought to have been hanged, drawn, and quartered. Such "divinities" as the last must be inquired for in the infernal regions.

II. Nothing can be more opposed to every legitimate principle of art and æsthetics, than the attempt to reduce the different orders to so many express and immutably fixed types. The consistency so aimed at is attended with almost the worst species of inconsistency, because it totally excludes such modification as may be most suitable for the particular case. It is time for us to get rid of all the mechanical quackery to which we have so long submitted, and which has reduced architecture, as generally practised, to little better than a mere handicraft trade—to copying certain individual parts met with in former styles of the art, without any regard either to the genius of the styles themselves, or to the circumstances of the building required. What puerile trifling it is to affect scrupulous nicety as to the express shape and proportion of every little detail belonging to columns which are to be stuck up by way of portico before a dowdy house or other building, which is thereby only rendered a grotesque absurdity! In most other matters people think of attending a little to consistency and common sense; or should they fail to do so, they must submit to the derision of their neighbours. But in architecture, the most ridiculous incongruities and *disparates* are tolerated—tolerated! they are even applauded: and *bêtises* that would hardly be endured in the preparations for a temporary fête, may be perpetrated with impunity in buildings intended to be permanent.

III. "Geniality" is not an English word,—hardly can it be said to be as yet adopted by us; and what is more to be regretted, there is, I apprehend, very little of the thing itself among the artists of this country. At all events very little evidence of it is to be discerned in our architecture. Looking at the majority of the buildings which have been erected of late years—and they certainly have not been few in number, they must be allowed to confirm such opinion, disagreeable and unflattering as it is in itself. If we find the styles respectively aimed at, copied with passable fidelity, without any particularly gross violation of their principles, it is nearly the utmost that can be said in their favour; and as matters stand, such poor negative merit must be received as a positive one. How very far, however, it stops short of geniality, hardly needs to be said, it being sufficient to remark that the latter draws out, concentrates, and heightens all the good qualities of a style, and at the same time imparts to them some fresh charm, some additional unborrowed value: and that, even though the subject should be an unpromising or inconsiderable one in itself. If he cannot always create favourable opportunities, a man of real talent will, at least, do the very utmost that circumstances will permit—will convince us that he has not satisfied himself with merely turning out a decent, workman-like job, but has applied himself to his task as to a labour of love, with the feeling of an artist, not of a builder—not of a tradesman. Were we to believe some of those who, albeit without aught of the artist in their constitution, style themselves architects, their genius would blaze forth upon the world, were but sufficient opportunities afforded them. The man who cannot put together two ideas—except detestable ones—for a moderate-sized house, or church, would be able, nevertheless—if we choose to believe him—to erect the most splendid palatial and ecclesiastical edifices. John Nash was an architect of this stamp, and as it most unfortunately happened, opportunities, both many and of no ordinary kind, were thrown in his way. How he acquitted himself of them is but too well known. It is to no purpose that Theodore Hook affects to consider him the victim of harsh and illiberal criticism; or that *Professor* Brown, as he facetiously designates himself, tells us, *ex cathedrâ*, I suppose, that John was "a man possessing great taste for the grand and the picturesque." For the Grand! Surely the learned Professor must be speaking sneeringly and ironically, for never did Nash, on any one occasion, even approximate to the grand or the dignified in architecture. Never did he get nearer to it than 170 degrees E. or W. longitude of it. Still, incredible as it may appear, the enlightened Professor is not joking, but intends it to be taken as his serious opinion; for he elsewhere speaks of "the magnificent houses along the Strand, King William Street, and the splendid houses in the Bayswater Road!!" adding, "but when we behold the more magnificent columnar edifices on the east side of the Regent's Park, and the crescent on the west, where the houses are crowned with octagonal domes, we stand astonished with admiration!!" Most undoubtedly we do so, Mr. Professor Brown, for we stand absolutely "putrified" with astonishment that such masses of ugliness and vulgarity should ever have been erected. However, perhaps the Professor judges of Nash by his own quantum and calibre of talent and taste, in which case he has undoubtedly sufficient cause to look upon Nash as a very great man, he himself being but a mere dwarf and pigmy by the side of him, as his own designs abundantly testify. When we look upon those architectural abominations and atrocities, we do indeed stand astonished, but it is with the astonishment of unmitigated horror and disgust. Oh, Professor Brown, Professor Brown, unlucky was the day and hour when you dubbed yourself with that ambitious title. Could you get rid of it again—but no, that is impossible; it will stick to you for ever; it will render you the laughing-stock and the byword of the profession. You cannot *un-Professor* yourself now, or divorce yourself from the ill-sorted companion to which you have married your name. Doctors' Commons won't help you, Dr. Lardner will not run away with that "better-half" of you. Professor Brown you have made yourself, and Professor Brown you must now continue to be in spite of yourself. You cannot metamorphose back again into plain Dick Brown. I pity you, I compassionate you, I condole with you—yet infinitely more do I pity and compassionate those unfortunate devils who shall imbibe their architectural taste from the designs of Professor Brown!

ARCHITECTURAL ROOM, ROYAL ACADEMY.

(Concluded from page 181.)

Having made a month's pause, we will avail ourselves of it, before we resume our own comments, to express our astonishment at an opinion we have in the interval met with, in regard to the architectural portion of the Exhibition. Either we, or the writer in the Mirror, is egregiously mistaken, for he tells his readers that the designs for new churches and other public buildings are "very numerous and in good taste;" whereas we think that there are rather fewer of the kind than usual, and those for the most part of very mediocre quality. In fact, it is only by referring to the catalogue and our own notes, that we can recollect above one or two, so little is there at all striking in them—except, indeed, it be by making an unfavourable impression. Such, certainly, is the case with respect to one, which is singled out by the writer in the Mirror, viz. 1059, "The Estate building at Hackney for J. B. Nichols, Esq." by J. A. Taylor, which consists only of a crowd of ugly houses detached from each other, but all *dittos*, instead of being varied as to design,—no doubt a laudable idea enough, because it saves the architect a great deal of *trouble*, without, perhaps, at all diminishing his per centage. Such architecture may do very well for the latitude of Hackney, but it is not fit to be paraded upon the walls of a Royal Academy. Or if such things must be exhibited, they must also take their chance of being somewhat cavalierly treated, since it is not every one who is so complaisant as the critic in the Mirror—a mirror, by the bye, which flatters most confoundedly.

Some may think that the Mirror's opinions are scarcely worth noticing at all, since, instead of being put into positive and tangible shape, its criticism amounts to little more than quoting from the catalogue the titles of such designs as it would recommend, and have us understand to be meritorious, without our being so unreasonable as to ask for reasons. The Art-Union—from which something better might be expected—deals in nearly the same sort of criticism, being exceedingly laconic and oracular, or, we might say, that one had need consult an oracle in order to understand upon what grounds it mentions for approbation some of the things it does—for instance, "No. 1033, Design for an Opera House, by J. C. Tinckler." We confess that that subject struck ourselves, but certainly not with admiration, the taste displayed in it, seeming to us in some respects absolutely barbarous, and what was not positively barbarous, to be no more than barely endurable. Far more readily do we agree with the Art-Union when it says, "the churches now being erected through the country, such as that at Nuneaton by Mr. T. L. Walker, seem, thanks to the Church Commissioners, to be designed by the dozen, with no better recommendation than cheapness, and no other better point about them than the certainty that they cannot last many years." As to the quality of the design thus referred to, we ourselves cannot pretend to offer an opinion, because that and about half a dozen others of the earlier numbers in the architectural section of the catalogue, are put out of sight, perhaps very deservedly so, for there certainly is nothing at all prepossessing in what can now be distinguished of them—nothing to make us particularly anxious to become more intimately acquainted with them. That a Royal Academy, not bearing the title of an Hibernian one, should persist, year after year, and in spite of repeated remonstrances, in adhering to the blundering practice of *exhibiting* drawings by hanging them where so many frames and blank paper would cover the walls—if covered they must be—quite as well, is nothing short of marvellous. If no remedy can be devised, it would at all events be but becoming and proper that the highest and tip top places should be assigned to the works of the Professor and other Academician architects; let them be exalted, and there is no doubt that they would instantly perceive and correct what they now cannot discern, viz. the gross absurdity of admitting more drawings than can be properly seen when hung up. We certainly meet with a good many whose absence would have been no loss to the exhibition; and the very first upon the list, viz. No. 956, "View of Hyde Park Gardens, Paddington," is among them, it being a subject we are sorry to see either in reality or representation—a heavy mass of bloated insignificance. No. 980, "Lonsdale Square, Islington," R. C. Carpenter, is another "flare-up" concern of the same kind. The houses that are shown may be passable enough as dwelling-houses, but as architecture they have no pretensions, nor has a drawing of this class much claim to be admitted into an academical exhibition. There are one or two designs for the Taylor and Randolph Buildings at Oxford, and we may mention that by Messrs. Mair and Browne (No. 966), as being entitled to considerable praise—as much better, in fact, than any of those for the same edifice which were exhibited last year: and it is stated to have been one of the five selected in the first instance by the committee. We should have examined it more attentively than we did at the time, had we then known as much as we now do of the design which has been adopted. We need not inform our readers that this last is by Mr. Cockerell, the Professor of architecture; but we may assure them it is by several degrees more fantastical and outré than his design for the Royal Exchange, and in some respects perfectly nondescript as to style. How the Professor—who seems ambitious of obtaining for himself the title of the English Borromini—can reconcile the *extravaganzas* he has there shown, with the precepts he delivers *ex cathedrâ*, cautioning the students against aiming at mere showy effects, rather than architectural propriety, it puzzles us to guess;—and it would, no doubt, puzzle him still more to explain.

Messrs. Gough and Roumieu's design for "St. Pancras' National Schools," (No. 976) is a small but pleasing composition, in the Tudor style, with a rather unusual degree of decoration, therefore should the building itself turn out to be as satisfactory as the drawing represents it,—which, however, is not invariably the case, it will be nearly the best thing of its kind in the metropolis. No. 1096, "Interior of the new Library at Roehampton Priory," by the same architects, is also sufficiently creditable to them; but they must excuse us for not admiring that for "St. James' Dormitory Chambers, as proposed to be erected" (No. 1080)—yet, we hope, as never will be erected. Were it not too late, we should enter a similar protest against No. 977, "An Elizabethan Villa, now building at Hammersmith, from the designs of Mr. S. Gomme," for it is a most Gommy or '*gummy*' affair, as a friend of ours would call it,—a specimen of all that is most hideous and barbarous in that style, without any of its redeeming qualities; and it would seem that the architect's aim had been rather to exaggerate than to mitigate any of its deformities. It may be excusable enough in the possessor of a genuine relique of Elizabethan architecture to be somewhat jealously proud of it—for its antiquity if for nothing else; but that at the present day any one should think of building for his own habitation a 'bran new' absurdity of the kind we here behold, is to us most marvellous.

No. 982, "New Park near Devizes, showing the principal front, with alterations and new carriage entrance," does not impress us with any very high idea of the taste or ability of Messrs. Finden and Green. How far they have doctored up the house, we know not: for aught we can tell they may have improved it, but if they have it must have been deplorably bad indeed before, since it is bad enough—we should say, intolerably bad even now.

Though we wish there were a far greater proportion of interior views than we ever meet with among the architectural drawings, we could very well have spared one of those which Mr. T. L. Walker has sent, of the "Governor's Dining Room at the new Hospital, Bedworth, Warwickshire," viz. Nos. 1014 and 1088, they being nearly duplicates, showing opposite ends of the same apartments, which although very fair as to design, is not so remarkable as to call for such an unusual degree of illustration; and we almost wonder that two drawings of the same subject should have been admitted, when others were turned away for want of room; or that, as both were received, they were not hung up together as companions. It appears, moreover, to us that either the perspective is very faulty, or else the windows themselves poor in character, owing to the excessive breadth between the mullions, according to the drawing.

No. 1027, "View of the London and Brighton Railway Terminus, now erecting at Brighton, from the designs of" D. Mocatta, is exceedingly poor both as a drawing and a design; and we are afraid he cannot shelter himself under the excuse that the subject was an unfavourable one in itself, or that he was cramped in his resources; because there is certainly enough of it as to extent, and the same degree of decoration might have been far more effectively applied. The extended colonnade below is in itself appropriate and convenient enough, but as it is made to project from the loftier mass behind it, it seems rather to encumber than to ornament it; neither is it by any means unexceptionable in regard to design. We are very far from objecting 'upon principle,' to arches being turned upon columns: on the contrary, we consider some of the instances of such combination to be among the happiest effects of Italian architecture. What we complain of is, not that such mode is here adopted, but that it is treated most insipidly, and that want of artistical feeling pervades the whole design.

At first sight we mistook No. 1056, for a view of the Parthenon or some other Grecian Doric temple, but on referring to the catalogue discovered it to be "A project of a Curesal or Pump-room to be erected on St. Ann's Cliff, Buxton, with plans, elevations, and sections," by W. L. Granville; and there certainly are some miniature drawings on the margin, which may be the plans, &c., but which it is utterly impossible to make out at such a height above the eye; consequently all we can say is that, however ingeniously Mr. G. may have contrived the interior of his building he has not shown much invention, or particular propriety of character in the exterior of it.—We begin to get altogether sick of Grecian temples.

The "Façade of the Wesleyan Centenary Hall," No. 1058, is now exhibited as executed, the Lysicrates Monument, stuck upon it last year, being lopped off from it; which being the case we think that the frame might have been reduced also, for at present the drawing occupies twice the space the subject itself requires, and every square inch is or ought to be of value in this room.

No. 1065, "The Library, Northwood House," G. Mair, is a small interior subject that appears to deserve a more favourable situation than it has obtained. No. 1071, "Entrance Lodge to be built at Deane Park, the seat of the Earl of Cardigan," J. Crake—a name new to us—is also a clever design, in the Gothic style. We cannot say quite so much for No. 1110, "Design for a Gothic Roof in Guildhall, London," E. Woodthorpe, for though the drawing itself is a showy and elaborate interior, the new timber roof here proposed, is a poor and meagre affair. If, too, it is intended to make any alterations at all in that edifice, we think that the one most required, is to give it an entirely new exterior, the present one being so atrociously ugly that we wonder how even the corporation of London can stomach it. Taste they have,—at least have the reputation of possessing it, but it does not lie in architecture.—No. 1108, "Entrance front of a design for a Mansion to be erected at South Elkington, Lincolnshire," E. B. Lamb, is a good composition in what may be called the irregular or picturesque Italian villa style,—with a carriage porch and tower over it. While the offices are kept subordinate to the house itself, they are made to aid the general character very much, being treated consistently with it, and so as to give importance to the principal mass, and at the same time be of sufficient architectural importance in themselves. Both picturesque expression and propriety have been consulted, by introducing only a single ground floor window on this side of the body of the house: not only is great privacy thus secured, and the noise and bustle of horses and carriages shut out from the sitting rooms, but a degree of piquancy is imparted to the whole; the internal arrangement cannot be understood until we actually enter the house, which is not the case where there is a range of windows on each side of the entrance. And here we will bring our strictures to a conclusion, lest by continuing them we should be compelled to change our tone again, and have to speak not quite so favourably. Towards some our silence may be unbecoming, but there are a great many who have reason to congratulate themselves that we lay down our pen before we give them a touch of it. Very possibly we have passed over several drawings that we should have been able to notice with approbation, had they been hung where they could be seen; so long as the present system is persisted in, such is likely enough to be the case. That it is persisted in is no fault of ours: on the contrary, did it depend upon ourselves, we would correct it instanter,—if no other way, by cutting the formidable Gordian knot, and reducing the Five tiers of frames containing architectural drawings, now hung up, to Two. Three of them might very well be spared, for the quality of the Exhibition would be rather improved than not by their absence.

ON THE INJURIES TO HEALTH OCCASIONED BY BREATHING IMPURE AIR IN CLOSE APARTMENTS.

Notwithstanding the various inventions and improvements which distinguish the age we live in, it is lamentable to observe what little attention has been paid to the ventilation of apartments in which we are destined to pass the greater portion of our lives, and in which a constant and well-regulated supply of the element we breathe, is so essential to bodily health and mental enjoyment.

This inattention can only be accounted for either by the want of education in the major part of that class of persons who call themselves builders, or an apprehension on the part of those who aspire to the more elevated designation of architects, that the introduction of any thing new would expose them to the charge of a want of taste, or of that acquaintance with the style of the ancients to which it is the fashion so strictly to adhere (imitation being, in their opinions, more deserving of commendation than originality of design, or a desire to meet the improvements of the age, and fashion of more importance than health). If they construct our doors and windows in so superior a manner as to exclude every possible particle of air, they flatter themselves with having attained an advantage to which the inhabitants of ancient Greece and Rome did not aspire. They should, however recollect, in their apparent anxiety for imitation, that the ancient architects of warmer climates did not overlook the necessity of a free admission of air, and also that a constant supply and free circulation of this element, is as necessary for sustaining life as a given quantity for the combustion of the fuel we require to warm our apartments; our builders, nevertheless, only provide for the latter, as if the former, although the more important, was of minor consideration, or that they conceived the chimney draft sufficient for both purposes, when, in reality, it does not answer that for which it is principally intended—as by far the greater portion of the heat generated in our open fire-places is carried up the chimney, by sharp currents of air from occasional openings of doors, or such crevices as it may force its way through, being moreover, frequently productive of serious bodily injuries, particularly to those of delicate frames, while it cannot be sufficient for the purposes of wholesome ventilation; this air being colder than that already in the room, is consequently of greater specific gravity, and must form a lower stratum, not unfrequently felt by those placed round the fire, suffering from an undue proportion of heat at one side and of cold at the other.

It should also be borne in mind, that the openings of our fire-places being seldom more than three or four feet from the floor, the upper stratum of air is neither removed or purified by this under current, and must, from being breathed over and over again, be productive of most prejudicial effects, and that the contamination of this atmosphere is considerably augmented at night by the combustion of lights, the quantity of air breathed by an ordinary sized person being calculated to be about 2000 cubic feet per hour, and that two mould candles consume as much of the oxygen of this air as a human being, and that the nitrogen and carbonic acid gas which remain are peculiarly inimical to animal life, and that when carried up by the currents occasioned by combustion and respiration they form an upper stratum, where they remain, and must be repeatedly inspired before they make their escape into the chimney—the only ventilating flue with which our houses are provided.

It should also be observed, that the heat thus generated is in proportion to the quantity of oxygen abstracted from the atmosphere, which enters into combination with the carburetted hydrogen of the flame of candles, coal gas, oil or other inflammable matter, from which light is produced, that every cubic foot of carburetted hydrogen consumed unites on an average with two cubic feet of oxygen, that portion of the atmosphere required to support animal life, and that the product of this combustion is about 2½ inches of water, and one of carbonic acid gas, which, when inhaled in its pure state, proves instantly fatal, and the greater the proportion we inhale in addition to the animal vapours evolved from the lungs and skin, the more pernicious the effect.

Supposing for example that the perfect lighting of an ordinary sized apartment requires 15 cubic feet of carburetted hydrogen per hour, this would form about a pint and a half of water and 15 cubic feet of carbonic acid gas, for whenever carburetted hydrogen gas is burned with oxygen, or atmospheric air, these are the products of the combustion, whether the carburetted hydrogen is obtained from wax, tallow, oil, or coal. If, therefore, this lighting continue in an unventilated apartment for seven hours, one gallon of water is produced, the greater part of which must be deposited on the walls, windows, furniture, polished metal, or other cold surfaces with which it comes in contact, and to some articles of this nature it is known to prove highly prejudicial, in addition to the injury to health occasioned by an increased quantity of moisture mixed with the air we breathe—as one of the principal functions performed by this air for the preservation of health, is to carry off with it a considerable quantity of vapour in order to prevent its undue accumulation on the lungs; it is therefore evident, that after it has been already so loaded, it cannot properly perform these functions, and that consumption and other complaints are thus frequently induced.

The prejudicial effects of carbonic acid gas (which is the same as the choke damp of mines) as well as of the nitrogen of the air, which is set free by the abstraction of the oxygen, (and amounts in quantity to four times that of the oxygen,) are well known, and ought by all possible means to be provided against. This has been attended to within the last few years in our public hospitals, and the mortality, in consequence, considerably decreased, and likewise in several of our manufactories and public establishments, where the diseases generated, by the numbers of persons congregated in such establishments, have been proportionably diminished. In the House of Commons, also where hundreds of members with hundreds of candles burning at night tended so much to vitiate the atmosphere, important improvements in lighting as well as ventilation have been recently made, but in our domestic establishments little or no attention has been paid to this important subject, and the foundation of a variety of diseases must be the result, particularly from the foul air breathed at balls or other crowded assemblies.

The confinement of air in our churches and places of public worship, must also be highly prejudicial, as we are frequently exposed on entering one of these edifices in the summer months to an atmosphere 10° or 15° below that of the external air, independent of the stagnant state in which it has been allowed to remain during a whole week—often vitiated in a greater degree by the gaseous matter evolved from human remains, and even in private houses much inconvenience is experienced from the stagnant state of the atmosphere in close and gloomy weather, an evil which has been considerably augmented by close stoves, when made of iron and heated to a certain temperature.

But if stoves were constructed of masonry throughout, as in many other countries, or of fire tiles, or porcelain plates, embedded in mortar with well-regulated flues, they would be far preferable to open fire places, this substitution of imperfect conductors of heat being not only consistent with the soundest principles of economy in the preservation of heat, and its more uniform distribution through apartments, but more salubrious than the methods usually resorted to in this country of warming air by contact with iron stoves or pipes.

The healthy appearance of those who pass the greater part of their time in the open air sufficiently indicates its advantages; armies are also well known to have far greater numbers on the sick list when well housed, than when exposed in a campaign to the vicissitudes of the season, for weeks and months without any other covering than the canopy of heaven, or occasionally of a tent or hut, or the shade of a tree. These facts ought to satisfy us that we should admit the air as freely as possible into our apartments at all seasons of the year, as the temporary and often imaginary inconvenience of a little cold, when compared with the decided disadvantages of breathing impure air, is by far the lesser evil.

When ventilation in large establishments or public buildings can only be obtained by artificial means, it is produced by pumping air in, or drawing it out by a fan worked by steam or other adequate power, and affording it the means of free circulation either cooled, heated, or in its natural state, through well-regulated apertures in the floors, walls, or ceilings, and in coal mines by flues or shafts in which constant currents of air are maintained by the combustion of fuel or coal gas; this system might also be easily introduced into houses already built, by means of the existing chimneys; but with still greater facility if our architects and builders were to direct their attention to those points when erecting new ones.

The importance of this subject has been frequently pointed out by scientific men of considerable eminence, without attracting that attention which would have been the means of rescuing many persons from being imperceptibly hurried to an untimely end. It is, therefore, to be hoped that the powerful engine of the press will continue to lend its aid in exposing these evils, until it impresses upon the public mind, and more particularly upon our architects and builders, the urgent necessity of providing against them. Is it not possible, by some simple contrivance, to make the heat produced in the lighting of apartments available for their perfect ventilation? if any of these gentlemen succeed in so doing, they will be entitled to greater gratitude for this achievement in the purification of an element so essential to the preservation of our lives, than any claimed by those heroes whose victories have contributed so much to the miseries of the human race, and the destruction of the human species.

But we ought not, perhaps, to be so much surprised at the slow march of intellect in this respect, when we find so many centuries to have elapsed before it was so generally admitted, as at present, that pure water, another element bountifully supplied by nature, is preferable to any other beverage for insuring the health and happiness of mankind, and when we have so many temperance societies and other advocates for impressing upon the minds of our fellow subjects the necessity of becoming converts to the imbibing of this element in its pure state, ought we not, with still greater reason, to endeavour to make a similar impression as to the advantages of inhaling, with equal purity, the lighter fluid, of which we stand so much more in need, and which we so much more frequently require?

A gasometer of sheet iron formed of 269 pieces, and of an immense capacity, arrived at Antwerp on the 5th instant, by the *Soho* steamer from England, intended for the gas works in that town.

REPORT FROM THE SELECT COMMITTEE ON RAILWAYS.

Our readers are aware that the 11th clause of the Railways Bill, which was for the purpose of giving discretionary powers to the Board of Trade as to the regulation of railways, excited the greatest alarm on the part of the railway boards. Sir Robert Peel was consequently induced to move for a special committee to receive evidence as to the tendency of the proposed clause. This committee has now concluded its labours, and after a lengthened investigation has made its report. The committee after stating the arguments used on both sides, sum up by recommending that the Board of Trade should not at present have the discretionary power contemplated in the 11th clause of the Bill above quoted, and prefer that the supervision of that department should be exercised in the way of suggestion rather than in that of positive regulation. This, as it will be seen wards off the blow for another year, and we hope that the railway interest will be so far instructed by this attempt, as to take better measures to oppose any future aggression of the Board of Trade.

The evidence attached to the report contains much matter of interest to which we shall be obliged to refer in a discursive manner, but before we refer to this we feel it our duty to express the obligations which the profession owes to Brunel for the able and candid way in which he gave his evidence, throwing aside all personal considerations and feelings of partiality, uninfluenced by the blandishments of the Board of Trade, and not to be deceived by its sophistries, he boldly and unscrupulously stripped the railway department of its pretensions, and exposed the incompetency and ambition of its officers. We wish that it were in our power to give equal praise to the elder Stephenson, but with the exception of the noble tribute he gave to the merits of the Great Western railway, he presented a lamentable contrast to Brunel.—Mr. Labouchere exhibited an ability in the management of his cause, which we cannot but recognize, but we must at the same time regret that it was not exerted in a better cause.

From Mr. Laing's evidence and from the documents annexed we learn some particulars as to the constitution of the Railway Department of the Board of Trade, which as it is of some importance we have thought it desirable to notice. The Department is placed like the Statistical Department in charge of Mr. Porter, and for which he receives 200*l.* per annum extra, but it does not appear that he takes any very active part.—Lieutenant-Colonel Sir Frederic Smith is Inspector General of Railways, with a salary of 900*l.* per annum and travelling expenses while engaged out of London, but without retiring allowance. The Board of Trade observes that, "the provision of the act which excludes the appointment of any one connected with railways, and the high rate of remuneration, which would be requisite to secure the undivided services of any eminent civil engineer, are of themselves sufficient to direct and almost to restrict their Lordship's choice to some officer of the Royal Engineer corps, who has a competent practical knowledge of railways." Mr. Laing transacts the official business of the Department, and is the Law and Corresponding Clerk with a salary of 500*l.* per annum.—Mr. Porter and Mr. Laing are authorized to sign all notices, documents, &c., in the name of the Board of Trade.—Mr. Oswald acts as a junior clerk. The total expense of the establishment is estimated at 1400*l.* per annum. The engineer officers employed in the first instance to assist Sir Frederic Smith, were paid two guineas a-day and expenses. The Department is put under the superintendence of the President of the Board of Trade, as consulting member of the Board. It is in contemplation that the establishment must be slightly increased.

In the evidence of the several parties who were present at the celebrated Birmingham Conference for devising the means of preventing accidents, we learn for the first time the reason that the results were so very trifling. It seems that on discussion, the difficulties that stared them in the face as to forming any general system were so great that the attempt was given up in despair, and the parties present silently acquiesced in the resolutions, which had been prepared, at the same time recommending the regulations of the Liverpool and Manchester Railway for consideration and not for adoption. Frightened as they had been by newspaper clamour—into the endeavour to adopt some measure, they were confined in their original views, that as the accidents had not arisen from neglect on the part of the companies, neither yet had they sufficient experience to devise any effective remedies.

We find also some clue to the mode of proceeding of the well known committee of three, whose activity and inactivity were the cause of so much alarm in the early part of the agitation. It appears that when the railway body, dissatisfied with their conduct, found it necessary to take the matter into their own hands, the committee thought proper to disclaim having in any degree wished to bind the companies, a salutary step which seems to have had the best effect.—Mr. Labouchere was thus deprived of the support of this committee, whose neglect of their duties had excited so much indignation, and in place of this pliant body, he had to contend with the great railway interest, representing fifty millions of capital.

Brunel's evidence was the mainstay of the opposition, and abounds in practical information, which we wish that it was in our power to transcribe, but the limited nature of our space forbids. What he says as to engine drivers is of direct importance to the profession, and is so totally opposed to the vulgar opinion on the subject that we are compelled to insert it here.

There is another regulation suggested, and which therefore I presume is to be acted upon; it is that an engine driver shall be able to read his instructions. Now I dare say that appears to a great many gentlemen a very essential thing; but not only do I maintain that it is not essential, but I maintain that the mere laying down that rule as a rule, is a proof that the party suggesting it is not acquainted with the class of men we are dealing with, and that we must deal with, as engine drivers. I should have thought too, that Sir Frederic Smith's knowledge of the world and of military life, of privates, would have told him that the class of men who must be employed as workmen, are not a class of men who learn their instructions by reading, even if they can read; their knowledge is obtained entirely orally. A man of that class has not obtained, as we have, the power of reading and remembering what he reads. Those sort of men will read and derive a little amusement from what they read, but they have not obtained the power of learning things by reading, they learn orally entirely. As to the instructions, it is true we print them, and it is true we make them read them, and we make them sign them, partly to ensure their having an opportunity to see them, but very much to satisfy the public mind when an accident has occurred; but I do not believe the men obtain the slightest knowledge of their instructions by reading; they may read them through and get up with the printed letters in their eyes, but as to obtaining information from it, they do not; they obtain their information orally; and whether a man can read his instructions or not, does not at all affect the question of his being a good engineer or not. Our very best man on the Great Western Railway, the very best engine driver we ever had; a very superior man, who is now foreman of our engineers at Reading, a man whom I trust better than anybody I have got on the line, can neither read nor write, and yet he issues instructions, and he has a clerk who writes written orders; and it would be a serious mischief if any regulation of the Legislature should deprive us of him, and of a number of others that we have. I am not one to sneer at education, but I would not give sixpence in hiring an engine man, because of his knowing how to read or write. I believe that of the two, the non-reading man is the best, and for this reason: I defy Sir Frederic Smith, or any person who has general information, and is in the habit of reading, to drive an engine. If you are going five or six miles without anything to attract attention, depend upon it you will begin thinking of something else. It is impossible that a man that indulges in reading, should make a good engine driver; it requires a species of machine, an intelligent man, an honest man, a sober man, a steady man; but I would much rather not have a thinking man. I never dare drive an engine, although I always go upon the engine; because if I go upon a bit of the line without anything to attract my attention, I begin thinking of something else. The duty of the engine man is the simplest possible thing; he must first of all have a good constitution, and be able to stand rough weather; in fact, a gentleman cannot be an engine driver, or any man who can earn a livelihood in any quiet, comfortable way; he must know something of machinery, to a very small extent; of course he must know the parts of a locomotive engine, and he must be something of a workman, although the fine workmen rarely make good engine drivers; such a very low class of knowledge of the machinery, that I can hardly call it knowledge; a mechanic learns that in a fortnight or three weeks. He must be a sober man, and have all those qualities which are included in the general term of "steady;" I hardly know how to define them; but he must be accustomed to follow orders, not desirous of infringing them; not reckless, and be what is commonly understood by "a steady man."

Sir Frederic Smith was the first witness examined, being in support of the government recommendations—what were the arguments which he used we think it unnecessary to repeat, the public being sufficiently conversant with them. He bore testimony to the harmony with which the companies and their engineers had co-operated with him, and expressed his regret at its being disturbed by the difference which had arisen on the discretionary clause—an ill omen we should say as to the result which would be likely to be realized if the clause had become the law of the land. Sir Frederic was obliged to admit that most of his proposed regulations were inapplicable as general rules, and that the greatest injustice would be the effect of their stringent execution. It must be observed that the intended legislation would have authorized the Board of Trade to interfere with the traffic in many annoying ways, as for instance on the Manchester and Leeds railway, suppressing the mixed train, disturbing the arrangements of lines generally by prescribing an interval between the trains, regulating the speed and the load, crushing small companies by overburthening them with expenses, increasing the police, breaksmen, number of breaks, buffer springs, preventing assistant engines from pushing behind, carrying luggage with passengers, obliging to work by time tables.

Mr. Booth of the Liverpool and Manchester Railway exhibited his usual acquaintance with the subject, and expressed in the strongest terms his objections to the powers proposed to be given to the Board of Trade. He unequivocally stated that he did not consider any central authority or Board competent, in the present state of knowledge as referrible to railways, to take on itself the issuing of regulations. Mr. Booth, as well as the other witnesses who followed on the same side, forcibly dwelt on the melancholy consequences which must ensue from divided responsibility, and showed the injustice of allowing the Board of Trade to make rules, and then punishing the companies for the bad working of them. For a central authority to attempt to regulate the traffic on the Liverpool and Manchester would be productive of the greatest confusion and injustice, on account of the fluctuating nature of the traffic, requiring that arrangements should be made at the moment to conform to it. In appealing against the recommendations already made by the Board of Trade authorities, Mr. Booth forcibly urged that they were such as to show that they had not that experience which is necessary to make them capable of issuing regulations, and that he could not have confidence as to their general discretion in issuing regulations. The proposed fifteen minutes interval between the trains, he showed to be equal on his line to a distance of seven miles. Mr. Booth attributed in some measure the success of the Liverpool and Manchester Railway in escaping accidents to the very great traffic, which obliged every engine driver to be constantly on the alert. Very few accidents, observed he, occur in crossing Cheapside for example; every body is obliged to be on the alert, and, to look about him.—The proposed regulation as to ballast trains he showed would be absolutely impracticable, and time tables equally useless and mischievous. The propriety of leaving the responsibility with the companies, was supported by their witnesses on the ground that they had a stronger pecuniary interest in the safety of passengers, and prevention of accidents than any other parties, and were of course urged to adopt every possible precaution. One company was mentioned as having lost £10,000 by a single accident.

Brunel, whose examination occupied two days, followed in support of Mr. Booth. To the spirit which characterized his examination we have already referred. He expressed more strongly even than Mr. Booth his want of confidence in the officers of the Board of Trade generally and individually, and throughout his examination kept Mr. Labouchere's vigilance fully on the alert, frequently discomfiting him in his attempts to entrap him into a toleration of the interference of the Board, to which Brunel objected in toto. Upon the causes of accidents, the remarks of this engineer fully bear out the views which we maintained both on this and the steam vessel question, and are well worthy of perusal.

I think the officers of the Board of Trade are under a completely erroneous impression both of the circumstances which really lead to those accidents, and of the best mode of remedying them, and that they are without, and must always be without, any sufficient knowledge of the practical working of the system with which they propose to interfere; and I think that the accidents and the suggestions arising from those accidents themselves, prove what I assert. They certainly prove it to the minds of those who are familiar with the practical working of railways. I dare say it will be difficult to prove that satisfactorily to the Committee, from the very circumstance I have just mentioned, that they are not acquainted with the practical detail of the working; but still, if the Committee will allow me, I will attempt it. I think that the mere circumstance of which the officers who have been appointed have themselves given very strong evidence, namely, that notwithstanding the tremendous speed at which railway travelling is carried on, notwithstanding the appearance of almost trusting to Providence as we run along the lines, and the apparently great risks that are run, that notwithstanding all this, it is a notorious fact, and one which is admitted by the officers who have inspected railways, that it is a safer mode of travelling than any other adopted up to the present time; and that, notwithstanding all those apparent dangers, really there is very little danger comparatively: I think that ought to have led them to consider, that, in all probability, the dangers that still exist, do not arise from any glaring prominent defects in the system, which of course those who have brought it to this state of perfection must long since have seen, and that it would hardly be left to those officers to whom the thing must be new, to discover suddenly that we have passed over some of the most prominent and easily removed causes of danger; and I think that, as they become more intimate with the practical working of railways, they will see that the real cause of danger, small as it now is, consists of a multitude of small operating causes, which occasionally and accidentally are all brought to bear, and all operate to produce risk. But the real source of the danger, and the only one which there is any hope of removing, is in a complication of imperfections in a great number of the mechanical parts of the system. We have gradually discovered, that the wheels had better be a little wider in gauge than we made them at first; that they had better not be quite so narrow in the external gauge; that they should be about half an inch wider on the tire; that the guard-rails had better not touch them: that increased care should be given to the gauge of the rail; and that the tail-lamps must be put in a position in which they shall be less likely to be obscured. A number of small things of that sort are gradually discovered, generally speaking, without any serious accident; they are gradually discovered and removed; and thus the original chances of risk are diminished, till, in fact, they do not occur. All those who are familiar with the working of a railway, or with the manufacture of any article, or with the progress of any complicated system of that sort, well know that it is in vain to attempt to make workmen more perfect: it is in vain to attempt to trust to any regulations in such a manner as to expect, that when a new accident occurs, they shall all apply; and that it is still more vain to expect, that they will be all obeyed. It is by gradual and progressive improvements, in all the little details, that the risk of accident is diminished; and it is by that alone that the risk of danger will be removed. This is familiar to us, and to the persons working the railways; but I am sure it cannot have struck the gentlemen who have been sent to inspect the railways; because, first of all, no looking on occasionally will make them acquainted with that which we only learn by seeing it, and feeling it, and feeling the inconvenience of it every day. They also cannot learn it, because we keep progressing so fast, that the knowledge of one day will not apply to the next; and although their own suggestions which they have made after those accidents, and although the reports which have been made by several of them show very great investigation, and a very acute perception of the circumstances, which they happened to be able to lay hold of on the ground after the accidents had occurred, still those suggestions show that they are aiming simply at that which we know cannot be attained, namely, at perfection in the regulations and in the character of the men that we have to employ, and that it is by attention to the multitude of little details alone, th t approximation to perfection can be attained: that that is their view, is evident also, from the suggestions which they have all thrown out after seeing those accidents.

Mr. Brunel remarks on the application of two engines in conjunction.

All chances of collision of course are got rid of between those trains, and the average power of the whole is better obtained; although there again the necessity of understanding exactly the practical operation of the thing is evident, because it is not the case that two engines, when coupled together and drawing a load, will do twice as much as one engine. It is rather a curious circumstance, but I mean to say that the average power of the engines is best obtained by putting them together, if we take into consideration the chances of one engine running a little dry, or of any circumstance occurring to lessen the power of one engine, we do then get the average power of two or three better by sending them together than by sending them separately; and I have no hesitation in saying, that the general rule ought rather to be (though I think it would be bad to have any rule either way) to send them altogether than to send them in trains, each consisting of a single engine.

We are restricted by the space devoted to other objects from giving any greater length to the discussion of this report, and we must leave it congratulating engineers on this partial triumph, obtained at the last hour. We do sincerely trust that it will be a warning to make every exertion on the other questions that are likely to be agitated. Let a stand of this kind be made against the Ten Per Cent. Deposit Clause, let a committee be got on this question, and a relief much wanted will we hope be obtained. In concluding these remarks, we should be guilty of injustice if we did not notice the ability of Mr. Saunder's evidence, and express the great obligations the railways must entertain to Sir Robert Peel for his timely interference. The fairness shown by this statesman on this occasion will we hope prove an encouragement for obtaining a repeal of the obnoxious Ten Per Cent. Clause, as it affords a promise of our obtaining aid, if we do but show a fair case.

NEW AND USEFUL INVENTIONS.—No. 5.

By Philotechnicos.

Patent Decorative Carving and Sculpture Works, Ranelagh Road, Thames Bank, Pimlico.

This invention presents one of those great strides of machinery with which the present day abounds, for superseding manual labour in works of art as well as science. What would our forefathers have said at hearing that carving was to be done by machinery; the idea would have been considered preposterous, and the inventor, at least, a madman; but now it is almost received as a matter of course, and nothing is thought impossible; it is, moreover, most remarkable, that some of these valuable inventions are mere improvements upon simple inventions and schemes of ancient date, and familiar to nearly every one. Who would have thought that the common marking iron, used for stamping or burning the initial or name of the owner on implements of trade, should give the idea of a similar process for a more elaborate purpose—that of carving (if the term can be used) in wood? but so it is—or at least such is my anticipation from its proximity, which the reader may judge of from the description of the method adopted for the patent carving. An iron mould is first cast from a plaster or wood model. The iron mould is heated to a red heat, and applied to a piece of wood, previously damped, with great force, and repeated, until the wood is burnt to the required form. The char is then cleaned off, and any undercutting that may be required done by hand: when the operation is finished it has the appearance of old oak. The surface may be brought almost to a polish, when it assumes a highly finished appearance, nearly equal to the original, though of a first-rate master, from which it was copied. By the great pressure to which the wood is subjected, it is rendered much harder, and is consequently more secure against the action of the atmosphere or insects. The immense uses to which the patent carving can be applied must be obvious to all, and needs but little description; and will afford another opportunity —which I am always glad to give the hint of—to the "Commissioners for Building New Churches," to enliven their "interiors," which now present nothing but naked roofs, plain panelings, and any thing but gothic finishings. How does my imagination brighten at the prospect! seats, "as of old," with their beautifully carved finial standards—pulpits, paneled and moulded to richness—gallery fronts with elaborately carved tablets from scriptural subjects—the altar-piece beautifully ornamented with canopies, crockets, and finials—the roof with rich tracery, bosses, queer-looking heads, cherubim and pendants—the pew enclosures (if any, as I hope, ere long, to see the present kind, entirely abandoned, as in that neat little chapel of St. Katherine in the Regent's Park, where the body of the church contains none of those pen-like objects,) I should desire to see enlivened by the beauties of gothic carving—the communion table, chairs and enclosure, oh, what beautiful objects! elaborate to a degree; carved legs, carved backs, carved balusters—the organ, a gem, a specimen of Gibbons, with that fine, dark, brilliant polish sometimes seen in churches of the olden time. But where does my imagination lead me? were it of use to prophecy, to write, to agitate, I would do so with abundant pleasure; but I fear all the labour would be lost, all my advice thrown away, and all my time and research only wasted upon the desert air, ere they, the said Commissioners, will take the hint upon such a subject; but if they will not, surely the profession have some little influence, and will do their best to enhance the interest of our modern churches; 'tis to them I appeal, and earnestly solicit their support, in the introduction of such ornament as will display their taste and judgment, and give good scope for ingenuity. The patent carving bids fair to accomplish this, as the price—the iron ruler of all architecture—is so considerably less than that of real carving—about one third, and, in many cases, one fifth of its cost.

This invention is admirably adapted to the styles now so much in vogue, the Renaissance, Elizabethan, and Italian, the enrichments of which being so frequently repeated, make the cost of the original mould comparatively small; for upon repetition mainly depends the saving of expense. Articles of furniture are famous subjects upon which these magical operations may be performed; those old fashioned, comfortable-looking, high-backed, walnut tree chairs, with their crimson plushed seats and grotesque-looking ornaments, may be imitated to correctness. Cabinets—the pride of former days, with all their twistings and turnings, can be done with facility, and the work of years performed in as many days. It is needless to enumerate the very many purposes to which the patent process can be applied: suffice it to say, that any work carved in wood or moulded in plaster can be executed by its pyrotechnic influence, save and except the undercutting, which must be, as before stated, finished by hand. A tablet in which figures appear of cupids in high relief, is exhibited at the works, and proves full well the triumphal power of the process; and a medallion portrait of the Duke of Wellington, presented to me as a specimen, shows its use in that department.

Patent Anti-Corrosive Iron Tube Works, Brunswick Street, Blackfriars Road.

These tubes are of wrought iron tinned inside and outside, and are used for gas, steam, or water. The process renders them almost impenetrable to corrosion, and causes them to resist the action of gas or acids, for a much longer period than the common tubes; they are useful to brewers, distillers, operative chemists, and other manufacturers; and for the water companies they would be excellent, on account of the purity of the tin with which they are coated,—they are well adapted for service pipes, being less liable to burst by frost than their softer rivals.

ON THE HISTORY OF ANTIQUITIES.

Sir—The subject of the antiquities of those nations which occupied an early period of history, has frequently attracted the attention of men of learning, who have examined with the greatest care every record which could throw light on the subject of their inquiry.

These inquiries, however, have been always entered into in detached portions for the purpose of studying the history and antiquities of a single nation, and for that reason though they have been made by persons well qualified for the task, their efforts have been to a great extent fruitless, and it yet remains to collect into one focus the result of their separate labours, and by affording the opportunity for comparison to increase their value tenfold. Since the principal records of the periods to which I allude, consist in remains of the useful or liberal arts, such a comparison alone can at all exhibit the influence one nation has had on another in the progress of civilization, and enable us to connect many hitherto detached passages in the history of the arts.

No one has, perhaps, carefully compared the remains of ancient art to be found in Egypt, India, Etruria and Peru, yet we have some grounds for supposing that there has been a connection more or less close between the inhabitants of all those countries: in fact to go deeply into all these histories, by a personal examination of the principal remains, would be too arduous a task for any one individual. Besides the nations before mentioned, an attempt of this kind would embrace the history of the Chaldees, the early history of the Tartars, the Scandinavian tribes, the originators of Stonehenge, and the various constructions called Cyclopean, with the remains of now unknown origin in America, which have lately attracted the attention of the antiquaries of that continent.

Another branch of the same subject intimately connected with the former, and of which the importance is too obvious to require explanation, is that of inscriptions; and I have great reason to think that in this especially, our present ignorance arises rather from the want of a skilful combination of acquired materials, than from a deficiency in those materials themselves.

On these accounts I am ready to believe that any one entering upon this subject and fully carrying it out, (and its comprehensiveness would be its excellence), would confer an important benefit on art and literature.

I remain, &c.

E. L.

ON CONTRACTS.

Sir—I shall feel particularly obliged if you will be pleased to give your opinion, in your next publication, on the question given below, as it will be of great service in guiding me upon the business.

I remain, your most obliged,

Cardiff, May, M. R.

(Case.)

I have been employed in making designs for a Rectory House, and afterwards a specification of the several works, and a very full detailed estimate of every item of expense of building the same, to accompany the specification. Among other things contained in the specification was the sinking of a well (that a well should be sunk to a sufficient depth to obtain water), and in the detailed estimate was an item for sinking the well of 3*l*. 10*s*., as being informed by the Incumbent that the springs were very near the surface (which they are in the adjoining fields), and in the specification in the general condition is the following clause, that all extras, additions, or deductions made to the building shall be measured and valued according to the detailed estimate accompanying the specification. Now the site of the house is an eminence on the limestone stratum, and I have sunk a well to the depth of 78 feet below the surface, without any chance or sign of obtaining water, at an additional expense of 20*l*. over the 3*l*. 10*s*. allowed in the detailed estimate, (which sum I have not made a claim for). Through there being no water the Incumbent will not certify that the contract is fulfilled.—Please to state your opinion on the above.

[We are of opinion that from the wording of the specification alone, that the contractor has not strictly fulfilled the conditions of his contract in the eye of the law; it is one of those foolish unlimited stipulations we see too often inserted in specifications. The specification should have stated not exceeding a certain depth. However, if it can be clearly proved that the Incumbent held out to the parties tendering, that water could be procured near the surface, with a view that such parties should imagine it to be the case, and put down a price accordingly; we are then of opinion that the contractor would be relieved in equity, particularly if he proved that he had sunk the well to a reasonable depth, to show that he had used his best endeavours to procure water—which in the present case we are of opinion the contractor has done.]—Editor.

REVIEWS.

A Summer's Day at Windsor, and a Visit to Eton. By Edward Jesse. London, 1841. Murray.

As a guide-book or manual for the information of those who visit Windsor Castle and its immediate vicinity, this may fairly be styled a superior volume of the kind, it being tastefully got up, and containing several well-executed wood-cuts. That the subjects of the latter are well chosen, and thereby enhance the interest of the book, is more than we can add; for, with the exception of the frontispiece, which is a very useful situation's-plan of the castle, the print showing, in elevation, two bays of the exterior of St. George's chapel, another showing three ditto of the Tomb House, and one or two other cuts, the rest of the illustrations illustrate nothing. Sure we are, that had they not been given, no one would ever have missed such things as portraits of trees, facsimiles of prisoner's hand-writings, the ladies and gentlemen on horseback intended to represent Her Majesty with Melbourne & Co., or the very queer old-fashioned set-out of George III. at the Eton Montem. Of the castle itself—which it may be presumed is, after all, the principal of the lions at Windsor, nothing is shown beyond the Norman gateway—which conveys no idea whatever of the exterior generally—and St. George's Hall, and the Guard Chamber, which last is executed in a most disagreeably hard manner. Surely one or two more interiors might have been introduced; we do not say that such subjects can be furnished as cheaply as representations of stumps of old trees, &c.: we would gladly give every one of the latter for a single illustration of the other kind. While Mr. Jesse affects to entertain the highest respect for Sir Jeffry Wyatville, it is certainly no very great compliment towards that architect to keep him and his work as much in the background as possible—or, rather, to keep them quite out of sight. As regards the Castle in its present state, the letterpress is as unsatisfactory as the illustrations, there being very little indeed on the subject of the building, nothing amounting to opinion, while the description is excessively meagre; we have met with very much more from time to time in periodicals and newspapers. But the hundred and fifty pages must, of course, be filled with something, and so, indeed, they are, namely, with what has been given a hundred times before in various publications—a history of the Castle, interlarded with anecdotes as trivial as they are stale. In fact, the whole is a mere "cram,"—such a production as could have been executed by any journeyman bookseller. It is one of those things which are made to sell, for the same reason that other guide-books sell, and that court calendars find customers. But as the title-page bears a name, we naturally—and, as it now turns out, foolishly—expected to meet with something above the ordinary run of such performances. What Mr. Jesse may be as a naturalist we know not; but here he exhibits himself as a bookmaker, one of those whom Carlyle very unceremoniously calls "respectable literary thieves and paupers."

The Decorator and Artist's Assistant. Edited by J. Page, Author of the Acanthus.

The appearance of this periodical work is, we trust, a proof of increasing taste for design, and viewed in such a light, it meets with our best wishes. Published in weekly numbers at sixpence, and monthly parts at two shillings, it contains a variety of designs for architectural ornaments, furniture, jewellery, &c., and will no doubt be extensively patronized by the artisans to whom it is addressed. We wish that Mr. Page would in every instance give the authorities of the designs which he inserts, by which their value would be much enhanced. There is a want of boldness in the outlines, but as that is attributable to the etching, we cannot object to it.

The Acanthus.

As a homage to the architectural profession we present to their notice Mr. Page's Plate of the Acanthus, designed, drawn and engraved by himself. Mr. Page is, we believe, a self-taught artist, and we know him to be meritorious and hardworking; we hope therefore these will be claims to the patronage of the profession for which he has shown so much respect. As an object of study the luxuriant plant depicted in this engraving will well repay the student who lays out his half-crown upon it. It is a cheap and elegant ornament for the portfolio. We are informed that the drawing obtained a gold medal at the Society of Arts.

We have been obliged to defer our farther notice of Mr. Clegg's "Practical Treatise on the Manufacture and Distribution of Coal Gas," until next month.

PAPERS ON HARBOURS AND RIVERS.

Report on the navigation of the Forth. By Robert Stevenson & Sons, Civil Engineers.

Prefatory Note.—Having been called upon, by the magistrates of Stirling, to revise, with a view to its being printed, the following Report, which was made as far back as 1828, we have done so with much care. It affords us great satisfaction to be enabled to state, that the views contained in the Report have derived additional confirmation from our past experience, more especially in the case of the River Tay, whose navigation was formerly obstructed by obstacles which, although composed of different materials, closely resemble, in their position and extent, those which at present hinder the advancement of the trade of the Forth. By the partial removal of the various fords, the depth of water in the Tay, at spring tides, has been increased from 11 feet 9 inches to 16 feet; and the works, which are not yet completed, have occupied little more than two years. The hardness of the materials which compose the Fords of the Forth may render their removal more tedious; but it ought not to be forgotten, that it, at the same time, ensures greater permanency in the form of the excavated channel. It is therefore with increased confidence that we repeat the recommendations of the Report of 1828.

Robert Stevenson & Sons.

Edinburgh, Dec. 10, 1838.

The Firth and River Forth are navigable for the largest class of merchant vessels, as high as the port of Alloa: and in spring tides, vessels drawing 9 feet water may proceed to Stirling, lying 10½ miles above Alloa, while those drawing 7½ feet water, may reach the mills of Craigforth, 5 miles above Stirling. The improvement of the navigation between Alloa and Stirling, has long been regarded as a desirable object, and was brought under the notice of the Reporter by the magistrates of Stirling, in the month of November, 1825, when it was proposed to petition Parliament for leave to bring in a bill for this measure. * * *

Above Alloa the river becomes very circuitous. By the navigation the distance from thence to Stirling is 10½ miles, while in a direct line it measures only 5 miles. It has been proposed to render the navigation of this part of the river more direct, by cutting through the links, or peninsular necks of land, for which the track of this river is so remarkable. This would shorten the navigable track; but it would have a direct tendency to deteriorate the navigation below, as a great volume of the tidal water, which at present passes over and scours the lower banks four times in the twenty-four hours, would be cut off and diverted from its course. The cutting of the links and straightening the river would also, in a material degree, interfere with the vested rights of the proprietors of the banks, by depriving some of the benefit of a water communication, and destroying the valuable salmon fisheries of others. This plan, therefore, though worthy of consideration, is, upon the whole, judged inexpedient in the existing state of things. The Reporter proposes to improve the present channel of the river by deepening it, and removing part of the numerous obstructions called Fords, and he therefore now proceeds to describe in detail each of these obstructions, and the works which are considered necessary for their removal.

Between Alloa and Stirling there are seven principal fords, or shallow parts of the river, which form so many obstructions to the navigation. It is not believed that incumbrances of a similar geological structure are to be met with in almost any other river in the kingdom. The Firths of Tay, Moray, Clyde, Solway, and the Rivers Mersey, Severn, Thames, and Humber, have their peculiar tides and difficulties, both in the form of rocks and sand banks, but none of these channels are impeded by successive chains of imbedded stones and rocks, appearing at low water, like those called the Fords of Stirling. Various hypotheses have been started to account for the existence of these fords. Some have supposed them to be artificial, arising from stones having been thrown into the shallowest parts of the river at an early period, to render it fordable for cattle. But from the minute examination which the progress of this survey has enabled the reporter to make, he has no hesitation in stating, that they are natural barriers of rock traversing the valley of the Forth, and are what geologists term *whin-dykes*, which, from the continued scouring of the bed of the river, have assumed the irregular appearance now presented by them at low water. Similar formations of whin or greenstone rock occur on the southern face of the Abbey Craig, and also on the northern side of Stirling Castle. The fords, like the cliffs at these places, consist of stones, varying in size from a cubic foot to a cubic yard, imbedded in a matrix of friable rock. The joint effect of the crooked channel of the river, and the obstructions caused by the fords, produces a great retardation in the velocity of the flood, which, in the upper parts of the river, is very sensibly less than that of the flood in the Firth, and travels at the rate of only one mile in five minutes. Although this retardation may be considered to be in part due to the operation of the river current, yet it is obvious, from its languor, that this cannot be the principal cause, and it is therefore to be sought for chiefly in the obstructions offered by the fords. On the days of new and full moon, it is high water at Alloa Pier at four hours and forty minutes; at Tullibody Pier at five hours and ten minutes; at Powis Hole at five hours and ten minutes; and at five hours and ten minutes at Stirling Shore or Quay. The consequence is, that the tide does not attain its maximum height at these three last places, until it has been ebb tide for half an hour at Alloa. It appears further, from this train of observation, that the perpendicular rise of spring tides at Alloa, is about 19 ft. 4 in.; at Tullibody, 16½ feet; at Powis Hole, 12 feet; and at Stirling, 7 ft. 8 in.; while the corresponding rise of neap tides at these stations is respectively 11½ feet, 11½ feet, 7 feet, and 3 feet. There being, therefore, a rise of 19 ft. 4 in. in spring tides at Alloa, and only 7 ft. 8 in. at Stirling, the available depth at that place is less than it would have been had there been no rise on the bed of the river, by 11 ft. 8 in. Before leaving the subject of the tides, it may be proper to remark, that the maximum point of high water at Alloa Pier is 4 inches above the level of the high water at Tullibody Pier, while it is 2 inches lower at Powis Hole, and 3½ inches higher at Stirling Shore.

The great object, therefore to which the reporter would direct the exertions of the Magistrates of Stirling, as Conservators of the Navigation of the Forth, is to the removal of the Fords, which are the chief obstructions to the free passage of the tide waters. The advantage of deepening the bottom in the upper reaches of the river is obvious, as the natural effect of such a change is to permit the tide to flow over the lowered ridges at an earlier period of the tide, and thus to allow high water to take place sooner, before the tide below may have fallen to any considerable extent; while, at the same time, an increased depth is obtained. Vessels may then start from Alloa earlier in the flood-tide, and reach the shallowest parts of the river, near Stirling, at the top of high water. In this view of the method of improving this part of the navigation, it is very satisfactory to know, that a navigable track through the whole of these obstructions may be formed at a comparatively small expense, by the common and simple process of blasting with gunpowder, and the use of flats or lighters fitted with cranes and other apparatus. The Reporter will now describe, in detail, the extent of the operations he considers necessary at the different fords.

On the reach between Alloa and Throsk, he proposes that a buoy, provided with suitable moorings, should be laid down at the seaward extremity of the bank, on the eastern side of Alloa Island, about a quarter of a mile above Alloa Pier. This buoy will be useful as a direction for avoiding an extensive spit of sand, on either side of that island. On its western side a perch or beacon is to be erected as a further guide for that channel.

The commencement of Throsk Ford is about a mile and a quarter above Alloa Pier. The channel on this ford is very shallow, and when the river is in its state of summer water, it dries nearly all the way across; but as this part of the river has the advantage of a perpendicular rise of about 18 feet in spring tides, and 13½ feet in neap tides, the navigation is comparatively little impeded. On referring to the plan and longitudinal section of the river, it will be seen, by the parts coloured red, that little excavation is proposed here. A buoy, however, is intended to be moored in a central position to show the deepest water, and, as a farther direction, a perch is to be erected on the starboard hand. This perch will also serve to point out the proper channel for passing Tullibody Island.

Cambus Ford is about a mile and a quarter above Throsk. The bottom of the channel towards the lower end of this ford consists of large stones and roots of trees, and in its upper part, large boulder stones appear above the surface at low water. The rise of tide at this ford is 16½ feet in spring tides, and 11½ feet in neap tides. The navigable channel to be cleared measures about 500 yards in length, and 30 yards in breadth at the bottom. An average cutting of one foot in depth will give about 20 feet at high water of spring tides at this place. A perch is to be erected on the larboard hand, opposite Tullibody Yare or Pier, and another on the starboard hand, to the westward of the Mouth of the Devon. By this means vessels will be enabled to avoid the foul ground at the bank on the opposite side of the river. The track of Cambus Ford is so obvious, that it is not considered necessary to moor a buoy to point out the deepest channel.

Badneath Ford is about three quarters of a mile above Cambus. Its bottom consists of two irregular lines of boulder stones, crossing the bed of the river with numerous detached masses of the same description. From the winding direction of the channel at this place, the navigation is rendered more difficult than at either of the fords below: and, in clearing it, considerable works of excavation will be required. In spring tides the rise of the water at the lower end of this ford is 16 ft. 6 in., and at the upper end 13 ft. 4 in.: there is therefore a fall of 3 ft. 2 in., on a length of about 1150 yards, which occasions a rapid at low water, when the river is in its summer state. In neap tides, the rise is about 11 ft. 2 in. at the lower end, and 8 feet at the upper end. The length of the channel intended to be excavated at this ford is about 565 yards, and its breadth will, as already proposed, be 30 yards at the bottom. An average depth of cutting over its whole extent of about one foot will be required in order to give a depth of 18 feet at high water of spring tides. A perch is to be placed on the larboard hand at the lower end of this ford, and a buoy at the upper end. A perch must also be placed at Fallin Point on the larboard hand. In passing Polmaise and Scobbie's Pow, no difficulty occurs; near Bannockburn, however, there is a bank where a perch will be required as a direction for the deepest channel.

Manor Ford, about two miles and a quarter above Bandeath, has an irregular and stoney bottom. At the lower end of this ford, the rise in spring tides is 13 ft. 8 in., and at the upper end 12 ft. 6 in.: and in neap tides about 8 feet and 6 ft. 10 in. respectively; there is consequently a fall at low water of 14 inches which occurs on a length of 666 yards, and produces a considerable rapid at this place. The extent of ford proposed to be cleared measures about 666 yards in length, and the breadth and depth of the channel to be formed will be the same as that already specified. This will require an average cutting of 18 inches in depth. From the curved form of this channel, a perch will require to be laid down on the larboard side, for each end of the ford, and a buoy must be moored in a central position on the starboard hand.

The Sow Ford is about three quarters of a mile above the Manor Ford, the bottom is stoney and irregular, and its direction also forms a curved line, but as the bottom presents fewer obstructions to the current than the two fords immediately below, there is no visible rapid at this place. Spring tides here give a rise of 11 ft. 9 in., and neap tides 6 ft. 9 in. It will be seen, on referring to the plan and section that the works of excavation at the Sow Ford are not extensive. Instead of mooring buoys to point out the direction of the deepest water, it is proposed to erect two perches, the one on the starboard and the other upon the larboard hand. Wherever perches can be introduced they are considered preferable to buoys, which are more expensive both in their first cost and future maintenance.

The Abbey Ford is situate about a mile above the Sow Ford, and has already been excavated to a limited extent with a view to its improvement: but the excavation wants extension, both in breadth and in depth, to render it useful. The current here is still so much obstructed that it causes a considerable rapid when the river is in its summer state; the fall being no less than 2 ft. 6 in., on an extent of about 500 yards. Spring tides rise, at the lower end of this ford, 11 ft. 6 in., and at the upper end only 9 feet; and neap tides rise 6 ft. 9 in. at the bottom, and 4 ft. 3 in. at the top. The length of the excavation will be about 565 yards, with a breadth of 30 yards, similar to that of the other fords. The average depth of excavation, in order to obtain 13 feet at high water of spring tides, will be about 2 feet. Connected with this ford, two buoys are proposed to be moored on the larboard hand, the one at the lower, and the other at the upper extremity of the ford; and a perch must also be erected on the starboard hand.

The Town's Ford is situate about 500 yards above the Abbey Ford. The foul ground at this place extends about 1000 yards in length, and the works of excavation, in obtaining a navigable track, similar to that of the other fords, will be proportionally more extensive. Spring tides rise only 7 ft. 8 in. at the Town's Ford, and neap tides about 3 feet. Its bottom is very irregular and rocky, forming a great obstruction to the trade of the town, and the navigation of the upper parts of the river. The average depth of cutting at this ford will be 2 feet. For pointing out the deepest water of the new channel which it is intended to excavate, three buoys upon the larboard hand are considered necessary.

The results of the operations which the Reporter has described will be to deepen the river at those points where the obstructions occur; and the depths which are intended to be obtained at high water of spring tides are as follows at the various fords, viz.:—Throsk Ford, 22 feet; Cambus Ford, 20 feet; Bandeath Ford, 18 feet; Manor Ford, 16 feet; Sow Ford, 15 feet; Abbey Ford, 13 feet; Town's Ford, 13 feet.

By thus proportioning the depths at high water on each ford to its distance from Stirling, it is expected that vessels drawing 13 feet will have sufficient water over the lower fords at any period of flood, and will thus be enabled to reach Stirling at the very top of high water, and get the full advantage of the most favourable time of tide in the shallowest parts of the river.

The shore, or quay of Stirling, extends 200 feet or thereby along the right bank of the river, and consists of a breast-wall built in a rude manner with boulder stones, without the usual and necessary provision of defenders or wooden stretchers to prevent vessels from receiving injury while lying at their moorings. Vessels must consequently lie off in the stream to the great inconvenience of the mariner and trader. In any improvement, therefore, upon the navigation of the river, the unserviceable state of the quay-wall at Stirling should not be forgotten; but measures should be taken for rebuilding it, at least to some extent. The accommodation on this wharf is also very circumscribed and defective, but it may easily be extended and improved, as proposed to the Magistrates by the Reporter some years since. The road from the shore should also be formed on a more easy line of draught. It would likewise prove a great convenience to the southern parts of the town and the lower districts of the county, if an additional wharf, and a road from thence, were formed about the central part of the Town's Ford; as also proposed in the report above alluded to. In conclusion, the Reporter has to state as the general result of his inquiry, that it appears, from the annexed estimate, that by an expenditure of about £10,126 4s. the fords of the Forth might be cleared, so as in spring tides to admit the passage up to Stirling of the ordinary class of merchant vessels drawing about 13 feet water; and he cannot but think the importance of such an improvement far outweighs the capital required for its attainment. The position and rising importance of Stirling is too obvious to be longer neglected. It is the natural emporium of the Western Highlands, and lies in front of an extensive and fertile district, containing many valuable waterfalls and other facilities for the establishment of large manufactories.

ROBERT STEVENSON.

Abstract estimate of the probable expense of the works of excavation, mooring buoys, and erecting perches or beacons in the several fords and reaches, on the river Forth, between Alloa and Stirling, agreeably to the foregoing report.

	£	s.	d.
For the expense of works of excavation and removal of stuff, and for mooring a buoy and erecting a perch connected with the reach between Alloa and Throsk, - - -	£ 72	1	0
For works of excavation, &c., at Cambus Ford -	618	18	0
For ditto ditto Bandeath Ford -	654	13	0
For ditto ditto Manor Ford -	918	7	0

"ON THE IMPROVEMENT OF RIVERS, &c."

SIR—In your review last month of my Treatise on the Improvement of the Navigation of Rivers, you have given an entirely erroneous version of my views, by an unfortunate mal-arrangement of your quotations. This has possibly arisen in the press, nevertheless every scientific or practical man must feel bound, after merely reading your review, to pronounce the work quite undeserving of the approbation with which you and other literary characters have been pleased to honour it.

In chapter 2, is my definition of the regimen, or state of those rivers which are free from bars, and the plain inference to be drawn from this chapter alone must be, inasmuch as "like causes produce like effects," that we can only ensure the improvement of defective, or bar rivers, by approximating their condition to that of those which are in the required state.

In chapter 3, I give a representation of those features of the regimen, or state of bar rivers, which mark the difference between them and those which are free from bars.

In chapter 7, "*on the course to be adopted for the improvement of the depth on the bars of rivers, and in their channels*," I state, "the reasoning in the preceding pages on the causes of the formation of bars, suggests the course to be adopted for their amelioration, by the removal of all those inner banks, or shoals, stretching like dams across the river, which have the effect of preventing the rapid discharge of the backwater during the proper tidal duration of the ebb."

Again, "seeing that the existence of bars is to be attributed to the too great declivity of the bed of the river, or to that of its low water surface, the impropriety of forming dams across a tidal river, with the view of converting it into a line of navigation by the means of locks, ought to strike every reflecting mind as a measure which should never be adopted when there exists any possibility of obtaining the requisite depth of water by deepening the bed of the river."

In lieu of giving the above, you have merely quoted as my means of improvement, a case or exception, in which I have supposed the existence of impediments to carrying the preceding views into execution, such as the great expense of lowering a long length of rocky bed, which expense the trade of the port might not be able to bear.

Considering the error into which you have been misled, by forming your opinion upon the excepted case, in lieu of the general rule which I have advanced, I am not surprised that your views of the utility of my theory do not coincide with the favourable opinions it has elicited from other scientific quarters.

In my account of the former theories on the cause of the formation of bars, I have given the names of every author who to my knowledge has advanced upon the subject any thing beyond the opinions generally held. I did not give the name of the author of the fourth theory, because my quotation is only from a paper signed Nauticus, in the Nautical Magazine for 1837, page 487; a work much used for the diffusion of information connected with hydraulic engineering.

I perceive in your May number that Mr. Henry Barrett avows himself the author of the paper signed Nauticus.

Mr. Barrett also takes credit to himself as the originator of the suggestion of the "formation of harbours with double entrances," a principle which he says, "is now recommended by the commissioners in their report of a survey of the harbours on the south east coast." But there is no piracy of Mr. Barrett's conceptions in this, inasmuch as harbours with double entrances have been in existence for many centuries; neither is there any resemblance between the *bonâ fide* harbours of refuge proposed by the Government Commissioners to be constructed in five fathoms at low water, upon the principle of the Plymouth or Cherbourg breakwaters, and the harbours proposed by Mr. Barrett to be constructed at Dungeness, or Lowestoffe Ness; the latter being mere inland excavations, with channels of approach to them to be cut through the drifting shingle beach; but which channels and excavations are to remain for ever afterwards clear of deposit according to the theory of their projector Mr. Barrett. In my humble opinion they would speedily fill up again and become *terra firma*, notwithstanding the double entrances. Any scientific or practical man on examining Mr. Barrett's plans for harbours, will immediately perceive the error which has been made in believing that there would be any current *through* the harbour, as this could only take place if the course from one entrance to the other, *through* the harbour, were shorter than by the coast line.

In the Nautical Magazine for 1838, page 97, is a full description of Mr. Barrett's harbours of refuge, and a reply to his theories on bars. "Lowestoffe Ness is a flat point of sand and shingle, which has been slowly but continually increasing and extending further into the sea; towards the centre of this Ness it is proposed to excavate a basin of some three acres, and it is intended to open a channel north and south into the sea on either side of the Ness. These entrances being protected with short piers, and once opened to a depth of fifteen feet at low water, (no very easy job,) are thenceforth, and for ever after, so to remain at the simple *ipse dixit* of the engineer. I doubt it; I will ask any unprejudiced person acquainted with this part of the coast, the flow of tide, and the harbours in the neighbourhood, whether it is not much more likely that it will not only be barred up, but "blocked up and lost?" But Nauticus (Mr. Barrett) says, "The sole cause of bars at the mouths of harbours is the conflicting action of effluent currents passing into the ocean at *right angles* with the shore," and in reference to this theory of Mr. Barrett, and his subsequent statement that "there is no exception to this rule to be found on the whole surface of the globe," Investigator quietly observes, "assertion is not argument, nor a reference to the maps of the world, demonstration on such a point." Investigator also calls upon Nauticus (Mr. Barrett) for the names of the scientific men who he states are converts to his theories. In Mr. Barrett's letter of the 25th ult., to give weight to his statements he also adds, "numbering as I do among converts to my *thesis*, some of the most eminent scientific and practical men of the day;" and again, in reference to his theory, "I state this from observation of more than twenty years made on harbours and bars on various parts of Europe and in Africa." Now, Mr. Editor, I repeat with Investigator, that it would be far more satisfactory to be able to reason upon facts produced by Mr. Barrett, in lieu of loose statements, and the shadows of opponents. Without troubling Mr. Barrett to give us an account of the rivers on the coast of Africa, (though by the bye I have lately seen that an attempt has been made to get rid of the bar of the Kowie River, by giving the latter a direction at right angles into the sea, in lieu of its old oblique course, which by Mr. Barrett's theory ought not to have been attended with a bar), I will merely ask if my information be correct as to the statement, that the river Yare (with which Mr. Barrett is locally well acquainted) is now made to discharge its waters at right angles into the sea, and that the depth on its bar is much greater than at any known former period; or when it discharged its waters into the sea with an acute angle with the shore, when the navigation was nearly lost, and the inhabitants had to cut a direct channel through the dunes into the sea.

I am your obedient servant,

W. A. Brooks.

Stockton-on-Tees, June 1841.

KENT, THE ARCHITECT.

Sir—While I quite agree with Mr. East in regard to Kent's merits as an architect, I cannot help regretting that he should have slurred them over—at least, have passed over them so lightly without at all dwelling upon them, or even mentioning by name, a single building by him. I am rather surprised too, that while speaking of Kent, Mr. E. should not have taken Mr. Allan Cunningham to task, for the supercilious and even contemptous tone in which he has expressed himself of one who deservedly ranked so high in his day both as an architect and landscape gardener, in which last capacity he may be considered the father of the so-called English style of laying out pleasure grounds. A just tribute to his memory, in that character, has been paid to him by the writer of a paper on the subject of ornamental gardening in the Foreign Quarterly; of Kent's abilities as a painter, perhaps, the less that is said the better, but Holkham alone, would suffice for his architectural reputation, for though susceptible of improvement in some respects, it is incontestably one of the most complete residences in the kingdom,—a perfect model in regard to internal arrangement and convenience, and likewise elegance of style, and variety of effect. Every part of the plan is carefully studied, and every apartment is beautifully finished. Though by no means aiming at architectural decoration, the statue gallery is one of the most charming rooms I ever beheld,—of a beauty actually fascinating, and the view from the octagon tribune at either end affords a most striking scenic effect. Never have I seen a single plan of Palladio's which at all approaches that of Holkham, or I may say, which is not more or less disfigured by glaring blemishes and defects. Nevertheless, Cunningham makes no scruple of saying: "little interest attaches to a controversy about such a design: it is heavy and monotonous, and stamped with all the faults, which were many; and all the beauties which were few, of him who proudly wrote himself 'Painter, Sculptor, and Architect.' "—No doubt this is a neatly turned, antithetically pointed sentence; yet it is ungenerous and unjust; particularly when it is considered what an immense stride forward Kent took, from the clumsy and monotonous arrangements which had till then prevailed in the mode of laying out houses of that description.

Such being the case, I am surprised that Mr. East should not have instanced Holkham, as being the noblest work of its class and period in our architecture of the last century. That he is not sparing of admiration towards Kent is evident enough; but at the same time he has expressed himself in such general—or rather such exceedingly vague terms, that it is hardly possible to make out any definite meaning. Nay, he almost seems to deny Kent one of his chief merits, when he talks of his being an artist rather than an architect, since the princely residence above-mentioned is one pre-eminently marked by excellence of plan, and other strictly architectural qualities. Or shall I say that Holkham did not occur to Mr. E.'s recollection when he was writing his more florid than perspicuous eulogium? If unacquainted with what Arthur Young says of Holkham, he will doubtless thank me for pointing out to him that writer, whose Tours, though professedly agricultural, contain a very great deal also of interesting matter, relative to the mansions and seats he visited in different parts of the country,—far more indeed than is to be obtained from others who have confined their attention to buildings and collections of pictures. I may also here mention a paper exclusively on the subject of Holkham, in the fifth volume of Elmes' Annals of the Fine Arts, which may be recommended as an able piece of architectural criticism.

I remain, &c.

Z.

CANDIDUS *versus* S. L.

When S. L. spoke of my making so free with the Professor of Architecture, it certainly looked very much as if he thought it rather a piece of presumption on my part to make any animadversions at all on opinions delivered from such an authoritative quarter. Nevertheless he now professes to wonder where I find any expression of his that seems to discountenance discussion of the opinions of public men,—in which light, I presume, the Professor of Architecture at the Royal Academy may fairly be considered, in regard to his own art, although he is not a public character in the political world. Whether it be with regard to these last alone that S. L. is ready to allow "the roughest handling," I know not; but he might perhaps have spared himself the qualifying proviso, viz., "if it be kept within the bounds of truth and reason," because it would be exceedingly difficult indeed to ascertain and lay down those bounds in a clear and satisfactory manner. I myself, for instance, should say that I did not in the slightest degree transgress them. Or, "by keeping within the bounds of truth and reason," are we to understand that we are at liberty to say only just as much and no more than will be approved of, and allowed to be perfectly reasonable, by the party animadverted upon, or by those who take just the same side of the question? In such case, I most assuredly have on many occasions shown myself to be an outrageously unreasonable sort of person;—I hope I ever shall continue to do so.

To come to something more tangible,—S. L. says he cannot see the propriety of adopting the mode suggested for Gothic windows; yet to most other persons I think it must be obvious enough, because all the objections—and I will add reasonable ones—against glazing with small *quarrels* or panes set in lead, are removed at once, and still the beauty and character of the style, as regards moulded mullions, and tracery, fully preserved. Such window may very properly be compared to an open screen,—and wherever placed, a screen of that kind may, I conceived, be described as *open*, in contradistinction from one with solid panels—though filled in with glass.

When he talks of Gothic being objected to by most persons on the score of its interfering too much with comfort, if it is to be properly treated, I must confess I do not understand him; because if "properly" treated, that style may be made to conduce quite as much to comfort and even to luxurious refinement, as any other; that is provided it be treated not only "properly" in regard to the elements and details of the style, but ably and intelligently, so as at the same time to secure all those improvements in domestic architecture we are now familiar with.—As for fac-similes of old halls and manor houses, I would leave them to such fac-simile people as would relish a Gothic dinner off the wooden trenchers of the good old times. Most assuredly, George IV., who was supposed to be as studious of personal comfort and convenience as any gentleman need be, was not one of the persons alluded to by S. L.; otherwise he would have had modern sash windows put into all the private apartments of Windsor Castle.

S. L. still insists that *invention* is the *object* of the architect when he employs either the Grecian or Roman style, though he allows—perhaps upon downright compulsion, that originality is not always the result. Nevertheless it would certainly appear that *direct imitation* is not generally aimed at; or shall we say that the numerous modern copies of ancient porticos we have beheld of late years, are so many proofs of invention though unluckily no originality has ensued from it? As for the originality of St. Stephen's, Walbrook—I am S. L.'s most humble servant, but he really must excuse my admiring it. I am aware that to extol it, is perfectly orthodox; yet it never was my doxy, nor was it that of Dr. Anderson, who has given it the "roughest handling" imaginable in his Essay. With regard again to the spire of Bow Church, I admit it to be original enough—as unlike any thing in classical architecture as possible; still it is no favourite of mine; nor is it worthy of being put into competition with that of St. George's, Bloomsbury, which last I will boldly assert to be by far the finest composition of the kind in the metropolis—I might say in England; nor am I altogether solitary in this opinion, having heard nearly the same opinion of it expressed by several professional men. I am asked, however, if I can point out any modern Gothic building possessing as much originality as the two examples quoted for my edification by S. L., I therefore say that the design for the New Houses of Parliament, displays quite as much originality, and of a far better kind, and would also refer to Cossey Hall, and Harlaxton as being highly satisfactory specimens of modern buildings, in which the Gothic has been treated with originality *con amore*. The hardest charge of all against me remains to be answered: I am quite regardless, it seems, of decency in the choice of my expressions—I believe I was once so indecorous as to write at full length, the naughty word "breeches-pocket," and I may possibly on some other occasions, have expressed myself with rather more energy than decorum; but I am not conscious of having ever made use of any expressions of which a gentleman would be ashamed, although of many that would shock those demure, hypocritical persons who are choice indeed as to their words, and seldom further than mere words. However, if S. L. can show up my indecencies and indecorums, he is perfectly at liberty to do so; and then I shall understand better than I now do, in what they consist. For my own part I have no great fancy for the milk-and-water style of writing, nor do I think it at all calculated to operate efficaciously. Did I consider architects to be infants, I should prepare and administer my doses accordingly; whereas there are many it would require a Sixty-Candidus power in order to make any impression upon them. Dainty drawing-room phrases are therefore quite out of the question: to use them—pshaw! it would be like trying to tickle a rhinoceros with a rose-leaf.

Candidus.

DESIGNS WANTED.

Sir—In the *Times* newspaper of to-day (June 4th) is an advertisement inviting architects to send in designs for a Corn-Exchange to be erected at Sudbury, in Suffolk, the drawings for which are to be sent in on the 10th; so that barely three days altogether are allowed for making them, and not even that, unless a person chooses to go entirely by guess, without writing to the secretary (at Sudbury) for further particulars, or rather, for particulars, no other information being supplied by the advertisement than that there will be an area of 78 by 50 feet, yet whether that is the extent of the whole site, or merely of the part of the building appropriated to the Exchange itself, does not very clearly appear.

Surely the people who insert such advertisements must suppose that architects keep a stock of ready-made designs by them, suited for every occasion; or perhaps they may imagine that architectural designs can now be manufactured by steam, and perhaps we shall next be told that the required drawings are expected to be sent down by return of coach or train.

Undoubtedly, if an architect be pricked on with a golden spur, he will be stimulated to extra exertion. But on this occasion, the golden spur has been hammered so very thin, that it is as light as a feather. Hardly, perhaps, will you believe me when I say, that the two premiums amount together to the *extraordinary* sum, as it may very properly be called, of Eight Guineas! viz. Five for the first, and Three for the second! The man who would nibble at such a bait, would nibble the cheese put as a bait upon a mouse-trap. Leaving the preposterous shortness of time allowed out of the question, no professional man, I conceive, would pay attention to such an invitation, stamped as it is with excessive paltriness on the very face of it. Therefore, if responded to at all, it is likely to be so only by junior clerks and office assistants. It might be imagined that so gross a practical blunder as that of affording no time whatever for at all considering the subject—hardly sufficient, indeed, for putting down the first rough ideas upon paper—would not be committed by even the most ignorant. Nevertheless, such we find to be frequently the case, and what is more, that the profession itself makes no effort to put an end to it. One way would be to show up and make an example of every case of the kind. And I would further suggest, that the Institute ought to keep an exact register of all competitions advertised in the public papers, and of their respective particulars and conditions. But, unfortunately, the Institute does not seem disposed to bestir itself in earnest or to the purpose on any one occasion. It seems to be not only without the power, but without the slightest inclination, to effect any good, either for the art itself, or for those who follow it.

I remain, &c.,
Anti-Humbug.

New Steamer at Brighton.—We learn from Brighton that a new steamer built at North Shields for a company at Brighton, and fitted with Mr. Smith's patent screw propeller, on the plan of the Archimedes, arrived at the Chain Pier, on Tuesday morning, from the river Tyne, after the remarkable quick passage of 48½ hours. This vessel is intended to ply from Brighton to the adjacent ports, and to be occasionally used as a tug in towing vessels in and out of Shoreham Harbour. She is about 110 tons, with engines of 45-horse power.

Steam Communication between Dresden and Prague.—The first steam boat that ever made the passage between Dresden and Prague arrived from the latter city on the 30th ult. She is called the Bohemia, and was built expressly for that service, being flat-bottomed, having 121 feet in length, and 13 ft. 6 in. in breadth. Her engine is of 49-horse power, and she is capable of carrying 40 passengers, and a considerable quantity of merchandise. When laden with a full freight she draws only 16½ inches of water, and makes the passage in about 16 hours. She is to travel to and from the two cities every three days.

NEW INVENTIONS AND IMPROVEMENTS.

STEAM ENGINE FURNACES.

EXPERIMENTS ON THE ECONOMICAL EFFECTS OF FURNACES OF DIFFERENT CONSTRUCTION, AND ON DIFFERENT KINDS OF FUEL.

These experiments have been made by a committee appointed by the Society of Industry of the Grand Duchy of Hesse, and their object has been,

1st. To ascertain the useful and economical results of furnaces for boilers constructed on different principles.

2nd. To establish the relative value of the combustibles most generally used in the country.

We do not consider it necessary to enter into the details of the experiment; we will only mention the results.

In order to decide the first question, a common boiler was set over a furnace of brickwork provided with a chimney, and this apparatus for heating was submitted to various modifications, as regarded the form and structure of the hearth as well as the disposition of the flues.

In order to resolve the second question, experimental trial was made of good dry wood chopped from the beech tree; of good coal from Roer, called *Fettschrot*; and of square pieces of turf from Greisheimer, perfectly dried, and of the heaviest kind.

The different modifications used in the construction of the furnace were the following:

I. Furnaces without flues or draught chimneys, the boiler being suspended freely above the fire.

II. A simple flue passing round the boiler, the bottom part of which only was immediately exposed to contact with the fire burning in the grate.

III. A double flue, that is, a flue going twice round the boiler in the same direction.

IV. A stove arched in the shape of a cupola, and having an opening in the middle of the arch, which became gradually wider towards the top, and by which the heat ascended, and was communicated to the bottom of the boiler, to be afterwards conveyed by three holes, placed at regular distances, into a circular passage which surrounded the boiler; to issue thence through three similar apertures differently arranged, and which communicated with a second passage placed higher, whence the draught was at length conducted into the chimney.

V. Two half flues, that is, each of which did not extend beyond half the circumference of the division of the boiler. The fore part of the flame (on the side next the door) ascended from the stove, and was distributed half into the flue on the right, half into the flue on the left, and was finally conducted into the chimney at the point where they met.

VI. Four half flues, or two on each side the boiler (from right to left); the flame issuing from the side opposite the door entered into the lower flue, then passed half the circumference of the partition of the boiler, and entered into the upper flue, whence it was finally conducted into the chimney.

The relative effects of these different arrangements have been ascertained, both with respect to the quantity of water evaporated in the boiler, as well as that of the combustible employed; particular care being taken to keep up the same level in the boiler after each experiment.

In the following table, which contains results of the experiments, the numerals indicate the different methods of construction of the furnaces in the order in which they have been described above; the figures placed underneath indicate the relative qualities of the combustibles employed to obtain a similar result; consequently the greater amounts indicate the worst methods of employing combustibles:—

Wood	VI	V	III	II	IV	I
	63	68·8	68·69	72·19	72·23	100
Turf	VI	III	IV	V	II	I
	53	66	71	72	76	100
Coal	III	IV	II	V	IV	I
	73	76	83	85	91	100

The following are the conclusions to be deduced from the foregoing table:

1. The fire over which the boiler was placed without flues was attended with a less advantageous use of combustible than those with flues.

2. The utility of flues is much more perceptible in fires of wood or turf than in coal fires, because the result is a saving in fuel of about one-fourth to one-third with wood, and almost of one-fourth to one-half with turf, and only of one-tenth to one-fourth with coal, by the addition of flues.

3. The mode of construction with four half flues (No. VI.) may be considered to be generally the most advantageous. Next to this the construction with a double flue (No. III), which in its mode of action bears the nearest resemblance to it. With respect to the arrangements Nos. II., IV., V., the effects they produce are nearly similar.

4. The double flue (No. III), which surrounds the whole boiler, is attended with better results than the single flue (No. II); according to the same principle, four half flues (No. VI) are attended with better results than two half flues (No. V).

5. With the fire of wood and of turf, two half flues (No. V) have more effect than a whole flue (No. II), and four half flues (No. VI) more than two whole flues (No. III); in short, flues which encircle only half the boiler are in this case more effectual; while with a coal fire it is precisely the contrary. The cause of the difference is doubtless this, that in such combustibles as wood or turf, which blaze brightly, a retardation of the heated air, which in these half flues produces a sudden change in the direction of its motion, is more advantageous than with coal.

With respect to the calorific power of the different fuels, there results from equal weights of turf, 96, and of coal, 250, when that of wood is considered equal to 100.

The great difference that is found in combustibles, with respect to their natural quality and their composition, as well as in their degrees of dryness, can scarcely admit of forming points of comparison between these latter results and any other given case. It is well known that there are turfs which from an equal weight throw out more heat than wood; but the results with respect to the different methods of constructing furnaces are more to be depended on; because in these are remarked a degree of regularity in their effects, and it is easy to account for the causes on which the differences depend.—*Moniteur Industriel.—Inventor's Advocate.*

LOCOMOTIVE EXCAVATOR.

This French machine is stated to be the invention of M. Gervais, of Caen. The trial of the apparatus was made in the presence of a committee of the Society of Emulation at Rouen, and of many of the distinguished residents of the town, and the result is said to have left no doubt of the possibility of making excavations by the power of steam. It is said to be particularly applicable in digging canals, and making the excavations for railways. The apparatus is placed on a large heavy kind of carriage, in the fore part of which there is a steam-engine of six horse power, with oscillating cylinders and a tubular boiler, which works the machine, and also turns the two fore wheels very slowly, so that the whole is gradually moved forward as the work progresses, large pieces of wood being laid down to form temporary rails over which the machine is propelled. Towards the back of the machine there are two machines similar to dragging machines, which raise the earth that has been dug out, and deposit it in a horizontal endless chain of buckets, which carry the excavated earth beyond the limits of the trench, and there deposit it, forming an even and regular bank on each side. The excavating apparatus is placed about the middle of the carriage. It consists of four iron shafts parallel to each other and equi-distant, the whole four having their axes in the same plane, and forming an angle of fifty degrees to the horizon, the incline being towards the back of the machine. Each shaft has attached to it five double arms, equi-distant from the bottom to the top, and each arm is furnished with a spade-shaped tool. These shafts, therefore, present forty spades working at different heights, which dig a ditch nearly three metres in width and upwards of one metre in depth. Each of these excavating tools when in action strikes against the earth ten times in a minute. These revolving excavating shafts are put in motion by the steam-engine, and the action of the engine is so regulated that the whole machine progresses at the rate of about twelve metres an hour. The whole of the machinery, including the carriage, weighs about 21,000 kilogrammes, or 15 tons. When, owing to the nature of the soil or the presence of large stones, the action of the tools is resisted, the locomotion is stopped, and the whole apparatus is made to back, so as to enable men to remove the obstruction. The trenches dug by this machine are very exact, the sides are perpendicular and smooth, and the earth thrown out forms on each side a regular embankment. A machine of this kind was some time since shown by M. Gervais to the French Academy of Sciences, on which they reported very favourably, but it was not provided with the means of locomotion, nor was it on so large a scale as the machine at Rouen. *Ibid.*

CALOTYPE.

It has been known for some time, that Mr. Fox Talbot, in the progress of his experiments to render more perfect the art of photogenic drawing, had discovered a means by which paper could be made far more sensitive to light than heretofore. The impressions, however, so quickly obtained by this new method, are in the first instance *invisible*, but by a process similar to the first, they are made to appear with even greater power than in ordinary photogenic drawing. On Thursday evening, June 10, Mr. Talbot read a paper at the Royal Society, in which he described the new process, called, for distinction's sake, *Calotype*; and as the subject is one of general interest, we shall here briefly describe it:—The paper is covered with iodide of silver, by washing it successively with nitrate of silver and iodide of potassium. Afterwards it is washed over with gallo-nitrate of silver, the greater part of which is removed by immersion in water, but enough adheres to render the paper exceedingly sensitive to light. The paper is then dried, and placed in the camera obscura, and the image of a building, or other object, is generally obtained in less than a minute. This image, however, is usually quite invisible; and the mode of rendering it visible (which is the most curious part of the Calotype process,) consists in washing it again with gallo-nitrate of silver and then gently warming it, which generally causes the appearance of the picture with great force and vivacity in the space of a minute or less. The gallo-nitrate of silver is formed simply by mixing solutions of nitrate of silver and gallic acid. The operation requires to be executed with great care and precision, but is not difficult in other respects. The theory of the process remains, at present, unexplained.—*Athenæum.*

IMPROVEMENTS IN FURNACES AND BOILERS.

Charles Wye Williams, of Liverpool, gentleman, for certain improvements in the construction of furnaces and boilers. Enrolled at the Petty Bag Office, May 17. Claim first.—The use and application of metallic pins as conductors for transmitting heat. This part of the invention consists in inserting metal pins in the plates of which boilers, evaporating pans, &c., and pipes, &c., attached to the same, are composed; part of each pin extending through the bottom of the vessel into the liquid to be heated or evaporated, and the other part projecting outside of the vessel into the fire beneath it, by which arrangement a greater quantity of heat is transmitted to the liquid than there would be by the usual method.

Claim second.—The mode of giving the longitudinal and vertical movements to the fire-bars of a furnace; also the extension of the fire-bars outside of the furnace, so as to receive fuel from a hopper, and spread it evenly over the fire-grate.

The fire-bars are serrated (the elevated parts being wedge-shaped, and the depressions quite smooth), and incline downwards from the fire-door towards the bridge of the furnace, their lower ends resting on a bar, on which they are capable of moving verticallly up and down as on a centre; the other ends terminate beneath a hopper outside of the fire-place, but within the fire-door; they are supported at this end by eccentrics placed on a horizontal shaft, which, being turned by hand, or by gearing from the steam-engine, communicates the up-and-down movements to the fire-bars, and the fuel being received from the hopper on to the outer ends of the fire-bars, is urged with a gradually diminishing force towards their inner ends, and spread evenly over the surface of the fire-grate. By the continued movements of the fire-bars the generation of clinkers is prevented.—*Inventors' Advocate.*

IMPROVED APPARATUS FOR CUTTING AND SHAPING METALS.

Joseph Whitworth, of Manchester, engineer, and John Spear, of the same place, gentleman, for certain improvements in machinery, tools, or apparatus for cutting and shaping metals, and other substances. Enrolled at the Petty Bag Office, May 17.

The first part of this invention consists of an improved die for cutting screws. The principle upon which this die is formed may be described as effecting the following object, viz. to cut a screw-thread at any required depth with dies, which have themselves been cut by a master-tap, double the depth of the thread, larger in diameter than the shaft on which the thread is to be cut. The improved die is formed from the common die, by dividing the same either into two equal parts (the plane of section being parallel to the sides of the die), or into three unequal parts, in which latter case the two planes of section are parallel with each other, but at an inclination to the sides of the die. In working this die, its plane of direction, instead of passing from the axis of the shaft on which the thread is to be cut to the centre line of the die, as in ordinary dies, passes outside of the said line. The patentee shows an improved stock, of a very simple construction, to be used with the die.

The second part of this invention is an improved mode of actuating the planing machine, described in the specification of a patent obtained by Mr. Joseph Whitworth, in 1839.

The third part of this invention consists of improvements in slotting machines, the chief feature of which is the compound moving table. This table consists of three parts, the lower part sliding along the bed of the machine; the middle part moving at right angles to the lower one; and the top one having a rotary movement communicated to it.

The fourth part is an improvement in the slotting bar. An angular groove is cut down the back of the bar to receive a strip of metal tapped for small set screws, by which the positions of the cutters are adjusted, and in the front of the bar recesses are scooped out round the cutters, to afford room for the cuttings.

The fifth part is an improvement in the slide lathe, and consists in attaching an apparatus to the headstock or mandril frame of the lathe, for the purpose of forming, together with the change-wheels, a more perfect communication between the mandril and guide-screw.

The last part consists of an apparatus for "truing up" the wheels of carriages and engines on railways. The apparatus is applied to a pair of wheels in the following manner:—one end of a connecting rod is attached by a stud to the outside bearing of each wheel below the axle, and the other ends of these rods are fastened to a horizontal bar parallel to the axle; on this bar a sliding bar composed of two parts moves, each of its outer ends being provided with a grinder or cutter, placed opposite to and in contact with the outer rim or tire of each wheel; the inner ends of this sliding bar are joined together by an eccentric pin passing through them, fastened on a horizontal wheel, which has its bearings on the under part of the horizontal bar; this wheel is turned by an endless band, from a small pulley on the axle of the running wheels. Motion being communicated to the horizontal wheel, it will, by means of the eccentric pin, cause the two parts of the sliding bar to move alternately a short space backwards and forwards, by which means the grinders on their outer ends will be caused to traverse from side to side of the tire of the wheels as they revolve, and thereby grind down any inequalities of the same.—*Ibid.*

UNIVERSAL CHUCK FOR TURNING AND BORING.

Alexander Stivens, of Manchester, engineer, for certain improvements in machinery or apparatus to be used as a universal chuck for turning and boring purposes. Enrolled at the Petty Bag Office, May 19. The patentee claims the peculiar and novel arrangement of apparatus constituting a universal chuck, without confining himself to the number, size, or dimensions of the levers working on the central boss.

The chuck is formed of two plates, viz., a front plate and a back plate, in the former of which are formed three radial mortices; the three holding nogs or dies are attached by screws to dove-tail slide-pieces, which slide backwards and forwards in the mortices. In one of these pieces a nut is formed, in which a screw works, its outer end being supported in a bearing on the edge of the front plate, so that on turning the screw round by means of a key applied to its outer end, the slide-piece will be made to traverse to and fro in its mortice. To each slide-piece is attached one end of a straight lever, the other ends of which levers are attached to an equilateral triangular lever, working loosely on the centre boss of the chuck; by this means, on the screw being turned, the slide-pieces will advance or recede simultaneously within their mortices.—*Ibid.*

IMPROVEMENTS IN DETACHING LOCOMOTIVE AND OTHER CARRIAGES.

Francis Pope, of Wolverhampton, Engineer, for improvements in detaching locomotive and other carriages. Enrollment Office, May 24. This invention consists of an ingenious piece of mechanism by which a horse can be instantly detached from the vehicle to which he is attached, or one carriage can be separated from another on railways. When applied to horse carriages, each shaft terminates in two iron side plates carrying a pin which form the axis of the shafts, and is the means by which they are attached to the carriage. There are also two side plates attached to the carriage, carrying a pin which forms the axis of motion to a bent lever or tongue; this tongue when turned back embraces the pin on the end of the shafts, and holds it securely in the recess formed for it. The tongue is held down by a peculiarly formed spring catch, to which a lever is affixed. So long as the tongue is held down by this catch, the shafts are securely held to the carriage, but on pulling the lever the catch is disengaged, the tongue flies over and the shafts and horse are released. When applied to railway carriages three of these attachments are employed, the centre one being a bar corresponding to the end of the shafts in the former case, and the two outer ones being chains. The three catches are simultaneously acted upon by an apparatus terminating in a handle which runs up to the seat of the guard. The claim is to the mode of constructing and applying apparatus as described.—*Mechanics' Magazine.*

CASE-HARDENING IRON.

Robert Roberts, of Bradford, Lancashire, Blacksmith, for a new method or process of case-hardening iron. Enrolled at the Petty Bag Office, May 25. This method consists in heating the iron and plunging it into cast iron in a state of fusion and turning it about, when it will become cased to any required thickness from $\frac{1}{16}$ to $\frac{1}{2}$ an inch, when it is to be plunged into cold water, and will then be found to be effectually case hardened. The claim is to the method or process of case-hardening iron, by coating, covering, or combining wrought iron with cast iron.—*Ibid.*

IMPROVEMENT IN PADDLE-WHEELS.

Henrry Charles Daubeny, Esq., Boulogne-sur-mer, France, for a certain invention or improvement in the making and forming of paddle-wheels, for the use of vessels propelled in the water by steam or other power, and applicable to propel vessels and mills. Enrollment Office, May 25. The floats are mounted on spindles or axes, one end of which work in a box or centre, the others in the circumference of the paddle-wheel. Near the ends of the spindles which works in the box, there are short levers which work against a traverse, so as to expose their broad surface to the water, while they enter and quit it edgeways. By this feathering operation, all the inconveniences arising from back water are obviated. In order to relieve the paddles from the effects of heavy seas, they are provided with an escapement consisting of two or more cogs let into the box of the wheel, and traversing round with it in a groove provided for that purpose in the flanch or carrier, fixed on the end of the main shaft; in this groove there are bridges which cause the cogs in passing them to throw up their front ends, and thus present their hind ends opposite to abutments formed in the face of the carrier, which, coming in contact with the hinder ends of the cogs, turn the paddle-wheel round. In the event of this wheel being struck by a heavy sea, the blow causes it to revolve faster than the carrier, and thereby relieves it from the injurious effects of the concussion. When the force of the sea is expended, the abutments again come in contact with the cogs, and the wheel is driven round by the effects of the engine. A mode of placing paddle-wheels in an inclined position is shown, by which means external projecting paddle-boxes are dispensed with.—*Ibid.*

IMPROVEMENTS IN STOPCOCKS.

Henry Bridge Cowell, of Lower-street, St. Mary's, Islington, Middlesex, ironmonger, for improvements in taps, to be used for or in the manner of stopcocks, for the purpose of drawing off and stopping the flow of fluids. Enrolled June 2, at the Roll's Chapel Office.

The first part of this invention consists in applying a moveable stopper to the spout of a tap, such stopper being suspended at the lower ends of two upright connecting links, one at each side of the spout, which link pass down through holes or sockets in the metal of the head of the tap. The upper ends of these links are connected to a piece of metal or collar, situated above the head, and fitted around a screw that turns in the same, so that on the screw being turned it will either rise or fall, and consequently raise or lower the stopper, thereby opening or shutting the spout of the tap. The fluid which escapes round the sides of the orifice of the spout on the stopper being lowered will be collected in the hollow mouth of the tap, so as to run out in a compact stream from the lower orifice.

The second part of this invention consists in applying to a ball-cock (similar in its parts to the tap just described) a second ball and lever, provided with a click or detent, having a tooth, which catches into a notch or notches cut in the circumference of an enlarged head on the end of the screw before mentioned. The click is mounted on a centre pin fixed in the collar of the screw, so that whenever the other ball descends the tooth catches into one of the notches, and turns back the screw, thereby opening the passage through the cock for the water. The usual ball is kept submerged during the flowing in of the water into the cistern, by means of the click preventing the screw to which it is attached from being turned; but when the surface of the water reaches the second ball, and raises the same upwards, the click will be lifted up about its centre of motion, so as to disengage its tooth from the notch in the head of the screw, whereupon the other ball will immediately rise to the top of the water by its power of floatation, and close the passage of the cock.

The third part of this invention consists of another kind of tap, similar in some respects to the one first described.—The moveable stopper is fitted in the manner of a piston into the cylindrical hollow of the head of the tap, so as to move up and down therein by the action of a screw working in a cap that surmounts the head of the tap; by turning this screw round, the stopper is pressed down on the upper orifice of the water-passage of the spout, and at the same time over the annular orifice of a circular channel formed within the head of the tap, and passing round the water-passage, through which channel the water is conveyed to the passage. Thus on depressing the stopper the flow of water will be stopped, but on raising the same the water will be permitted to flow again.—*Inventors' Advocate.*

PROCEEDINGS OF SCIENTIFIC SOCIETIES.

INSTITUTION OF CIVIL ENGINEERS.

February 23.—William Cubitt, V.P. in the Chair.

The following were balloted for and elected: Colonel Sir Frederick Smith, R.E., William Chadwick, John Bazley White, jun., Charles Lorimer Hensman, Joseph Whitworth, and Evan Hopkins, as Associates.

"*Description of a new mode of Steering, as applied to boats of light draught of water, navigating shallow and rapid rivers.*" By Captain Henderson, Assoc. Inst. C.E.

The ordinary method of steering with a single rudder, fixed in the usual manner, will bring a vessel round in about four times its length, upon an axis at the point of union between the dead wood of the vessel and the rudder. It was found desirable for the particular service on the Ganges and Burhampooter, for which the vessel in question was designed by the Assam Company, that great facility should be given for coming round rapidly; to accomplish this, the stem and stern of the vessel are alike provided with rudders, of a form adapted to the curvature of the craft. The stern rudder is considerably larger than the other, and occupies the space usually allotted to the dead wood, which is cut away; a more immediate influence is thus exerted upon the boat. The rudders are raised or lowered according to the draught of water, by means of capstans fixed upon the projecting ends of the shaft of a pinion, which is geared into a toothed racked of peculiar construction, on the back of each rudder post. The effect of this arrangement is, that the centre of revolution is transferred to a point nearer the centre of the vessel, and deviating from the true centre, in proportion to the relative dimensions, position and figure of the two rudders, and of the lines forward and abaft the vessel, which is thus brought round in little more than its own length.

The vessel, of which a model accompanied the paper, is fitted with condensing engines working expansively, with a pressure of steam of 20 lb. in the boiler; the cylinders are placed at an angle towards the paddle shafts, and act directly upon the cranks without the intervention of side levers.

"*Description of a Coffre Dam used in excavating Rock from the navigable Channel of the river Ribble.*" By David Stevenson.

The navigation of the river Ribble being much impeded by natural bars or weirs of sandstone rock, compact gravel, or loose sand, several ineffectual attempts were made to remove these hindrances, and eventually a joint stock company, called the Ribble Navigation Company, was formed for that purpose. Messrs. Robert Stevenson and Sons (of Edinburgh) were consulted, and under their directions the present works were commenced: their plan was to cut a channel in the rock wherever it was necessary, and to remove the gravel and sand by steam dredging, forming at the same time a low rubble wall upwards of a mile in length, for the purpose of directing the course of the river so as to obtain a permanent and straight navigable track for the shipping. The first of these operations is alone treated of in the communication.

About half a mile below Preston, a bed of sandstone rock, upwards of 300 yards in length, stretches quite across the river; some portions are entirely free from any deposit of sand or mud, and the higher parts are frequently left dry during the summer months. This natural weir exerts such an influence upon the flow of the tides, that neap tides which at 12 miles distance rise 14 feet, are not at all perceived at the quay at Preston.

It was proposed to cut a channel through this bar, 100 feet in breadth, affording an average navigable depth of 20 feet at high water of spring tides. In some places, therefore, the excavation would be 13 ft. 6 in. deep. After much consideration it was determined to make use of a series of coffre dams, as the most effectual and economical mode of proceeding. Their construction may be thus briefly described:—

A double row of wrought-iron bars, 2½ inches diameter, with *jumper* points worked upon them, were inserted vertically into the rock at regular intervals of 3 feet apart laterally, the second row being placed 3 feet behind the front row. When a sufficient number of bars were fixed, a tier of planking, 3 inches thick, with clasps to enable the planks to be fixed to the rods, was placed withinside. The lower edges of the planks were cut out roughly to the inequalities of the rock; they were then lowered, and by means of an iron rod, with a crooked end, those parts which did not touch the bottom were ascertained, and a change in the form made, until the plank rested its whole length on the rock: the lower edge was then bevelled off, and being finally lowered to its place, the plank was beaten down by the force of a heavy mallet, upon an upright piece of wood resting upon the upper edge of the planks; the lower bevelled edge yielding to the blows, sunk into the irregularities of the rock, and thus ultimately, in connexion with the puddle behind it, formed a perfectly water-tight joint. The lower planks being fixed, the upper ones were placed upon them; transverse tie bars were inserted at intervals; and the clay puddle was formed in the usual manner. In order that the navigation of the river should not be impeded, the diagonal stays were all placed inside the dams. These stays had joints at the upper ends, and being slipped over the tops of the iron rods, and kept in their places by cotters, their lower ends could be moved either horizontally or vertically, as the irregularity of the rock required:—as the excavation proceeded, longer stays were easily substituted, by merely removing the cotter, sliding up the short stay, and replacing it by another suited to the increased depth. The sides of the dam were kept together by bars of iron connected to two horizontal wale pieces, 10 inches by 6 inches, placed on the outside of the vertical iron rods. When the dam was thus constructed, the water was pumped out by a steam engine of 10 horses power, with two pumps of 12 inches diameter.

The whole of the excavation, which was 300 yards in length, and 100 feet in width, was to be completed with three lengths of coffre dams, so contrived as to include within the second stretch the lower side of the first dam, in order to excavate the rock in which that row of piles was fixed. The first and second lengths have been most successfully executed; the third is now in progress, and the excavation is proceeding very rapidly. The sandstone rock does not require gunpowder. The total quantity to be excavated is estimated at 31,000 cubic yards; all the stone which is raised is used in the construction of the wall for directing the course of the lower part of the river.

Some doubt existed in the mind of the engineer as to the security of the fastening of the iron rod piles by merely jumping them from 15 to 18 inches into the rock; they have, however, proved to be perfectly firm during heavy floods, when the whole dam has been submerged, and the velocity of the current which was rushing over it was not less than five miles per hour.

This paper was accompanied by two drawings, showing the general arrangement of the work, as well as the details of the construction of the coffre dam.

March 2.—The President in the Chair.

The following were balloted for and elected: Peter Hogg, Henry Oliver Robinson, Thomas Oldham, Edward Jones Biven, and Robert Ransome, as Associates.

"*On a new form of Railway Chairs and improved Fastenings.*" By Charles May, Assoc. Inst. C.E.

At the suggestion of Mr. Cubitt, V.P., a series of experiments was instituted at the works of Messrs. J. R. & A. Ransome, of Ipswich, for the purpose of determining the most advantageous form of the chairs, and most secure mode of fastening them upon the sleepers of the South Eastern Railway. The result of these experiments has been to produce the cast iron chairs, and wooden treenails as fastenings, which were exhibited at the meeting, and described by the author.

In the event of a chair breaking, it is desirable that the fracture should occur in such a manner as to prevent any of the loose pieces being thrown into situations where they would interfere with the passing trains; to ensure this, the weakest part of these chairs is across the seat—they are, however, stronger in that part than any other chair now in use. In order to ascertain the proper relative proportion between the strength of the jaw and that of the seat, many experiments were made by varying the forms, and wedging the chairs, until they broke, sometimes in one and at other times in the other part; it was then easy to add so much strength to the jaw as would, without waste of metal, cause the fracture to take place invariably across the seat.

For the purpose of ensuring perfect accuracy of form, with a smooth internal surface, so that wedges of a uniform shape and size might be used, the chairs are cast upon metal cores: the joint-chair has an upper piece, overlapping the wedge, to keep the rail in a perpendicular position, and to prevent the end of it from being thrown up or forced away laterally, if the wedge should accidentally be removed. This form of chair was originally planned by Mr. John Harris, the engineer of the Stockton and Darlington railway, where it has been in use above twelve months, giving perfect satisfaction. The rail is so placed in the intermediate chairs, that when it receives the pressure of the wedge, it is held firmly down on the seat, against the lower part of the jaw, and at the upper part against a slightly projecting rib, which bears against the neck of the rail.

The holes for the fastenings are so arranged as not to be in the same line; a large portion of the current expense of the maintenance of way on railroads arising from replacing the sleepers which have been split by the spikes being driven in the same line in the grain of the wood.

The mode of fastening adopted in this case is, to use treenails of dry English oak, compressed into two-thirds of their original bulk, by being forced under a fly press, into metal tubes, in which they are placed in a chamber heated to about 180°, where they remain 16 hours: the pressure upon the body of the treenail (the head not being compressed) is sufficient to materially increase the specific gravity without injuring the fibre, or diminishing the strength of the wood, and it retains the form thus given until it has been driven into a damp sleeper, when the expansion is sufficient to fix it firmly.

The ordinary mode of fastening chairs with iron spikes has been found disadvantageous, because one blow too many causes a reaction, and frequently loosens them, whilst treenails may be driven to any depth, and the heads subsequently split with small wedges if necessary.

Rails should be 'keyed-up' so tightly as to ensure security, still leaving a large amount of surplus strength in the chair to resist any shock to which they may be exposed:—with wedges of varying dimensions, the chairs, which are frequently of unequal quality, and carelessly cast, are liable to be brought nearly to the breaking point, and to give way as soon as they are subjected to any additional strain. This has been avoided in the chairs and wedges under consideration, by giving them exact uniformity of dimensions.

The wedges adopted are of English oak, cut out of square timber, so formed as to drive equally well with either side to the rail, and compressed into five-sixths of their bulk, by the same process as is used for the treenails.

Many advantages will result from this form of chair and wedge, with the treenails for fastening; the time occupied in laying the rails is diminished; the holes for the fastenings may be bored in the sleepers by machinery, at a diminished cost, and greater accuracy of gauge obtained at the same time; the required inclination of the rail being given in the chair, no cutting away of the sleeper is necessary; the sole of the chair is fixed horizontally upon the surface of the sleeper, and all of them may be placed accurately in the same plane, thus bringing to bear upon the hitherto roughly executed details of railway engineering, those mechanical contrivances by which the cost is diminished, whilst the dependance upon the skill and attention of the workmen is avoided; at the same time insuring the accuracy of the line, upon which so large a portion of the economy of working a railway depends.

Specimens of the chairs, wedges, and treenails, accompanied this communication.

Mr. Cubitt observed, that two modes of preparing treenails had been hitherto adopted: one was, by forcing the wood through a steel die, in which case neither the form nor the diminished bulk was preserved, as on leaving the die it swelled nearly to its original size. The other was by passing the wood between rollers: this latter process had been found to cause permanent injury to the fibre of the wood, by crushing the capillary tubes, and consequently depriving it of much of its strength. To the mode of preparing the treenails under consideration, neither of these objections existed. He anticipated many advantages from the use of this form of chair, wedge, and fastening. They would certainly be cheaper even in the first cost than the ordinary chairs, fastened down by iron spikes. The usual calculation for a double line of rail was 880*l.* per mile for the chairs, wedges, and spikes. The cost of these chairs, with the compressed wedges and treenails, would be 786*l.* per mile. The price of the compressed treenails for railway purposes would be 5*l.* 10*s.* per thousand; that of iron spikes was 6*l.* 5*s.* per thousand. The wedges 2¼ inches square, cost 2*l.* per thousand for each inch of their length, so that those for the joint-chairs, which are 8 inches long, average 16*l.*, and those for the intermediate chairs, of 6 inches long, cost about 12*l.* per thousand. Each joint-chair, with wedge and treenails, costs 2*s.* 10*d.*; and the intermediate ones, with their appendages, 2*s.* 1*d.* each.

One great cause of expense on railways was the fracture of the chairs during the laying. He knew an instance where in a length of 20 miles of railway 180 tons of chairs had been broken, either by wedging or in driving down the spikes. This was in the ratio of one chair in ten. In the ordinary mode the oak wedges are driven home by a 14 lb. sledge hammer, whereas with the new chair the compressed wedges and treenails are driven by a light wooden mallet.

Mr. Pim remarked that the wood fastenings used for the chairs on the Dublin and Kingston Railway had been compressed by rolling. He considered the present plan much superior.

Mr. Vignoles corroborated the statement of the cost of chairs of the ordinary construction. On the railways of the north of England oak treenails had been used as fastenings for a considerable period. The plan now proposed presented many advantages, not only in the construction of the chairs, which appeared well designed and excellently cast, but in the form and mode of preparation of both the wedges and the treenails.

In answer to a question from the President, whether the compressed treenails could be applied with advantage in ship building—Mr. Mills was of opinion they could be so employed, provided the fibre was not injured by the process. He believed that sound wooden treenails were better fastenings for ships than iron bolts, and quite as good as copper, whilst by their use the expense was materially reduced. Turned treenails of locust wood were at present preferred to all other kinds.

Mr. S. Seaward understood that, at the Royal Dockyards, treenails which were crooked as much as three times their own diameter were preferred to straight ones. He believed that the late Mr. H. Maudslay had constructed some machinery expressly for turning them crooked.

Mr. Hawkins remarked that the treenails were frequently crooked, because the rending caused them to follow the direction of the grain of the timber. Twenty-two years since, Mr. Annesley took out a patent for building ships without ribs. He used for fastenings, treenails compressed by being forced through steel dies, just before driving them into the planks, so that their expansion fixed them firmly in the planking. He built a vessel of very light construction, the sides of which were formed of five thicknesses of ¾-inch boards, held together by compressed treenails, without any ribs. It had proved very stiff and durable.

In reply to a question from Mr. Vignoles, whether the swelling of the compressed treenails in the ribs would not have the effect of preventing the possibility of the "butt end" of a plank starting—Mr. Mills believed that such an event was of rare occurrence; treenails were subjected more to a lateral strain; they were frequently "backed out" after the planks had been fitted into their places; when the latter were properly bent they retained their shape, and had no tendency to spring out.

Mr. S. Seaward, in support of the opinion that leaks did occur from planks starting, instanced the "Marquis of Huntly," East Indiaman, which was injured in the Downs, by a collision with another vessel; she proceeded on her way to China, but during the whole voyage out and home forty extra men were employed at the pumps. On being taken into dock, it was found that the "butt end" of one of the bow planks had started for 8 or 9 feet in length, and nothing but constant labour and attention had kept the ship afloat, at an expense of 7,000*l.* to the owners.

March 9.—The PRESIDENT in the Chair.

The following were balloted for and duly elected: Joel Spiller, as a Member; John Pope, as a Graduate; Thomas Routledge and Frederick Taylor, as Associates.

"*Description of a Bridge for a Railway crossing above a Turnpike Road, where the depth between the soffit of the Bridge and the surface of the Rails is limited, to twenty-one inches.*" By John Pope, Grad. Inst. C.E.

This bridge was designed by Mr. W. Cubitt, V.P., to meet the conditions of a clause in a Railway Bill, which required that there should be a clear width of opening for headway through the bridge in every part, 30 feet wide by 20 feet high, whilst at the same time the height of the embankment limited the space between the under side of the bridge and the surface of the rails to 21 inches.

The railway is carried on three cast iron girders, each 3 feet deep at the centre, diminishing to 6 inches at each end, with a bearing of 2 feet on cast iron wall-plates, supported by brickwork abutments. The flanches of the girders are 8 inches wide, and the metal every where 2 inches thick. Balks of Memel timber, 12 inches square, are laid transversely, close jointed, their ends bearing upon the flanches of the girders: on these timbers the chairs are fixed, and the rails are laid. The whole depth employed is—

The flanch of the girder	- -	2 inches
Thickness of timber balks	- - -	12 „
Depth of the rail and chair	- -	6½ „
		20½

One of the girders on each side supports the parapet wall in which it is completely encased, and being faced with cut stone, assumes the appearance of a flat camber arch, 3 feet in depth.

A detailed drawing, showing minutely the construction, accompanied this communication.

ARCHITECTURAL SOCIETY.

Conversazioné held Tuesday evening, the 1st of June, 1841, William Tite, Esq., President in the Chair.

After the report of the proceedings of the Society during the session was read, the President delivered a very interesting lecture, "*On the researches made in Egypt, at the expense and under the authority of the Tuscan Government.*" By Signor Rosillini. The lecture was illustrated by a variety of drawings, models, and valuable engravings, which very considerably enhanced its interest.

At the completion of the lecture the President announced the agreeable duty which he had to perform, in the distribution of the prizes which had been awarded by the Society for competition during the past session; at the same time he expressed his regret that the students had not been more active in the other classes of competition, and stated that although prizes had been offered by the Society for competition in the class of original design, in the class of measured drawings from a public building, and also for the best fairly transcribed notes of the Professor's lectures, yet it became his painful duty to state that no competition whatever had been attempted in either of these classes; neither was there any competition for the prize offered for the best drawing of the human figure from a plaster cast in the possession of the Society. Having made these observations, the President proceeded to the distribution of the two prizes which had been awarded, viz., to Mr. Arthur Johnson, for the greatest number of the most approved sketches from subjects given by the Architectural Society during the session 1840 and 1841; and to Mr. Frederick Johnstone, for having produced the best drawing from a plaster cast in the possession of the Architectural Society, session 1840 and 1841. The President called the attention of the meeting to some specimens of a patent which had been obtained for uniting lead and other metals without solder, which he was of opinion was worth the consideration of persons connected with building. He then announced that the business of the meeting, and of the session was concluded, and in so doing directed the attention of the visitors and other gentlemen present to the various specimens of art contributed for the evening's entertainment; among which was a very beautiful drawing, being a representation of the shield to be presented to Lord Eglinton, in commemoration of the late tournament held under his superintendance, both the design and drawing were by Mr. Henry Nixon. Also a newly invented ball-cock patented by Mr. Henry Abraham, the architect; likewise a cast in bronze of an elaborately chased Roman vase, together with sundry specimens of Roman tesselated pavement.

There was also exhibited a very beautiful model in plaster of Mr. Tite's (the President) portico of the New Royal Exchange, as approved and decided by the Gresham Committee, to be erected—it elicited considerable praise and attraction. There was another model of the New Church now erecting at Muswell Hill, under the direction of William Barnes, Esq. Also sundry models by Mr. Samuel Nixon, as well as numerous drawings by Henry Nixon, Clayton, G. B. Moore, Punnett, Meredith, William Barnes, G. Mair, William Grellier, William Nunn, &c. &c. The meeting was numerously attended, and was favoured by the presence of many of the leading and most scientific men of the day.

ROYAL INSTITUTE OF BRITISH ARCHITECTS.

June 7.—A paper was read by the Rev. R. Burgess, Hon. Member, on the Roman temples. Mr. Burgess traced, in a most interesting and entertaining narrative, the history of the temples of antiquity, from the rays encircling the heads of the heathen deities, originally applied as a protection to the heads of their statues, and the niches in which they were subsequently ensconced, down to the gorgeous edifices of the Roman empire.

June 21.—Mr. T. L. Donaldson, Fellow, read a description of the column erected at Petersburg in honour of the late Emperor Alexander. The construction of this monument rivals that of the best ages of antiquity. The shaft is monolithic, of polished granite, 84 feet in length. The pedestal is also a single block of the same material, and so carefully has the durability of the work been considered, that two vast masses were successively rejected after they had been extricated from the quarry as not being sufficiently perfect. Possessed as we are in Great Britain of granite quarries capable of supplying stones of almost unlimited dimensions, it is to be regretted that such an example should be lost upon the directors of our public works. Unfortunately the example is likely to excite nothing but feelings of horror and contempt for so outrageous a dereliction of the principles of economy!

A paper was afterwards read on the open roofs of the middle ages, by T. Morris, Esq.,—many examples were exhibited and described. It appeared to be the general opinion of the meeting, that the scientific skill displayed in these beautiful and picturesque combinations of timber work has been greatly over-rated. Some have signally failed, as at Eltham, while in others, as at Westminster Hall, the principle resolves itself, on examination, into the simplest elements of roofing. The durability of these structures seems rather due to the mechanical construction of the carpentry, in which they are worthy of the greatest admiration.

MESSRS. COOKE AND WHEATSTONE'S ELECTRIC TELEGRAPH.

(From the Railway Times.)

We have given many occasional notices of this admirable invention—of its adoption on the Great Western and Blackwall Railways, and its surprising performances in both instances—but it still remains to us to lay before our readers such a detailed account of the apparatus as may enable them to comprehend fully the mode of its operation, and to estimate duly its great practical efficiency. We cannot help thinking that it must be owing in a great measure to a prevailing paucity of information on the subject of the invention, that it is not making its way more rapidly into use, and believe we shall render good service to the railway interest by doing our best to make its value more clearly, distinctly and generally known. For the following descriptive details, and the numerous engravings by which they are illustrated, we are indebted partly to the evidence given by Professor Wheatstone before the Select Committee of the House of Commons on Railways, and partly to a set of drawings with explanatory letter-press recently published by the Professor's managing partner in the invention, Mr. Cooke. Some doubts it will be recollected were raised respecting the proportions in which Messrs. Wheatstone and Cooke divided between them the merit of the invention; but these doubts have been for ever removed by the statement on the subject which we published three or four weeks ago, drawn up at the mutual request, and (we believe) to the satisfaction, of these gentlemen, by their friends Sir I. Brunel and Professor Daniell.

Professor Wheatstone having been requested by the Committee of the House of Commons to explain to them the mode in which he proposed to communicate intelligence between two distant points, made the following answer:—

I have here a copy of the drawing of the specification to the first patent taken out by myself and Mr. Cooke; in all essential particulars, the instrument here represented resembles the one at the Great Western Railway. Here is what may be called a dial (see Fig. 1,) with five vertical magnetic needles. Upon this dial 20 letters of the alphabet are marked, and the various letters are indicated by the mutual convergence of two needles when they are caused to move; if the first needle turns to the right and the second to the left, H is indicated. If the first needle deviate to the right, and the fourth to the left, then B is indicated; if the same needles converge downwards, then V is pointed to. These magnetic needles are acted upon by electrical currents, passing through coils of wire placed immediately behind them; here is the representation of one of those coils, with the position of the magnetic needle with respect to it (Fig. 6). Each of the coils forms a portion of a communicating wire, which may extend to any distance whatever; these wires, at their termination, are connected with an apparatus, which may be called a communicator, (Fig. 1,) because by means of it the signals are communicated; it consists of five longitudinal and two transverse metal bars, fixed in a wooden frame; the latter are united to the two poles of a voltaic battery, and, in the ordinary condition of the instrument, have no metallic communication with the longitudinal bars, which are each immediately connected with a different wire of the line; on each of these longitudinal bars two stops are placed, forming together two parallel rows. When a stop of the upper row is pressed down, the bar upon which it is placed forms a metallic communication with the transverse bar below it, which is connected with one of the poles of the battery; and when one of the stops of the lower row is touched, another of the longitudinal bars forms a metallic communication with the other pole of the voltaic battery, and the current flows through the two wires connected with the longitudinal bars, to whatever distance they may be extended, passing up one and down the other, provided they be connected together at their opposite extremities, and affecting magnetic needles placed before the coils which are interposed in the circuit, there must be a similar complete apparatus at every different station.

"There is another very essential part of the apparatus I wish to mention, which is, the means we have of ringing a bell before the communication begins, in order to call the attention of the observer. The general principle of the alarum is this; to the detent of an alarum, on the ordinary construction of a clock alarum, a piece of soft iron is fixed, and opposite to it there is a bar of soft iron bent to the form of a horse-shoe; round this bent bar, wire, covered with silk, is wound, forming numerous coils; it is a property of soft iron to become powerfully magnetic when an electric current passes through a coil thus surrounding it. When the horse-shoe bar thus becomes magnetic, it therefore attracts the detent, and the bell immediately rings; when the current ceases the magnetic power ceases also, and the bell

Fig. 1.—Original Electric Telegraph.

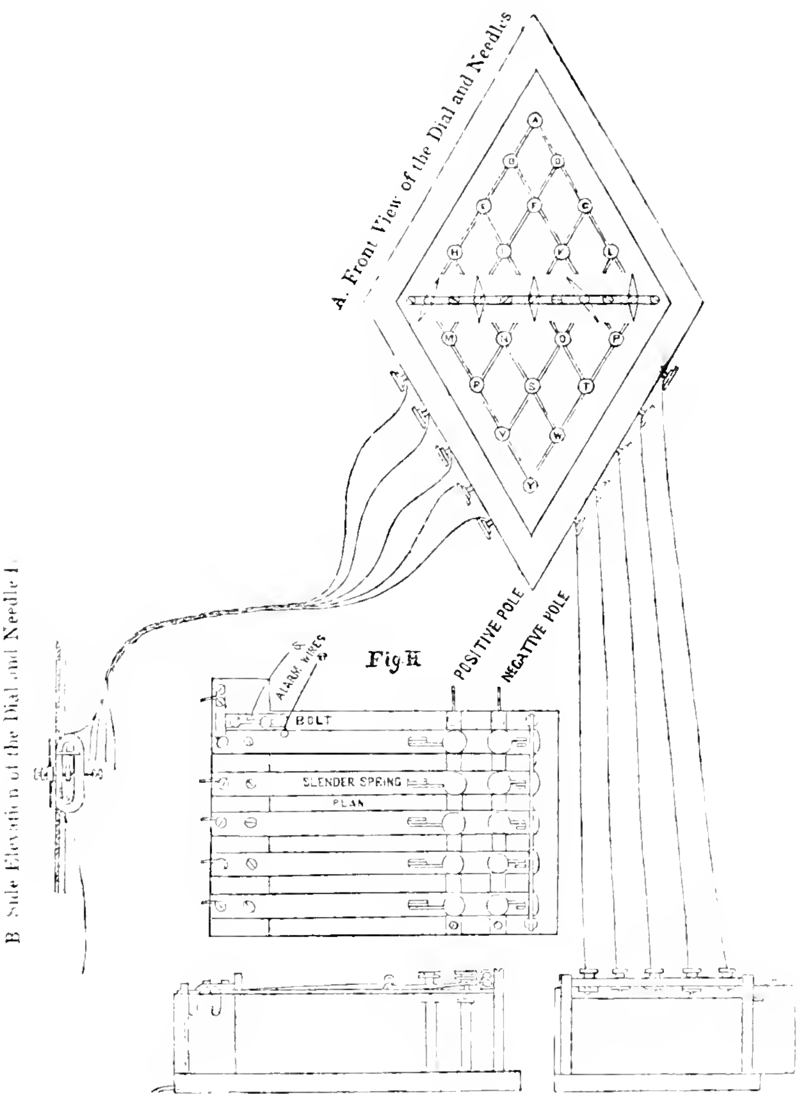

Fig. 2, Perspective view of a Tunnel

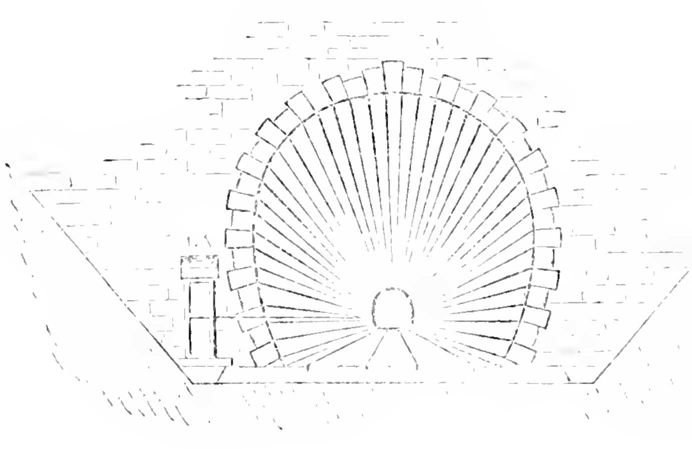

discontinues to ring. There are several other contrivances made to effect this purpose. Some other arrangements there are to which Mr. Cooke has particularly directed his attention, relating to the means of establishing communications at intermediate parts of the line where no fixed stations exist. To effect this, posts are placed at every quarter of a mile along the line, for the purpose of establishing a temporary communication with either of the adjacent stations; the guard of a train may thus carry with him a portable instrument, by means of which he can send up a message to a station either way, whenever it may be required. The wires are kept insulated from each other by a mixture of cotton and india rubber, which is a very good insulating material; then these prepared wires are all passed, with certain precautions, through an iron tube, which in some parts of the line is buried beneath the ground, and in other parts of the line is raised above it."

Lord Granville Somerset put this case:—"Suppose the Great Western Railway were completed between London and Bristol, do you contemplate the possibility of carrying your telegraph through the whole way, so as to signify from London to Bristol any thing you wish to communicate, and *vice versa* from Bristol to London?"—Professor Wheatstone replied, "The experiment has not been tried, but I have every reason to believe that it can be done. One very important circumstance I have ascertained is the little power requisite to produce this effect; it was formerly thought, that to send a current to any considerable extent very strong batteries must be employed, but in fact a very weak battery is sufficient, provided only it consist of a number of elements proportionate to the distance. So far as my experiments have gone, I think I should be able to effect a telegraphic communication between Bristol and London. Possibly several stations might be required, but, at any rate, the stations may be at far greater distances from each other than would be required for any ordinary system of telegraphs; my opinion is, that the intermediate stations will not be required."

Mr. Loch asked whether there was any appreciable loss of time in making a communication from the Paddington station to the extremity of the line to which the telegraph is now carried? Professor Wheatstone: "From some experiments I made some years ago, published in the *Philosophical Transactions*, when I first turned my attention to the possibility of effecting telegraphic communications, I ascertained that electricity travelled through a copper wire at the rate of about 200,000 miles in a second; consequently there is no appreciable time lost in the communication of the electrical effect; the only time that would be lost would be at relay stations, if they were necessary."

Chairman: "Could you communicate from Dover to Calais in that way?—I think it perfectly practicable."

Professor W. added the following observations:

"An electrical telegraph offers a great many advantages over an ordinary telegraph; it will work day and night, but an ordinary telegraph will act only during day; it will also work in all states of weather, an ordinary telegraph can only work in fine weather. There are a great number of days in the year in which no communication can be given by an ordinary telegraph, and besides, a great many communications are stopped before they can be finished, on account of changes in the state of the atmosphere. No inconveniences of this kind would attend the electrical telegraph. Another advantage is, that the expense of the separate stations is by no means comparable to that of the ordinary telegraph; no look-out men are required, and the apparatus may be worked in any room where there are persons to attend to it. There is another advantage the electric possesses over the ordinary telegraph, viz. the rapidity with which the signals may be made to follow each other. Thirty signals may be conveniently made in a minute; that number cannot be made by the ordinary telegraph. There is one thing I will take the opportunity to mention—I have been confining the attention of the Committee to the telegraph now working on the Great Western Railway, but having lately occupied myself in carrying into effect numerous improvements which have suggested themselves to me, I have, conjointly with Mr. Cooke, who has turned his attention greatly to the same subject, obtained a new patent for a telegraphic arrangement, which I think will present very great advantages over that which at present exists. It can be applied without entailing any additional expense of consequence to the line now laid down, it will only be necessary to substitute the new for the former instruments. This new apparatus requires only a single pair of wires to effect all which the present one does with five, so that three independent telegraphs may be immediately placed on the line of the Great Western; it presents in the same place all the letters of the alphabet according to any order of succession, and the apparatus is so extremely simple, that any person, without any previous acquaintance with it, can send a communication and read the answer."

Fig. 3, Longitudinal view of a Tunnel.

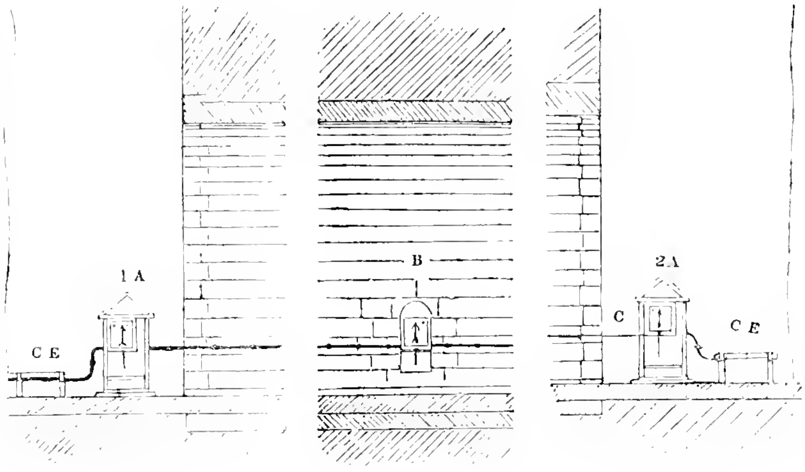

Fig. 4.—Application of the Telegraph to Crossings, &c.

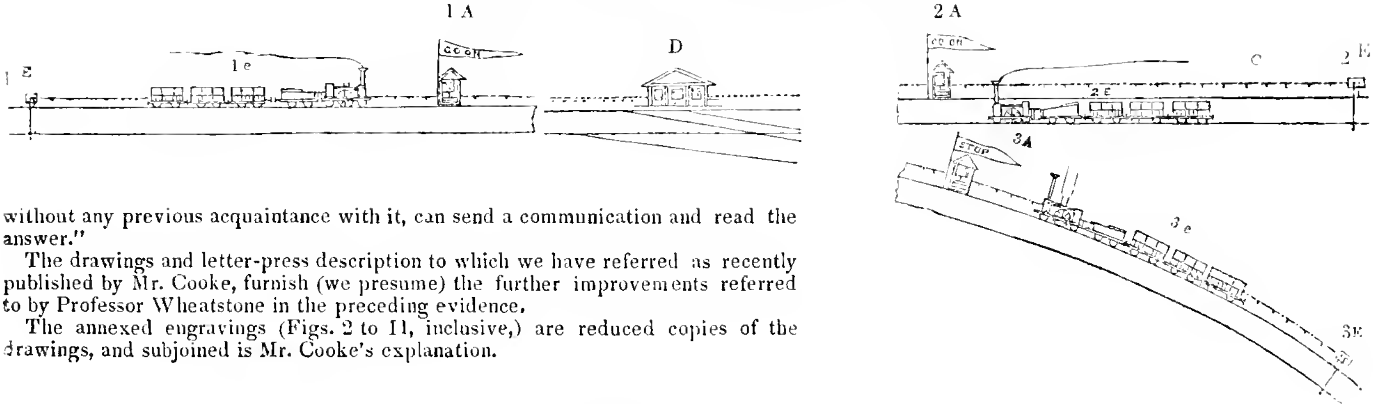
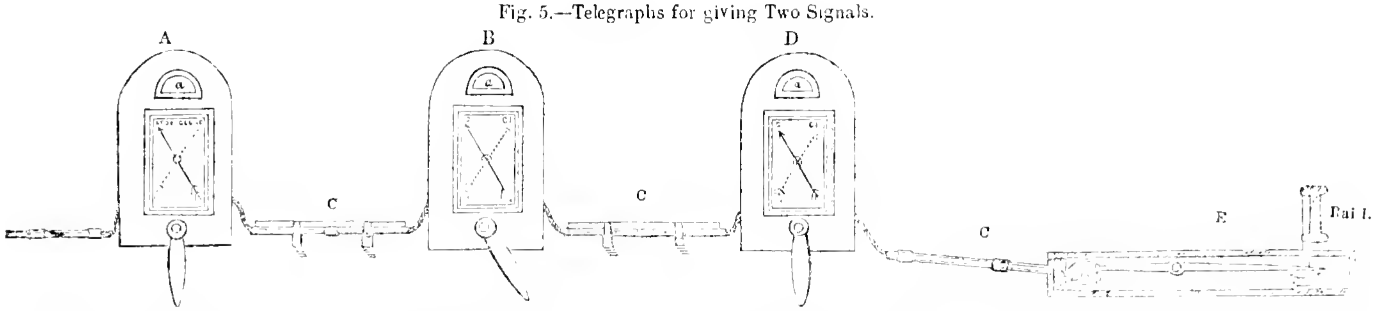


The drawings and letter-press description to which we have referred as recently published by Mr. Cooke, furnish (we presume) the further improvements referred to by Professor Wheatstone in the preceding evidence.

The annexed engravings (Figs. 2 to 11, inclusive,) are reduced copies of the drawings, and subjoined is Mr. Cooke's explanation.

Fig. 5.—Telegraphs for giving Two Signals.



Figs. 2 and 3 show the application of the electric telegraph to tunnels.

1 A, 2 A. Telegraphs fixed in policemen's boxes near the entrances of tunnels.

B. Intermediate telegraph near a shaft within a tunnel, always ready to work with 1 A, 2 A, in case of need.

C. Protecting tube for conducting wires.

C E, C E. Tube leading to engine-warner; *vide* Figs. 4 and 5 with explanation.

Fig. 4. Application of the electric telegraph to level crossings, approaches to stations, and switches, &c.

1 A, 2 A, 3 A. Telegraphs fixed in policemen's boxes, one or two miles from a level crossing or station.

C. Protecting tube for the conducting of telegraph wires, either carried on posts with a railing over it or under ground.

D. Telegraphs at stations or level crossings, corresponding with 1 A, 2 A, 3 A.

1 E, 2 E, 3 E. "Engine-warners," (for details *vide* Figs. 5, 6, 7 and 8,) by which an engine gives notice of its approach, at the distance of one or two miles, both to A and D, Fig. 5. If the station or crossing be clear, D replies to the policeman at A to allow the train to "Go on," or else to "Stop," according to circumstances; the engine-man never venturing to pass A till the policeman has given the signal to "Go on." This will ensure the watchfulness of the policeman; but even in case of his absence, the conductor would inquire by the telegraph A for permission from D to proceed. In the figure, the policemen at 1 A, 2 A, Fig. 4, have received permission from D (as is indicated by the pointing of the handles of the telegraphs at D, corresponding with the indications on the telegraph both at D and 1 A, 2 A,) to allow their respective trains to proceed. The policeman notifies in the usual manner, by the white flag, or signal that the line is clear. The train 3 e had been stopped by the policeman at 3 A, in obedience to a signal from the station D, in reply to the "warning" given by the engine of its approach from 3 E.

N.B.—The signal given from the "engine-warner" E, at A and D, is "Stop," accompanied by the ringing of an alarum. This signal remains till answered from D.

Fig. 5.—Telegraphs for giving two signals, as represented above at A, B, and D, each having an alarum (a), which sounds when a signal is given either from E, D, A, or B.

Thirty-one telegraphs, giving two such signals, are working from eight in the morning till ten at night, on the Blackwall Railway, between the stations and the termini, to direct the working of the fixed engines.

E represents the details of the "engine-warner."

An upright bolt passes through one rail of the "approaching" line of road, the upper end rising slightly above the rail, so as to be depressed by an engine-wheel, or other very heavy body passing over it. The lower end of the

Terminal Telegraphs.

Fig. 6

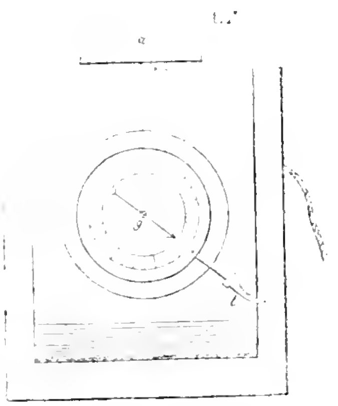


Fig. 7

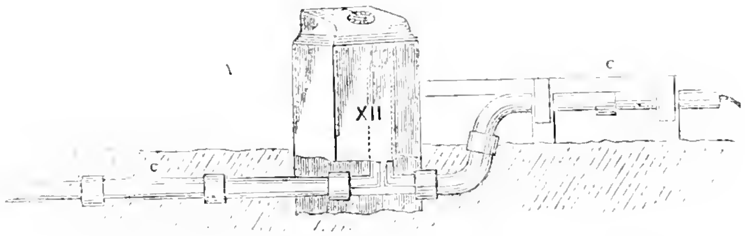
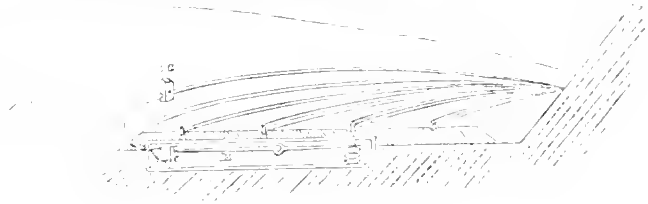
Fig. 8. An Intermediate and Portable Telegraph.





Section of Railway.

Fig. 10. The Electric Detector, for detecting injury caused to the wires, &c.

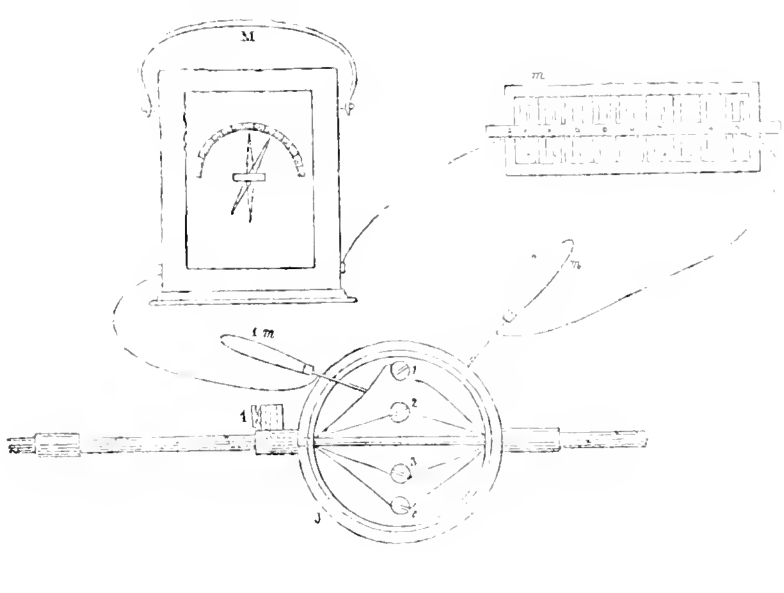


Fig. 9. Telegraph of a simple form.

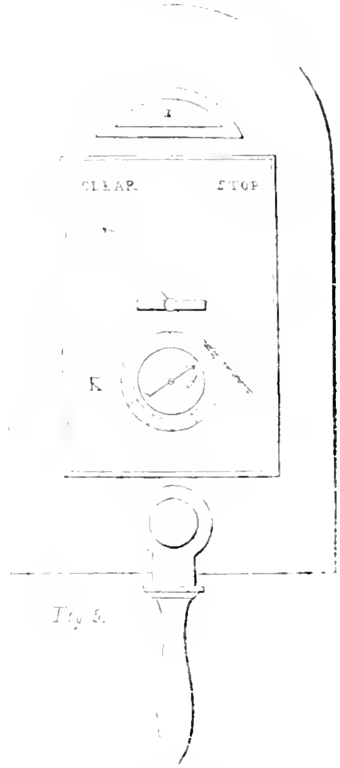

bolt rests upon the arm of a lever supported by a spring capable of offering a resistance equal to at least half the pressure of one wheel of a carriage.

Upon a train passing, one arm of the lever is depressed, which, raising the other arm, breaks the electric circuit at e, and causes the alarum to be sounded and the warning signal to be given at A and D; the other wheels of the train produce no further effect till the warning has been replied to from D, which at the same time restores the electric circuit of the "warner" for another signal. Though the "warner" might be let off by mischievous persons with a crowbar, no inconvenience would be occasioned beyond arousing the expectation of the policeman for the time occupied by a train in passing the space between E and A, when the fact would be discovered, and reported by a signal to D. The object of the "warner" may obviously be attained by a variety of simple mechanical means.

Figs. 6 and 7.—Terminal telegraphs, for more extensive communications than those already described, giving 30 or 60 signals by the pointing of a revolving index-hand at letters on a fixed dial, as in a common clock; the person giving the signal turns the concentric hand *t*, till its pointer stands opposite the signal to be given, as shown in Fig. 6, when instantaneously, the index hand *g* in all the corresponding telegraphs in the circuit, viz. Figs. 6, 7, 8, &c. point at the same signal. Fig. 8 is an intermediate and portable telegraph, to be carried with each train, and applied, in case of need, to convenient arrangements at each mile-post or bridge along the line. The section of a railway below Fig. 8 illustrates this subject. An iron cap to the mile-post being unlocked and taken off, the portable telegraph is placed within a ledge fitted to receive it, making thereby the necessary connexions with the conducting wires, when it is at once fit for working with the "terminal telegraphs." This form of telegraph can be worked by any person at first sight, and requires no battery to be carried with it. It is fitted up with a water-proof cover and lantern, for rainy weather and night use.

N.B.—All forms of this electric telegraph are "reciprocal" in their action *i. e.* they give the same signals, in the working as in the recipient apparatus, and work equally from either end or from intermediate points.

Fig. 9 represents a very simple form of telegraph, on exactly the same principles as Figs. 5, 6, and 7, but combining the powers of both; the arrow giving two signals, for the purposes explained when applied to tunnels, level crossings, &c., and the small index K being adapted for a more extensive communication, when circumstances require it.

am prepared to support Mr. Cubitt's opinion of the effect of the weirs. I do not give any opinion of the proper mode of dealing with the peculiarities of the river Severn. I form my opinion on general scientific principles—that the effects described, by Mr. Cubitt will take place. I am now constructing sea walls where there will be a weir, but I have never constructed one across a river. The present weirs are of great length. I have heard of the mode in which it is proposed to construct them. I see no use for a foot frame in the present case. I think it will stand, as the stones are to be dropped in. I do not think the water will have any effect upon the stone so deposited. The pressure is removed to a great extent by the sheet piling. The water will go over the top of the sheet piling, and find its way through the stone works. It will perforate in a gentle manner, and not disturb the stone work. In flood there will be no fall at all, because it will be the same height above as below. I don't think I ever saw a large weir of this kind: I have seen small ones in canals, and I can apply the effect produced in other places to the present case. Many weirs in this country and others are formed simply by loose rubble stone. The finest I ever saw, which is on the Boyne, is so constructed. A weir of this description is made water-tight by the sheet piling above it. If it should slip I should pack it again with fresh stone; it would be little expense. I am getting packing done now at 6d. per yard for labour. The former stone would be available. I am aware of the object of putting the weirs across the river; it is for the purpose of getting a higher level above. It is placed obliquely, to afford greater facility for the passage of flood water. I am of opinion that it would. I have myself proposed it. It is now being done in the river Shannon. I am not engaged there, but I have made many experiments on the subject. When the weir is placed right across the river it diminishes the water way by the whole superficial area of the weir. It is the same when it is placed obliquely, until the water flows over. As soon as the water rises over the weir the circumstances are altered, and there would be less obstruction, in proportion to the length of the weir, when it is placed at right angles. The summer water would be at the same level, above and below, in either case. In time of floods the water comes down at all points of the weir at equal depth. It would always do so with an oblique, but not with a right angled one. I don't see any reason why, in an oblique weir, the water should make to the lower angle; it would pass down parallel with the axis of the river, or to the banks, if the banks are parallel. That is my deliberate opinion. This principle may be applied in all cases of flood. The water will not fall in the same manner, but will take the shortest line. If the water is rapid it will form an acute angle at the crown of the weir. I don't think water a foot deep will fall in this way. If you want to double the capacity of the weir you should more than double its length. If you did so with a weir directly across, you must widen the river.

Mr. Cubitt explained, that wherever he proposed to put a weir, if the river was not wider at that part than above and below, he proposed to widen the river at that part for the whole extent of the weir, to an extent at least equal to the cross section of the weir; the consequence of which would be, if they took the cross sections, the channel would amount to the sectional area, at least, to the section of the river above and below.

Mr. Mc'Neil's examination, resumed.—I have made experiments as to carrying a double quantity of water over a weir. I simply speak of the quantity passing over, not of its approach. Not knowing the river, I can say nothing about the dredging.

By Serjeant Wrangham.—I do not know how much it is intended by the Upton weir to pen up the water at the tail of the weir above. Whatever height of water is penned back above the present summer level at half a mile above Upton weir, will be so much abstracted from the water-way of the river. When the current passes over the weir, it will pass at a higher level than before the weir was there, by very nearly the depth of the water penned back by it, added to the depth of the column of water passing over the weir. In cases of flood the section of water-way for carrying off the flood will not be diminished to the extent of the water penned back, because the dam below is at the same time increasing in height, until it comes to the same level, when the weir becomes no weir at all. Supposing the water to be penned back within a few feet of the top of the bank, the river above being contracted, all the water that can pass will pass over the weir.

Re-examined by Mr. Serjeant Merewether.—The question just put to me relates solely to the capacity to retain, and not to obstructions and the facilities of avoiding them. The discharge of water over the weir will be in proportion to the length of the weir. I have heard of this principle for seven or eight years. The construction of the Breakwater in the Plymouth Sounds is the same as it is proposed to construct these weirs. I consider it to be the best mode of constructing weirs.—I have been professionally employed on many rivers. The weir on the Boyne stands very well. If the force of a river be five miles per hour, it would strike a weir directly across at the same force, but if the weir is oblique, the force which strikes against it is represented by a line drawn at right angles, and if the hypothenuse is five, the force that would strike that side would be nearly three. If a weir pens up five feet of water for a mile the water becomes stagnant, while it fills up to the weir; but if a fresh should come it would not produce any impediment to its passing over an oblique weir.

(To be continued.)

MISCELLANEA.

Daguerréotype Portraits.—A new discovery was communicated at the last sittings of both the Royal Society of London and the Institute of France in Paris, which is one of the most important improvements made in the Daguerréotype process, particularly when applied to the art of taking portraits. Mr. A. Claudet is the inventor of this discovery, which consists in the combination of chlorine, with the usual preparation. It is sufficient to expose the plate for one or two seconds to the vapours of that gas, to render it so sensitive to the effect of light, that the time of exposure in the camera obscura is shortened from 4 or 5 minutes to 10 or 15 seconds. This result must be of the greatest importance in taking likenesses, as the great difficulty in getting a person to sit immoveable for so long a period as was formerly required, always acted as a serious obstacle. Mr. A. Claudet is entitled to the warmest acknowledgments for his invaluable discovery, and for having been liberal enough to communicate it to the public. We understand that the inventor is carrying on his process at the Adelaide Gallery, and that his likenesses are exquisitely executed.

The Princess Royal Steam Pleasure Boat.—On Wednesday June 9th, this newly-built pleasure boat, propelled by the Archimedes screw, made her first pleasure trip from Brighton to Arundel and back. She was very recently built on the Tyne (under the direction of Messrs. Bass, W. Catt, jun., and Collins, the committee of the owners) from which port she arrived on the 8th June, in the short space of 48½ hours, the distance being upwards of 400 miles. She is of the following dimensions: length of keel 81 feet, breadth of beam 17½ feet, depth of hold 10 feet, of immersion 6½ feet, tonnage 101 tons register. There are two engines each of 23 horse power, the screw is 5 feet diameter, 6 feet pitch, and 34 strokes of the engine making 170 evolutions is the regulated speed. The velocity of the boat is about 8 knots an hour (equal to about 9¼ miles.)

Horsham.—The new church of St. Mark's (the first stone of which was laid in April 1840), was consecrated on the 3rd instant. It is in the early English style. The new school-room adjacent is also completed. Now the work is finished it is due to the architect, Mr. Mosely, and the builder, Mr. Darby, to say that both design and execution are highly creditable. Still, the continuation of the parapets the whole length of the building, and the adoption of stone in lieu of slate for the roof would have been decided improvements. Doubtless the *funds* influenced these matters. The church contains 900 sittings, and the cost, including gas fittings, boundary wall, and a few other extras, is less than £3500. It must, however, be stated that the ground was a gift, as was also the use of a stone quarry.

Faculty of Engineering in the University of Dublin.—The authorities of Dublin University seem to be anxious to aid in the present movement for extending instruction in the practical sciences, and have given notice of their intention to form a faculty of engineering in Trinity College. The faculties now are London, Durham, Glasgow and Dublin, and the schools Woolwich, Chatham, Sandhurst, Addiscombe, King's College, University College, Museum of Economic Geology, Putney, Durham College, Edinburgh Academy, Glasgow College, Dublin College, and the Mining School of the Royal Dublin Society.

Société des Architectes.—A Society of Architects is in progress of formation at Paris, on the model of the Institute here, which we hope it will worthily emulate.

Powers of Locomotive Steam.—A steam coach running at a moderate rate, which is about 21 miles per hour, would run over a distance of 500 miles per day of 24 hours, and at that speed would reach British India from London in about 8½ days—or Pekin in China in 11 days—or from Gibraltar to the Cape of Good Hope in 10 days—or from Quebec to Cape Horn in 17 days—or once round the globe in 51 days—or 7 times round the globe in one year—or a distance equal from the earth to the moon in about 16 months, or from the earth to the sun in 500 years.—*Greenock paper.*

Pompeii.—A search among the ruins of Pompeii, which took place lately led to the discovery of a marble statue, a silver vase, and a quantity of gold, silver, and bronze medals, in a good state of preservation.

Locomotive for Common Roads.—A gentleman residing at Southwell, Dr. Calvert, has constructed a machine, which he purposes to call "The *Alternate*," because he rides or walks in turn according to the ascending or descending inclination of the road he travels. By merely rising from his seat, and throwing part of the weight of the body upon the hands placed on a guiding bar, he *walks* with less fatigue than he could do without the machine, especially where the ascent is not very steep. On descending he sits down and *rides* at his ease with considerable speed. The propelling action (the most powerful that can be exerted, and one of the most lasting is that of rowing. *Nottingham Journal.*

Paper from Asparagus.—We have pleasure in hearing that one of the most famous paper manufacturers, M. Dierecks, of Ghent, has collected all the stalks of asparagus that come from the tables d'hôte and great houses of the town, in order to convert them into paper. Every evening two or three loads of these fibrous stalks are carried to the rolling mill, and thence to the stamping machine, which triturates them in the course of a few hours. The kind of paste which is thus produced does not require bleaching. It is put into a tub, and taken to the paper-making machine, from which it issues converted into excellent white paper, the expense of which is not half that of paper made from rags. We have no doubt that when this secret is once known, it will be eagerly appropriated by all large manufacturers. Asparagus mixed with the pulp of beet-root produces a kind of paper, which is even superior. —*La Fanal.*

A Steam Organ.—M. Lax, jun., has just invented a steam organ, which can be heard through the extent of a whole province. This instrument, consisting of vibrating plates of metal, is so regulated that it is acted on by steam of four or five atmospheres of pressure. These plates are merely very large steel bars, which can only be made to vibrate by very high pressure steam. This monster organ is fitted for popular solemnities and inaugurations of railroads. It may be placed upon a wagon in front of the engine, which will supply it with the same steam that moves the piston in the cylinders. The sound of this stupendous instrument would overpower the noise of the issuing steam, the working of the wheels, and the roaring of thunder.—*Le Fanal.*

Rope-making in America.—Mr. Buckingham gives the following description of the rope manufactory at Boston. "The ropewalk of the navy-yard is one of the finest I ever remember to have seen. It is nearly half a mile in length, two stories in height; it is built entirely of the same beautiful granite as that used in the construction of the dry dock, and is roofed with iron and slate. The window shutters are all cased with iron, and the whole is rendered fire-proof. Some very recent and excellent improvements have been introduced into the machinery here, by a native American engineer, Mr. Treadwell, by which a steam engine at one end of the building is made to furnish the requisite power for performing all the operations for rope-making, with very little aid from the labour of men, from the first combing of the hemp, and spinning it into threads, to the tarring and twisting the yarn, and the winding of the whole into the hawser or the cable required. I had seen some of the best ropewalks in England, both in the royal dock-yards, and in the private establishments of London, and other parts, but I remember nothing equal to this of Boston, either in the beauty and perfection of the building and the machinery, or the admirable uniformity of strain in every strand and every fibre in the rope produced; or the finished roundness, smoothness and flexibility of the hawsers and cables, of which several were submitted to our examination, both in progress and completed."

Steam Navigation on the Meuse.—One of the new steam-boats intended for the Liegeian Company of Navigation, was last week launched in the Meuse. It was towed as far as the railway to Val-Benoit, in order to put in the boiler. Without the boiler, and with the engine alone, the draught of water of the boat was 21 centimetres (8 inches); with the boiler it is 25 centimetres (10 inches). The engine, which is a low-pressure one, and according to the Jackson plan, weighs only 2,400 kilogrammes. It was constructed in the manufactory of Messrs. Derosne, Cail, and Co., at Charenton, near Paris. Excepting in England and on the Loire, there are not yet any engines like it. The engines of the steam-boats which were in operation last year on the Meuse, were considerably heavier. The vessel which has just been launched is 3 metres and 50 centimetres (11 feet) in depth, and 36 metres and 50 centimetres (118 feet) long. Every thing on deck is nearly finished, and it will soon be able to commence working. Great progress is made in the construction of the second vessel, and it will be ready for service in a short time after the first. It is estimated that the draught of these boats, with their load of fuel, will not exceed 35 centimetres (14 inches), while that of the former boats amounted to nearly 60 centimetres (24 inches); we are, therefore, induced to hope that steam navigation, unless when the waters are excessively low, may henceforth be generally adopted on the Meuse.—Another steam-boat of iron is now constructing in the manufactory of M. Petry, an engineer, at Grevegnée-les-Liége. Persons experienced in the art of boat-building, who have had opportunities of seeing this fine vessel, consider that the country has not produced any equal to it.

LIST OF NEW PATENTS.

GRANTED IN ENGLAND FROM 27TH MAY, TO 25TH JUNE, 1841.

Six Months allowed for Enrolment.

George Bent Ollivant and Adam Howard, of Manchester, millwrights, for "*certain improvements in cylindrical printing machinery for printing calicoes and other fabrics, and in the apparatus connected therewith, which is also applicable to other useful purposes.*"—Sealed June 5.

John Mee, of Leicester, framesmith, for "*improvements in the manufacture of looped fabrics.*"—June 5.

William Hannis Taylor, of Lambeth, Esq., for "*certain improvements in propelling machinery.*"—June 5.

Joseph Gibbs, of the Oval, Kennington, civil engineer, for "*certain improvements in roads and railways, and in the means of propelling carriages thereon.*"—June 5.

Miles Berry, of Chancery-lane, patent agent, for "*certain improvements in machinery or apparatus for ruling paper.*" (A communication.—June 5.

James Colley March, of Barnstaple, surgeon, for "*certain improved means of producing heat from the combustion of certain kinds of fuel.*"—June 8.

Henry Richardson Fanshaw, the younger, of Hatfield-street, Surrey, chemist, for "*improvements in curing hides and skins, and in tanning, washing, and cleaning hides, skins, and other matters.*"—June 10.

John George Bodmer, of Manchester, engineer, for "*certain improvements in machinery for propelling vessels on water, parts of which improvements apply also to steam engines to be employed on land.*"—June 10.

Edward Hammond Bentall, of Heybridge, Essex, iron-founder, for "*certain improvements in ploughs.*"—June 10.

Robert Oram, of Salford, Lancaster, engineer, for "*certain improvements in hydraulic presses.*"—June 12.

James Wiles Wayte, of the "Morning Advertiser" office, Fleet-street, engineer, for "*certain improvements in machinery or apparatus for letter-press printing.*"—June 12.

John Anthony Tielens, of Fenchurch-street, merchant, for "*improvements in machinery or apparatus for knitting.*" (A communication.)—June 12.

George Claudius Ash, of Broad-street, Golden-square, dentist, for "*improvements in apparatus for fastening candles in candlesticks.*"—June 12.

Edward Palmer, of Newgate-street, gentleman, for "*improvements in producing printing surfaces, and in the printing china, pottery, ware, music, maps, and portraits.*"—June 12.

Ezekiel Jones, of Stockport, mechanic, for "*certain improvements in machinery for prepairing slubbing, roving, spinning, and doubling cotton, silk, wool, worsted, flax, and other fibrous substances.*"—June 12.

Alexander Horatio Simpson, of New Palace-yard, Westminster, gentleman, Peter Hunter Irvin, and Thomas Eugene Irvin, both of Charles-street, Hatton-garden, philosophical instrument makers, for "*an improved mode of producing light, and of manufacturing apparatus for the diffusion of light.*"—June 17.

Thomas Walker, of North Shields, engineer, for "*improvements in steam engines.*"—June 18.

William Petrie, of Croydon, gentleman, for "*improvements in obtaining mechanical power, which are also applicable for obtaining rapid motion.*"—June 19.

John Haughton, of Liverpool, clerk, master of arts, for "*improvements in the method of affixing certain labels.*"—June 19.

James Henry Shaw, of Charlotte-street, Blackfriars, jeweller, for "*improvements in setting wheat and other seeds.*"—June 19.

Sir Samuel Brown, knight, of Netherbyers-house, Ayton, Berwick, for "*improvements in the means of drawing or moving carriages and other machines along inclined planes, railways, and other roads, and for drawing or propelling vessels in canals, rivers, and other navigable waters.*"—June 19.

John George Truscott Campbell, of Lambeth-hill, Upper Thames-street, grocer, for "*improvements in propelling vessels.*"—June 19.

Joseph Gauci, of North-crescent, Bedford-square, artist, and Alexander Bain, of Wigmore-street, Cavendish-square, mechanist, for "*improvements in inkstands and inkholders.*"—June 21.

Miles Berry, of Chancery-lane, patent agent, for "*a new or improved engine, machine, or apparatus for producing or obtaining motive power by means of gases or vapours produced by combustion.*"—June 23.

William Walker, the elder, of Standish-street, Liverpool, watch-finisher, for "*an improvement or improvements in the manufacture of the detached lever watch.*"—June 23.

George Thomas Day, of Upper Belgrave-place, Pimlico, gentleman, for "*an improved apparatus for creating draft applicable to chimneys and other purposes.*"—June 23.

John Henry Le Keux, of Southampton-street, Pentonville, for "*an improvement in line engraving, and in producing impressions therefrom.*"—June 23; two months.

John Goodwin, of Cumberland-street, Hackney-road, piano-forte maker, for "*an improved construction of piano-fortes of certain descriptions.*"—June 23; two months.

James Sidebottom, of Waterside, Derby, manufacturer, for "*certain improvements in machinery for apparatus.*"—June 23.

William Chesterman, of Burford, Oxford, gentleman, for "*improvements in filtering liquids.*"—June 23.

Robert Stephenson, of Great George-street, Westminster, civil engineer, for "*certain improvements in the arrangement and combination of the parts of steam engines of the sort commonly called locomotive engines.*"—June 23.

John Lee Stevens, of King Edward-street, Southwark, general agent, and John King, of College Hill, printer, for "*certain improvements in candlesticks and other candle holders.*"—June 25.

TO CORRESPONDENTS.

Mr. Mushet's papers; and Mr. Davies and Mr. Ryder's reply to Mr. Perkins' answer, that appeared in last month's Journal, were not received until the latter part of the month, they will appear in the next Journal.

M. Q.'s communication will appear next month—tracings will be returned when required.

"The Mammoth" is to be worked by the Screw, unless new orders have been lately given to the contrary.

We must beg of our American correspondents not to forward Pamphlets by Post, we have had several demands upon us for 5s. and 6s. postage for each.

A lengthened abstract of Mr. Hood's excellent paper "on the Properties and Chemical Constitution of Coal," has already been given in the Journal, and the paper besides has appeared in another periodical.

Works received and will be noticed next month—Mr. Ranken's Patent Wood Pavement, Report on "the Improvement of the Navigation of the Forth betwixt Stirling and Alloa." "Irish Railways." Mr. Sopwith's description of Geological Models, and Mr. Williams's work on the Combustion of Coal, 2nd edition.

Communications are requested to be addressed to "The Editor of the Civil Engineer, and Architect's Journal," *No. 11, Parliament Street, Westminster.*

Books for Review must be sent early in the month, communications on or before the 20th (if with drawings, earlier), and advertisements on or before the 25th instant.

Vols. I, II, and III, may be had, bound in cloth, price £1 each Volume.

ERRATA.

In Mr. Clark's communication "*On the Action of Central Forces,*" in the last month's Journal, page 182, 2nd column, 31st line from bottom, for $A_0^B C - A B$, read $A C = A B$. And page 183, column one, line 29, for $x = \frac{v^2}{r}$ read, $x \doteq \frac{v^2}{r}$.

the lateral cut is shorter here than the others, it is about 14 or 15 chains or 350 yards, the lift is 7 ft. 6 in. the dimensions are the same as the others, the length of the weir is 350 feet, the height from the bed of the river is about 11 ft. 6 in., the width of the river is from 100 to 130 feet. This takes us up to Red Stone Rock, and Cloth House, and to Stourport; the weir is to be in the cut there and the lock in the river, because the towing path is on the eastern side of the river, and we should have to pass over if we put a lock in the cut: I can't give the height of this weir. We dredge between Gloucester and Upton, because the shoals fall so much less in this district and are of a different character; they are shoals of deposit formed by the inequality of the sectional area of the channel. The shoals above Upton are hard beds of gravel and marl, which pen the water over in the summer season. The effect of dredging from Upton to Worcester would be to increase the liability of the banks to tumble in, and would also be inconvenient to the trader from the increased height of the banks, which are already too high; the same effect would be produced in a greater degree by dredging Upton shoal, unless there was something above. Compared with the present plan, dredging would be much more expensive, supposing it formed part of a continuous plan up to Stourport. If you removed the lock from Upton and put it at Diglis, you must have a double lift there, which would be inconvenient to the trade, as in point of fact it would be two locks. The extent of dredging in such a case must be to the extent of from 7 to 10 feet, which would be a serious matter, and would make cataracts from the locks. By the system of weirs we shall have 6 feet of water at all times from Stourport to Gloucester, which I believe would be sufficient for all purposes of trade on the Severn; I do not think it would be more than necessary for the canal boats. The build of vessels would alter if the water were deeper. In my opinion the trade of the river will be increased if these improvements are carried into effect. In my opinion if the maximum toll is imposed, these advantages will counterbalance it to the trade; I found that opinion upon the excessive delays, cost of lightering, pilferage, wear and tear, the increased power required to draw vessels up, the limited number of voyages and the light cargoes, which exist at present. The trade of Gloucester has suffered much in consequence, and has gone to other ports; to my knowledge many cargoes which, but for this, would have gone to Gloucester, have gone to Liverpool: this has been especially the case lately. I believe also that railways have increased the prejudice to the Severn. The cost of these improvements I estimate at £150,000, which will be sufficient, and more than suffice, and include contingencies, which I have estimated at 10 per cent. I am prepared to state in detail how it will be expended.

Cross-examined by Mr. Austin.

The original plan was made by Mr. Rhodes. I have been acting under Mr. Cubitt since Nov. 1825. I consider the merit or demerit of the present plan belongs to him. Mr. Cubitt was employed as consulting engineer, and Mr. Rhodes as acting engineer. I was employed by the committee of the late Severn Navigation Company. This is not the same plan as theirs, but the same with some alterations. Their plan was first made in 1838. There was a plan and sections. The original plan is at the Guildhall at Worcester. I have a reduced copy of it as altered. I took part in the formation of the original plan. It was adopted and altered by Mr. Cubitt. I said the deposit of shoals would depend on the drifts of the river. The river is divided in the plan into districts. The area of the first is at Upton, 3480 feet. That supposes a line drawn at the top of the bank and the bed of the river. The width is 104 feet, the average depth 11 feet. The next district is half a mile lower down, and has the same area; width 101 feet, average depth 10 ft. 6 in. The third is, area 3126 ft. width 98 ft. depth 11 ft. The fourth is, area 3101 ft. width 104 ft. depth 10 ft. 9 in. The fifth is, area 3529 ft. width 107 ft. depth 12 ft. The first section is half a mile below the Barley House, the second a mile ditto, the third a mile and half ditto, the fourth two miles ditto, and the fifth two miles and half ditto. That gives an average of 100 feet width and 10 feet depth, which is plenty of water for the necessities of the trade. There are no shoals there. When the water rises it expands also. The fall from Upton to Gloucester is about 7 inches, or 2·8 inches per mile. We propose to alter the whole river from Upton to Gloucester, to assimilate it at this part, and to maintain an uniform depth of 6 feet. The width of the river varies from 150 feet to 170 feet. I am not now prepared to give the Committee the detail of the cost of the works. Mr. Provis made the original calculation of the expense. The average dredging of the whole line will be less than 5 feet. The general estimate of the present plan was made by Mr. Cubitt at Worcester, in the autumn of last year. We had not a detailed estimate until within the last two months. I do not know that it is determined to lay down a quantity of rubble stone to be used between Upton and Gloucester. The depth of the water at the Upton weir immediately above is 7 feet, and below, 3 ft. 7 in. We propose to use the stuff dredged up in equalizing the width. Mr. Provis took the price of the stone from me. It was from 3*s.* to 3*s.* 6*d.* per yard, delivered not at the spot, but on the Severn. Part of it comes from between Worcester and Stourport, and the other part from Malvern. I can't tell the cost of the stone and timber between Worcester and Upton. We propose to coffer-dam at Bevere Island. The soundings for the shoals were under my direction. The borings were in many instances from 8 feet to 10 feet. Maisemore shoal was not bored, it being out of the direct line. We bored all the other shoals. We took 26 borings in the Worcester shoal.

By Mr. Serjeant Wrangham.—I do not know the quantity of work to be done for the purpose of improving the navigation. It will be a work of considerable amount to get a depth of five feet at Deerhurst shoal with a width of from forty to sixty feet. The dredge below Upton Lock will be on an average of from 4 to 5 feet for the same width for the length of a mile. I believe these excavations will not depress the level of water because they are shoals of deposit and not natural formations, and there is no fall from them. By dredging to Worcester you would be making the river a succession of rapids; if we deepened to a sufficient extent in low summer water we should get rid of the rapids, but we should lower the ponds above: it would do so even with the same sectional area. By narrowing the banks and increasing the depth the stream would flow faster: the shoals do not pen the water back except where it acts as a natural dam. From Diglis lock to Upton weir the total depth is 4 ft. 6 in.; this space contains a great number of rapids; the fall is 1½ inches per mile, with a soft bottom, but with a shoal of hard gravel and marl. I think that dredging up to Upton would not retain the level; there would be a diminution at Diglis lock of 3 ft. 9 in. by dredging, if the water was not penned back by our lock: that would leave a fall of 9 inches from Diglis lock to Upton. The river is not so broad from Diglis to Upton as below Upton; and being so, the fall above is greater than the fall below, but it must not be naturally so; it depends upon the inclination of the bed of the river, and the quantity of water carried. Many rivers, particularly the Thames and the Kennett, have had their navigation improved by artificial means. The current of the Thames is much faster than in the Severn. The velocity of the flood of the Severn is from 2½ to 3 miles per hour. Mr. Provis can give you a more satisfactory answer than I, as to the force with which that would strike our weirs. I have seen a portion of the surface of the weirs in the Thames washed off by the water. They are made in a very simple way—by piles, filled up. Our weirs will be much stronger than the Thames. During the six years I have been engaged on the Severn my attention has been particularly directed to these subjects, and the information I have given to the committee is the result of that investigation. Mr. Provis was called in about two months since. I have made a calculation of the time at which the river may become free again; and taking all things into consideration, I think it may become a free river again in forty years, with the exception simply of a toll for keeping the works in repair. My estimate applies itself to the cost of tonnage. I am sure I furnished Mr. Cubitt and Mr. Provis with sufficient information to give an opinion on the subject. The time now lost in consequence of the shoals is much greater than will be lost in going through the locks. The impediments to the navigation of the river now are much greater than can possibly exist under the improvements. I have passed vessels through the locks on the Thames in 3½ minutes; about 5 minutes is a fair average. Supposing a boat to start to Gloucester in a fresh, which, before the alteration, could get back in the same fresh, it would have greater facillty for doing so in consequence of the improvement of the river, notwithstanding the locks.

Mr. Provis, Engineer, examined by Mr. Serjeant Merewether:—I have executed works for Mr. Cubitt, and other engineers. The Menai Bridge was one of those works. The Birmingham Junction Canal was another, and I am now employed on works to the amount of £60,000 or £70,000. I was called in to give an estimate for the proposed works on the Severn, and Mr. Williams and I went down the river from Gloucester to Stourport, and I made my own observations in addition to the information given me by Mr. Williams. I have an estimate of the whole cost of the works, including 10 per cent. upon the cost of the works for contingencies, but exclusive of the land to be taken, which I do not pretend to value. The amount of that estimate is £133,108 12*s.* 3*d.*, being £121,007 16*s.* 7*d.* for the total cost of the works, and £12,100 15*s.* 7*d.* for contingencies. I have made such a calculation that, if the work were offered to me, I should have no objection to undertake it at that contract, providing the supervision was such as I liked. Were I employed as an engineer to examine that estimate, I should say that it is a fair sum to give to any man to do the required work. The cutting required at Upton will cost £4656 17*s.* 6*d.*; the lock at Upton (including the building, the gates, and every thing necessary to complete it,) £6321 4*s.* 2*d.*; the weir at Upton, (including all that is necessary, rubble stone, &c.) £3887. [It was here understood that the odd shillings and pence should be left out to simplify the statement.] This would make the total expense at Upton £14.865. Worcester, cutting £4210, lock £6231, weir £2848; total £13.379. Bevere: cutting £1082, lock and coffer dam (which I think will be required there) £10,768, weir £1569; total £13,421. Holt Fleet: cutting £3347, lock £5863, weir £1658; total £10,869. Lincombe Hill: cutting £5126, locks and dams (not coffer-dams but embankments) £8072, weir £2016; total £15,214. Total of the five totals £67,750. The five lock-houses will cost £1250. This includes all the work except the equalisation and works below Upton. The total dredging will cost £18,141. Protecting the sides of the river, £33,866. These two items make £52,007. The three totals make £121,000. With the best judgment I can form, I think this is sufficient for the work. I have made estimates to the amount of millions.

Cross-examined by Mr. Austin.—The quantity to be dredged between Upton and Gloucester, including both branches of the river, is 311,000 yards, which I estimate at 1*s.* per yard. I believe that to be the full price, and I include the taking away and depositing the soil, the whole of which is proposed to be used in narrowing the river. There is no intention to take any away, except, perhaps, throwing a little into some of the deep holes, and putting some of the best gravel on the towing paths, which are very bad. This work, will come to £15,500, which is a very large proportion of the total cost of dredging, leaving only £3000 more to be expended on dredging between Upton and Stourport. It is proposed to face the channel with rubble stone, at an inclination of 3 to 1, extending from the bottom of the dredged channel to the height marked in the section to represent the spring-tide level. There will be 193,520 square yards of rubble stone facing between Upton and Gloucester, or about 132,000 cubic yards, at 3*s.* 6*d.* per square yard, or 5*s.* 3*d.* per cubic yard. The stone can be procured at the Red Stone Rock, at Lincombe Hill, and at Holt Fleet. The mode in which the facing is to be done, is first to set the dredging machine at work, and then to throw the stone promiscuously into the channel, marks being set up for the guidance of the men who discharge the cargoes of stone. The rubble stone facing was my suggestion, and Mr. Cubitt has adopted it. I cannot tell how much sand or how much gravel will have to be dredged above Upton, as the quantity of dredging is so very small that I did not consider it worth while to examine very minutely. It would be a little harder to dredge stones than gravel, but not much, because if the stones were large we should remove the buckets from the machine and replace them with claws, which would take up detached stones. I estimate the excavation at 10*d.* per yard, which includes the removal of the soil, placing it behind the stone walls, and sloping it from the top. We shall be drawn to the plan of dropping in the stones for the weir till they rise to the surface, when they will be placed by hand, except where we make a cut, and then all the stones will be laid by hand. At the foot of the weirs it is proposed to have rubble stone, sloping at an angle of 3 to 1. We propose to make our weirs water-tight by having the sheet-piling jointed and grooved, and, as it will be driven comparatively dry, the swelling of the wood when it comes in contact with the water will be quite enough to make every joint water-tight. We do not resort to puddling. I have not made any estimate of the cost of the land which will be taken, nor for any compensation in case the drainage is affected. I have only estimated the cost of facing one side of the river at any place. This estimate has been in progress two months. I have not made any alteration in it from the first, saving to correct some little mistake respecting the quantities.

Re-examined by Serjeant Merewether.—The reason why I use stone instead of dwarf piling is because it is more durable than timber, and more proper to be used; but if it became a question, and it was deemed desirable to use timber in any particular part, then I should adopt timber. There are localities near the river where we can get stone very easily. The price I have stated is quite sufficient to cover any difference in the nature of the soil to be dredged. In constructing a weir we first put in piling. I have no reason to apprehend that the stone will be carried away, because there will be a great mass of it, placed at a considerable slope; I think the weirs will be quite strong enough to resist all pressure. I have not made any of these weirs myself, but I have taken drawings of some which have well answered the purpose for which they were designed. The walls are of the same description as those adopted by me in the river Dee, which is a rapid river. My cross-examination does not shake my conviction in the least, as to the strength of the wall.

Mr. Cubitt examined by Mr. Serjeant Merewether. The following are the principal items of his evidence:—Our plan will not affect the drainage below Upton at all, and will be the best with reference to expense. The dredging at Maisemore will be so small that the effect of it upon the Gloucester channel will be inappreciable. We shall dredge in the deep water channel. The plan proposed above Worcester has been adopted because in that district our object can be better and cheaper attained by it and with less injury to the surrounding lands. As an explanation of this, six inches of water going over a weir 600 feet long would take all the summer water in the Severn; 25 inches over a weir so constructed would make a good navigation and effect a good drainage of the land, and before injury could ensue the weir would become obsolete. We seek a channel of 45 feet from Upton to Diglis, with a rise at three inches per mile. The amount of dredging here would be upwards of 300,000 cubic yards, at 1*s.* per yard, which would be £15,000, which is the price of all the works at Upton. The lift between Worcester and Upton Bridge must be the sum of two lifts. If the two falls be brought to Worcester there must be two locks at the double fall, which would be more expense, in addition to the cost of £15,000 for dredging. I therefore think this is a sufficient reason why the weirs and locks should begin at Worcester. I apprehend there will be no difficulty whatever in the works answering their purpose when made. In putting the weirs across the river quite square it becomes a dead stop in proportion to the height and width of the weir to a portion of the section of the river, and backs up the water; but the quantity of water that falls over the weir is never of a longer sheet than the breadth of the weir, so that were the banks full there must be an obstruction. An oblique weir is the simplest, cheapest, and most efficient to dam up the river without injury. [To elucidate this, Mr. Cubitt produced a model of the proposed works and explained them in detail to the Committee, and also the scientific principles on which they were adopted.] I have considered the point of the sluices in the weir. I think them inexpedient. The flood gates would have no perceptible effect in such a case; and flood gates, as such, in the weirs would cost more than the weirs themselves. The weir is quite as capable of penning off the water without flood gates as with them.—If any works are put to improve Lord Sandys' drain it would not impede the navigation. My object has been to raise all the works, towing paths, &c., above the floods.—I do not intend to dredge away the quantity Mr. Provis stated at Maisemore shoal, or to do more to it than will be necessary to let the Maisemore boat pass. There is more in the Parliamentary sections than is necessary to be done, and so far there is a greater degree of safety.—I was first employed to make observations on this river by Mr. Lea, the Chairman of the Association at Worcester. I made my report to Lord Hatherton, the Chairman of the Committee of the Severn Association. I had met Mr. Williams professionally before. I was engaged with Mr. Rhodes in the plan of 1836; that was a plan involving the erection of weirs above and below Gloucester; the weir below Gloucester would have been in a portion of the river now avoided by the Gloucester and Berkeley Canal. The plans of the present day are the same amended; I approved of them in general, but not in all things. I have no doubt that we might get six feet of water by dredging up to Worcester, but it would be much more expensive. It is proposed to place a wall where we dredge. I have estimated for eight miles of walling and dredging; that will answer the double purpose of narrowing the river and securing the banks.

Mr. Cubitt cross-examined by Mr. Wortley.—Mr. Williams correctly described the mode of laying down the rubble stone. At one time I proposed to use dwarf piling in some places; and I still intend to do so, where I think it will be as cheap and efficient. In some respects it is preferable to stone, in others it is not so. I can't mention any part of the river in which I think it will be preferable. I do not propose to make the slopes of the banks perfect in all places, as Mr. Provis did, because I think there will not be stuff enough to do it. The channel of the Deerhurst shoal is rather straight; the deepest water is towards the left bank going down. It is not absolutely necessary to stone up to the high-water mark. The length of the dredging on the river between Upton and Gloucester upon my scheme, as marked on the sections, is between eight and nine miles. I should remark, that it is marked deeper than will be necessary for the navigation. I do not contemplate any works below the Gloucester and Berkeley Canal, nor below the entrance to the Gloucester and Hereford Canal. The continuous length of dredging in the sections, from Upton to Diglis is nine miles. We propose to start from Upton at a depth of 7 ft. 6 in.; and we do so because I don't think 6 feet sufficient. By the 6 feet spoken of as the depth we seek, I mean 6 feet above the lock sills. I save all the dredging there by penning the banks. Were we to dredge from Gloucester to Worcester to a width of 45 feet at the bottom, to the level of the lock sill of the Gloucester and Berkeley Canal, 5 feet in depth, with a slope of two to one, and rising 3 inches per mile, the quantity to be dredged would be 323,133 cubic yards. [Witness then answered a series of questions as to the volume of water that would flow in channels of different widths.] We shall scarcely affect the fall below Upton. We propose at Upton to form a close jointed waterproof weir, slanting, 600 feet long, with timber pilings drawn into the river, 10 feet apart; behind this we propose to drop stones into the river, without masonry. The expense of having the lock at Diglis, instead of Upton, would be very much increased on account of the additional fall. In some places where we construct our weirs we widen the river, in which cases the cross sections would be as great or greater than at present. I measured that section across the river at right angles to the stream. The height of the water above the weir is 6 inches. I know by principle, and partly by practice, that when the water is 2 feet above the weir the boats will go over. The water, in coming to the weir, does not diminish its velocity, and no more water would pass over the weir in consequence of its being oblique than if it were right angled. I do not make a pond, and therefore I do not cause a deposit. If you do any thing to diminish the velocity of the water coming through the weir it will tend to form a deposit; but if it be so constructed that the water coming through can keep moving on with the same velocity, it will have no more tendency to form a deposit than before the weir was put in. If I were to carry out the works at once I do not intend to make any alteration in the length of the weir; and if I did so at all, it would be to meet the views of others rather than my own convictions. If the river be increased beyond its natural width it will be more liable to deposits. The expenses of general maintenance of the works can never cease while the works exist. The expense of the navigation of the Ayr and Caldwell is very considerable. We do not alter the natural surface of the water at Diglis locks to any extent; if the weir were placed above the entrance to the canal, vessels would have the same depth of water. The reason I have for not placing it higher up the stream is that it would lengthen the cut very much, take more land, and much reduce the water to what I may call the harbour of Worcester. The length to the harbour is 1000 yards; it would increase the length of the cut about nine chains. There would be great passing of vessels from all places at the point, and therefore I think there should be a good harbour. If the vessels coming at the same time had to wait for the lockage, it would be the best place to wait in, but there would be little or no waiting, as they would pass the lock in three or four minutes. At Bevere Island I propose to put the weir below the mouth of the Salwarp; Mr. Rhodes in his last plan has placed it in the same place. By putting a weir in a shallow stream we raise the water; but the instant it gets so much above the weir as to lose a fall, from that instant the weir is no obstruction. I have had but little experience in salmon rivers; I understand there are good salmon in the Severn, and I should be very sorry to do anything to destroy them; I have nothing to do with how far these works will affect the rights of piscary; I have considered how to form the weirs so as not to obstruct the salmon in passing up the river; the weirs will not afford any facility for taking the fish. The average yield of the river at low summer water is from 40 to 60,000 cubic feet per minute above the Avon; the quantity of course differs below the Avon.

By Mr. Lowndes.—I have not personally taken the levels of the drains on the river Severn; I received information from Mr. Williams, and a great deal from Mr. Rhodes; I don't know that Mr. Rhodes personally took the levels. I received the greatest information on this point from the documents. I examined the drain on Lord Sandys' property myself; if you proved there was an under-drain there it would not matter on atom. I consider the sole operation of a drain to be to take the water off the surface of the land; the effect of an under-drain is to take off that which gets below the surface of the land. If there is an under-ground drain it does not follow that the level must be the same as that of the open drain. I do not know whether there is an under-ground drain at this place, but I believe all the drains on Lord Sandys' property come into the Severn below the weir.—When a fresh comes down the river the surface of the river will remain nearly the same as before the weir was put in. The works will raise the water on the river at Salwarp perhaps four feet. The value of the land to be taken will be proved hereafter by other witnesses. If it should be proved that 2000 acres for instance would be injured in their drainage by the bill, there has been no estimate made of the amount of compensation for that. I can't give any opinion as to the permanency of any damage that might ensue. I admit that the consequences of imperfect drainage would be to effect the atmosphere of the district. The state of the towing paths is not good; they give way on both sides of the river. When they have given way, it is generally the case that the land is encroached upon for a fresh one, which they are entitled to do. If they are entitled by their Act to take 10 feet on the side of the river, and that falls in, I am of opinion they can take 10 feet more; notwithstanding this, I do not think it is imprudent in us to undertake their management.

Mr. McNeil examined by Mr. Serjeant Merewether.—I am a civil engineer, and have been engaged in many extensive works for a period of 20 years. I have been present during the last few days of this enquiry. I have been engaged in works of a similar description to the present. Having heard the plan, I think it would effect the desired object. I think it would be best to dredge up to Upton. I think, also, that the weirs will effect Mr. Cubitt's object. With reference to expense, I think it is the best mode that could be adopted. I think the explanation given by Mr. Cubitt has been so clear, that nothing remains to be added to it.

Cross-examined by Mr. Austin.—I was called in on this business on Monday week. I had not made a previous examination of the river Severn. I never did so. I have been across it at Chepstow, but never practically examined it. I do not know any other river of a similar natural character. I under what circumstances, so awful a catastrophe would have occurred, of course not even those best acquainted with the subject could pretend to describe. Mr. Cottingham has caused about 150 wagon-loads of rubbish to be removed from the tower in order fully to ascertain its state, and there can be no doubt that the measures he intends to adopt will give full security. One great advantage, too, of his plans will be to expose the 52 stone columns of the tower (a remarkably fine piece of masonry) to the view of persons in the church. In the mean time, so imminent does he consider the danger, that he will not suffer the bells to be rung, and all attention to the other parts of the works is suspended until satisfactory reparation has been made. The restoration will now be effected at a comparatively trifling expense; had the discovery not thus timely taken place, the cost would have been enormous. It is worthy of remark that so little were these subjects understood only a comparatively short period ago, that the western front was declared to be secured for hundreds of years, and yet in six weeks only from the time of that declaration it was a mass of ruins.—*Hereford Journal.*

LIVERPOOL DOCKS.

It will be recollected that in the last February number of the Journal, we gave a letter of Mr. Hartley's, the Dock Surveyor, addressed to the Liverpool Dock Committee, in consequence of certain charges being brought against him by a Member of the Committee, whereupon a Sub-Committee was appointed to inquire into the charges. This Committee have lately made their report which is now before us, we are happy to announce, what we feel assured the whole of the profession were prepared for, that it completely vindicates Mr. Hartley from the charges. The report is too long for insertion in our Journal, but the following announcement we are sure will be all that is necessary for us to give.

"The sub-committee, having personally examined the accounts at the Dockyard, and the system of checks on labour and expenditure of stores, are unanimously of opinion, after a very strict investigation of the stock accounts, and careful examination of the books, which show in detail the expenses incurred in every department of work, and making allowance for the expense of the establishment and maintenance of a large stock, that the various works have been executed on very reasonable terms, and at lower rates than they could have been in any other way. The interests of the Dock Trust, in the conduct and management of the mechanical departments of the Surveyor's establishment, have been materially promoted by the system which has been pursued; and, as long as that system is kept up in the same orderly, vigorous, and efficient manner, no better system can be devised for the general benefit of the trust, the establishment being highly creditable to the Dock Surveyor, *whose indefatigable zeal, honour, and industry cannot be too highly commended.*"

Removal of Sunderland Light House.—At a late meeting of the Commissioners of the river Wear, the taking down of the Light House being discussed, as part of the plan of building the new North pier at the mouth of the harbour, Mr. Murray, the engineer, suggested the removal of the Light House, in its present entire state, to the eastern extremity of the new Pier, a distance of about 420 feet, so as to make it serve the double purpose of a stationary and a tide-light. Mr. Murray exhibited a model of the building, and after explaining how he proposed to effect this undertaking, the Board decided that he should proceed forthwith to remove it. This Light House was erected about 40 years ago, by the late Mr. Pickernell, then engineer to the Harbour Commissioners. It is wholly composed of stone; its form is octagonal, 15 feet in breadth across its base, 62 feet in height from the surface of the pier to the top of the cornice, where it is 9 feet in breadth across, and the top of the dome is 16 feet above the cornice, making a total height of 78 feet; and its calculated weight is 250 tons. Mr. Murray intends to cut through the masonry near its foundation, and insert whole timbers, one after another, through the building, and extending 7 feet beyond it. Above and at right angles to them, another tier of timbers is to be inserted in like manner, so as to make the cradle or base a square of 29 feet; and this cradle is to be supported upon bearers, with about 250 wheels of 6 inches diameter, intended to traverse on 6 lines of railway to be laid on the new Pier for that purpose. The shaft of the Light House is to be tied together with bands, and its eight sides are to be supported with timber braces from the cradle upwards to the cornice. The cradle is to be drawn and pushed forward by powerful screws, along the railway above mentioned, on the principle of Morton's patent slip for the repairing of vessels. However surprising the removal of such a building may appear to many, yet in New York, for some years past, large houses have been removed from their original situation to a considerable distance, without sustaining any injury. The immense block of granite, serving as the pedestal of the equestrian statue of Peter the Great, at St. Petersburgh, was conveyed four miles by land, and thirteen by water. Several Obelisks have likewise been transported at different times from Egypt to Europe; and lately, one was conveyed from Thebes, and erected by the French at Paris. But the fact that the Light House on our North Pier is composed of stones of comparatively small dimension, its great height, and small base, make the operation of removing it much more difficult than any thing of the sort ever attempted. We heartily wish the enterprising engineer every success in his bold and novel undertaking, which is to be carried into execution in the course of a few weeks from this date.—*Sunderland Herald.*

COMPETITION FOR THE MARSEILLES EXCHANGE.

The following conditions of competition for designing an Exchange at Marseilles, we have translated from *Revue Générale de L'Architecture.*

1st. The situation will be chosen in a *perimètre* commencing at the "Rue de la Prison," and proceeding up to the "Place de Justice," the Grand Rue as far as the Courts.

2nd. The competition designs must contain, not only the Exchange strictly so called, but also the Chamber and Tribunal of Commerce, the syndicat of the money-changers, the royal brokers, the merchant counsel, and all the necessary appendages to these, such as peristyle porticos, vestibules, vestries secretary's office, registry office, bureaux, counting houses, &c. &c. Also a dwelling place for the porter, a guard-house for a detachment, and a place to deposit cloaks, umbrellas, and walking sticks.

3rd. The great hall of the Exchange, including the interior porticos must contain at least 3000 persons, and consequently have a superficies of not less than 1000 square metres.

4th. The drawings must be done with care, the sections to be in a pale colour, the horizontal sections in Indian ink, and carmine for the vertical sections, yellow for the wood, Prussian blue for the iron, grey for the metallic roofs, and brick red for the tile roofs.

5th. Each design must be composed of the following separate pieces.

1. An explanatory and justifiable report.
2. A general plan of the whole.
3. A plan of the ground floors at one or two metres above the level of the great hall, and the same of the first floor.
4. Longitudinal and a transverse section through the interior of the edifice.
5. Front and back elevations.
6. Profiles and details of execution (this need not be paid so much attention to).
7. A descriptive device containing a scale of the works, and the cost after the current price of the country; the whole exactly and summarily expressed.

6th. As to the order of architecture, the best in whatever order it may happen to be chosen, and even the several orders may be blended, but keeping at the same time a tone of convenience, solidity, elegance, good taste, a noble simplicity, and a wise economy.

7th. The scale of the general plan to be, 2 millimetres to a metre, that of the sections and separate plans a centimetre to a metre, and that of the details of execution 5 centimetres to a metre.

8th. The competition is fixed at six months date from the 1st April. During the following fortnight the competitors to deposit their designs at the secretary's office, at the Chamber of Commerce, where they will receive a certain number according to the order of presentation, the names and address of the competitors must be enclosed in an envelope carefully closed, to which the same number will be affixed. Each competitor to have a receipt stating the formal deposition, the number of plans, and the particular number given them, but without indicating name or person.

9th. When the term for the preparation of the plans has expired, the designs will be submitted to the judgment of a committee chosen from the members of the Chamber of Commerce, and an equal number of artists. The decision will not be definitive until the sanction of competent authorities be given, and then the names only of the authors of the three best designs will be announced.

10th. The first design will receive the prize of 3000 francs (120*l*.), and then, without further remuneration or honours, will remain the property of the Chamber, who will have the right to alter it at their will, and to confide the execution to whom they please. The names of the other two authors of the second and third best designs will be honourably mentioned.

11th. Every design (No. 1 excepted), will be restored to their authors, as well as the sealed envelopes containing their names, on the production of the previously delivered receipts.

Marseilles, March 30, 1841.

CANAL STEAMER FITTED WITH MR. P. TAYLOR'S REVOLVING SCREW PROPELLERS.

On Wednesday the 5th of May, we had the pleasure of inspecting a new steam boat on the river Irwell, fitted by Messrs. Peter Taylor and Co., of Hollinwood, near Manchester, with steam engines and propellers of an entirely new construction, both inventions of Mr. Peter Taylor, and for which he has obtained patents. The vessel is 75 feet long and 10 feet wide, and built (with the exception of the gunwale and paddle-box,) entirely of iron. She appeared to perform very satisfactorily; at a speed varying according to the depth of water from about eight to nine miles per hour, which upon a confined water we believe has never been attained by any steam vessel. In noticing a trial some months ago of another vessel belonging to Messrs. Taylor and Co., which had then been newly fitted with similar propellers, we gave a description of the apparatus, which consists of a number of continuous curved vanes or segments of screws, or wings on two axes. In the instance now under notice five pairs are affixed upon one axis, and five pairs upon the other; the number being regulated by, and varied according to, the power of

Rope-making in America.—Mr. Buckingham gives the following description of the rope manufactory at Boston. "The ropewalk of the navy-yard is one of the finest I ever remember to have seen. It is nearly half a mile in length, two stories in height; it is built entirely of the same beautiful granite as that used in the construction of the dry dock, and is roofed with iron and slate. The window shutters are all cased with iron, and the whole is rendered fire-proof. Some very recent and excellent improvements have been introduced into the machinery here, by a native American engineer, Mr. Treadwell, by which a steam engine at one end of the building is made to furnish the requisite power for performing all the operations for rope-making, with very little aid from the labour of men, from the first combing of the hemp, and spinning it into threads, to the tarring and twisting the yarn, and the winding of the whole into the hawser or the cable required. I had seen some of the best ropewalks in England, both in the royal dock-yards, and in the private establishments of London, and other parts, but I remember nothing equal to this of Boston, either in the beauty and perfection of the building and the machinery, or the admirable uniformity of strain in every strand and every fibre in the rope produced; or the finished roundness, smoothness and flexibility of the hawsers and cables, of which several were submitted to our examination, both in progress and completed."

Steam Navigation on the Meuse.—One of the new steam-boats intended for the Liegeian Company of Navigation, was last week launched in the Meuse. It was towed as far as the railway to Val-Benoit, in order to put in the boiler. Without the boiler, and with the engine alone, the draught of water of the boat was 21 centimetres (8 inches); with the boiler it is 25 centimetres (10 inches). The engine, which is a low-pressure one, and according to the Jackson plan, weighs only 2,400 kilogrammes. It was constructed in the manufactory of Messrs. Derosne, Cail, and Co., at Charenton, near Paris. Excepting in England and on the Loire, there are not yet any engines like it. The engines of the steam-boats which were in operation last year on the Meuse, were considerably heavier. The vessel which has just been launched is 3 metres and 50 centimetres (11 feet) in depth, and 36 metres and 50 centimetres (118 feet) long. Every thing on deck is nearly finished, and it will soon be able to commence working. Great progress is made in the construction of the second vessel, and it will be ready for service in a short time after the first. It is estimated that the draught of these boats, with their load of fuel, will not exceed 35 centimetres (14 inches), while that of the former boats amounted to nearly 60 centimetres (24 inches); we are, therefore, induced to hope that steam navigation, unless when the waters are excessively low, may henceforth be generally adopted on the Meuse.—Another steam-boat of iron is now constructing in the manufactory of M. Petry, an engineer, at Grevegnée-les-Liége. Persons experienced in the art of boat-building, who have had opportunities of seeing this fine vessel, consider that the country has not produced any equal to it.

LIST OF NEW PATENTS.

GRANTED IN ENGLAND FROM 27TH MAY, TO 25TH JUNE, 1841.

Six Months allowed for Enrolment.

GEORGE BENT OLLIVANT and ADAM HOWARD, of Manchester, millwrights, for "*certain improvements in cylindrical printing machinery for printing calicoes and other fabrics, and in the apparatus connected therewith, which is also applicable to other useful purposes.*"—Sealed June 5.

JOHN MEE, of Leicester, framesmith, for "*improvements in the manufacture of looped fabrics.*"—June 5.

WILLIAM HANNIS TAYLOR, of Lambeth, Esq., for "*certain improvements in propelling machinery.*"—June 5.

JOSEPH GIBBS, of the Oval, Kennington, civil engineer, for "*certain improvements in roads and railways, and in the means of propelling carriages thereon.*"—June 5.

MILES BERRY, of Chancery-lane, patent agent, for "*certain improvements in machinery or apparatus for ruling paper.*" (A communication.—June 5.

JAMES COLLEY MARCH, of Barnstaple, surgeon, for "*certain improved means of producing heat from the combustion of certain kinds of fuel.*"—June 8.

HENRY RICHARDSON FANSHAW, the younger, of Hatfield-street, Surrey, chemist, for "*improvements in curing hides and skins, and in tanning, washing, and cleaning hides, skins, and other matters.*"—June 10.

JOHN GEORGE BODMER, of Manchester, engineer, for "*certain improvements in machinery for propelling vessels on water, parts of which improvements apply also to steam engines to be employed on land.*"—June 10.

EDWARD HAMMOND BENTALL, of Heybridge, Essex, iron-founder, for "*certain improvements in ploughs.*"—June 10.

ROBERT ORAM, of Salford, Lancaster, engineer, for "*certain improvements in hydraulic presses.*"—June 12.

JAMES WILLS WAYTE, of the "Morning Advertiser" office, Fleet-street, engineer, for "*certain improvements in machinery or apparatus for letter-press printing.*"—June 12.

JOHN ANTHONY TIELENS, of Fenchurch-street, merchant, for "*improvements in machinery or apparatus for knitting.*" (A communication.)—June 12.

GEORGE CLAUDIUS ASH, of Broad-street, Golden-square, dentist, for "*improvements in apparatus for fastening candles in candlesticks.*"—June 12.

EDWARD PALMER, of Newgate-street, gentleman, for "*improvements in producing printing surfaces, and in the printing china, pottery, ware, music, maps, and portraits.*"—June 12.

EZEKIEL JONES, of Stockport, mechanic, for "*certain improvements in machinery for prepairing slubbing, roving, spinning, and doubling cotton, silk, wool, worsted, flax, and other fibrous substances.*"—June 12.

ALEXANDER HORATIO SIMPSON, of New Palace-yard, Westminster, gentleman, PETER HUNTER IRVIN, and THOMAS EUGENE IRVIN, both of Charles-street, Hatton-garden, philosophical instrument makers, for "*an improved mode of producing light, and of manufacturing apparatus for the diffusion of light.*"—June 17.

THOMAS WALKER, of North Shields, engineer, for "*improvements in steam engines.*"—June 18.

WILLIAM PETRIE, of Croydon, gentleman, for "*improvements in obtaining mechanical power, which are also applicable for obtaining rapid motion.*"—June 19.

JOHN HAUGHTON, of Liverpool, clerk, master of arts, for "*improvements in the method of affixing certain labels.*"—June 19.

JAMES HENRY SHAW, of Charlotte-street, Blackfriars, jeweller, for "*improvements in setting wheat and other seeds.*"—June 19.

SIR SAMUEL BROWN, knight, of Netherbyers-house, Ayton, Berwick, for "*improvements in the means of drawing or moving carriages and other machines along inclined planes, railways, and other roads, and for drawing or propelling vessels in canals, rivers, and other navigable waters.*"—June 19.

JOHN GEORGE TRUSCOTT CAMPBELL, of Lambeth-hill, Upper Thames-street, grocer, for "*improvements in propelling vessels.*"—June 19.

JOSEPH GAUCI, of North-crescent, Bedford-square, artist, and ALEXANDER BAIN, of Wigmore-street, Cavendish-square, mechanist, for "*improvements in inkstands and inkholders.*"—June 21.

MILES BERRY, of Chancery-lane, patent agent, for "*a new or improved engine, machine, or apparatus for producing or obtaining motive power by means of gases or vapours produced by combustion.*"—June 23.

WILLIAM WALKER, the elder, of Standish-street, Liverpool, watch-finisher, for "*an improvement or improvements in the manufacture of the detached lever watch.*"—June 23.

GEORGE THOMAS DAY, of Upper Belgrave-place, Pimlico, gentleman, for "*an improved apparatus for creating draft applicable to chimneys and other purposes.*"—June 23.

JOHN HENRY LE KEUX, of Southampton-street, Pentonville, for "*an improvement in line engraving, and in producing impressions therefrom.*"—June 23; two months.

JOHN GOODWIN, of Cumberland-street, Hackney-road, piano-forte maker, for "*an improved construction of piano-fortes of certain descriptions.*"—June 23; two months.

JAMES SIDEBOTTOM, of Waterside, Derby, manufacturer, for "*certain improvements in machinery for apparatus.*"—June 23.

WILLIAM CHESTERMAN, of Burford, Oxford, gentleman, for "*improvements in filtering liquids.*"—June 23.

ROBERT STEPHENSON, of Great George-street, Westminster, civil engineer, for "*certain improvements in the arrangement and combination of the parts of steam engines of the sort commonly called locomotive engines.*"—June 23.

JOHN LEE STEVENS, of King Edward-street, Southwark, general agent, and JOHN KING, of College Hill, printer, for "*certain improvements in candlesticks and other candle holders.*"—June 25.

TO CORRESPONDENTS.

Mr. Mushet's papers; and Mr. Davies and Mr. Ryder's reply to Mr. Perkins' answer, that appeared in last month's Journal, were not received until the latter part of the month, they will appear in the next Journal.

M. Q.'s communication will appear next month—tracings will be returned when required.

"The Mammoth" is to be worked by the Screw, unless new orders have been lately given to the contrary.

We must beg of our American correspondents not to forward Pamphlets by Post, we have had several demands upon us for 5s. and 6s. postage for each.

A lengthened abstract of Mr. Hood's excellent paper "on the Properties and Chemical Constitution of Coal," has already been given in the Journal, and the paper besides has appeared in another periodical.

Works received and will be noticed next month—Mr. Ranken's Patent Wood Pavement, Report on "the Improvement of the Navigation of the Forth betwixt Stirling and Alloa," "Irish Railways." Mr. Sopwith's description of Geological Models, and Mr. Williams's work on the Combustion of Coal, 2nd edition.

Communications are requested to be addressed to "The Editor of the Civil Engineer, and Architect's Journal," *No. 11, Parliament Street, Westminster.*

Books for Review must be sent early in the month, communications on or before the 20th (if with drawings, earlier), and advertisements on or before the 25th instant.

Vols. I, II, and III, may be had, bound in cloth, price £1 each Volume.

ERRATA.

In Mr. Clark's communication "*On the Action of Central Forces,*" in the last month's Journal, page 182, 2nd column, 31st line from bottom, for $A_B^C - A B$, read $A C = A B$. And page 183, column one, line 29, for $x = \frac{r^2}{r}$ read, $x = \frac{v^2}{r}$.

the lateral cut is shorter here than the others, it is about 14 or 15 chains or 350 yards, the lift is 7 ft. 6 in. the dimensions are the same as the others, the length of the weir is 350 feet, the height from the bed of the river is about 11 ft. 6 in., the width of the river is from 100 to 130 feet. This takes us up to Red Stone Rock, and Cloth House, and to Stourport; the weir is to be in the cut there and the lock in the river, because the towing path is on the eastern side of the river, and we should have to pass over if we put a lock in the cut: I can't give the height of this weir. We dredge between Gloucester and Upton, because the shoals fall so much less in this district and are of a different character; they are shoals of deposit formed by the inequality of the sectional area of the channel. The shoals above Upton are hard beds of gravel and marl, which pen the water over in the summer season. The effect of dredging from Upton to Worcester would be to increase the liability of the banks to tumble in, and would also be inconvenient to the trader from the increased height of the banks, which are already too high: the same effect would be produced in a greater degree by dredging Upton shoal, unless there was something above. Compared with the present plan, dredging would be much more expensive, supposing it formed part of a continuous plan up to Stourport. If you removed the lock from Upton and put it at Diglis, you must have a double lift there, which would be inconvenient to the trade, as in point of fact it would be two locks. The extent of dredging in such a case must be to the extent of from 7 to 10 feet, which would be a serious matter, and would make cataracts from the locks. By the system of weirs we shall have 6 feet of water at all times from Stourport to Gloucester, which I believe would be sufficient for all purposes of trade on the Severn; I do not think it would be more than necessary for the canal boats. The build of vessels would alter if the water were deeper. In my opinion the trade of the river will be increased if these improvements are carried into effect. In my opinion if the maximum toll is imposed, these advantages will counterbalance it to the trade; I found that opinion upon the excessive delays, cost of lightering, pilferage, wear and tear, the increased power required to draw vessels up, the limited number of voyages and the light cargoes, which exist at present. The trade of Gloucester has suffered much in consequence, and has gone to other ports; to my knowledge many cargoes which, but for this, would have gone to Gloucester, have gone to Liverpool; this has been especially the case lately. I believe also that railways have increased the prejudice to the Severn. The cost of these improvements I estimate at £150,000, which will be sufficient, and more than suffice, and include contingencies, which I have estimated at 10 per cent. I am prepared to state in detail how it will be expended.

Cross-examined by Mr. Austin.

The original plan was made by Mr. Rhodes. I have been acting under Mr. Cubitt since Nov. 1825. I consider the merit or demerit of the present plan belongs to him. Mr. Cubitt was employed as consulting engineer, and Mr. Rhodes as acting engineer. I was employed by the committee of the late Severn Navigation Company. This is not the same plan as theirs, but the same with some alterations. Their plan was first made in 1838. There was a plan and sections. The original plan is at the Guildhall at Worcester. I have a reduced copy of it as altered. I took part in the formation of the original plan. It was adopted and altered by Mr. Cubitt. I said the deposit of shoals would depend on the drifts of the river. The river is divided in the plan into districts. The area of the first is at Upton, 3480 feet. That supposes a line drawn at the top of the bank and the bed of the river. The width is 104 feet, the average depth 11 feet. The next district is half a mile lower down, and has the same area; width 101 feet, average depth 10 ft. 6 in. The third is, area 3126 ft. width 98 ft. depth 11 ft. The fourth is, area 3401 ft. width 104 ft. depth 10 ft. 9 in. The fifth is, area 3529 ft. width 107 ft. depth 12 ft. The first section is half a mile below the Barley House, the second a mile ditto, the third a mile and half ditto, the fourth two miles ditto, and the fifth two miles and half ditto. That gives an average of 100 feet width and 10 feet depth, which is plenty of water for the necessities of the trade. There are no shoals there. When the water rises it expands also. The fall from Upton to Gloucester is about 7 inches, or 2·8 inches per mile. We propose to alter the whole river from Upton to Gloucester, to assimilate it at this part, and to maintain an uniform depth of 6 feet. The width of the river varies from 150 feet to 170 feet. I am not now prepared to give the Committee the detail of the cost of the works. Mr. Provis made the original calculation of the expense. The average dredging of the whole line will be less than 5 feet. The general estimate of the present plan was made by Mr. Cubitt at Worcester, in the autumn of last year. We had not a detailed estimate until within the last two months. I do not know that it is determined to lay down a quantity of rubble stone to be used between Upton and Gloucester. The depth of the water at the Upton weir immediately above is 7 feet, and below, 3 ft. 7 in. We propose to use the stuff dredged up in equalizing the width. Mr. Provis took the price of the stone from me. It was from 3*s.* to 3*s.* 6*d.* per yard, delivered not at the spot, but on the Severn. Part of it comes from between Worcester and Stourport, and the other part from Malvern. I can't tell the cost of the stone and timber between Worcester and Upton. We propose to coffer-dam at Bevere Island. The soundings for the shoals were under my direction. The borings were in many instances from 8 feet to 10 feet. Maisemore shoal was not bored, it being out of the direct line. We bored all the other shoals. We took 26 borings in the Worcester shoal.

By Mr. Serjeant Wrangham.—I do not know the quantity of work to be done for the purpose of improving the navigation. It will be a work of considerable amount to get a depth of five feet at Deerhurst shoal with a width of from forty to sixty feet. The dredge below Upton Lock will be on an average of from 4 to 5 feet for the same width for the length of a mile. I believe these excavations will not depress the level of water because they are shoals of deposit and not natural formations, and there is no fall from them. By dredging to Worcester you would be making the river a succession of rapids; if we deepened to a sufficient extent in low summer water we should get rid of the rapids, but we should lower the ponds above; it would do so even with the same sectional area. By narrowing the banks and increasing the depth the stream would flow faster: the shoals do not pen the water back except where it acts as a natural dam. From Diglis lock to Upton weir the total depth is 4 ft. 6 in.; this space contains a great number of rapids; the fall is 1½ inches per mile, with a soft bottom, but with a shoal of hard gravel and marl. I think that dredging up to Upton would not retain the level; there would be a diminution at Diglis lock of 3 ft. 9 in. by dredging, if the water was not penned back by our lock; that would leave a fall of 9 inches from Diglis lock to Upton. The river is not so broad from Diglis to Upton as below Upton; and being so, the fall above is greater than the fall below, but it must not be naturally so; it depends upon the inclination of the bed of the river, and the quantity of water carried. Many rivers, particularly the Thames and the Kennett, have had their navigation improved by artificial means. The current of the Thames is much faster than in the Severn. The velocity of the flood of the Severn is from 2½ to 3 miles per hour. Mr. Provis can give you a more satisfactory answer than I, as to the force with which that would strike our weirs. I have seen a portion of the surface of the weirs in the Thames washed off by the water. They are made in a very simple way—by piles, filled up. Our weirs will be much stronger than the Thames. During the six years I have been engaged on the Severn my attention has been particularly directed to these subjects, and the information I have given to the committee is the result of that investigation. Mr. Provis was called in about two months since. I have made a calculation of the time at which the river may become free again; and taking all things into consideration, I think it may become a free river again in forty years, with the exception simply of a toll for keeping the works in repair. My estimate applies itself to the cost of tonnage. I am sure I furnished Mr. Cubitt and Mr. Provis with sufficient information to give an opinion on the subject. The time now lost in consequence of the shoals is much greater than will be lost in going through the locks. The impediments to the navigation of the river now are much greater than can possibly exist under the improvements. I have passed vessels through the locks on the Thames in 3½ minutes; about 5 minutes is a fair average. Supposing a boat to start to Gloucester in a fresh, which, before the alteration, could get back in the same fresh, it would have greater facility for doing so in consequence of the improvement of the river, notwithstanding the locks.

Mr. Provis, Engineer, examined by Mr. Serjeant Merewether:—I have executed works for Mr. Cubitt, and other engineers. The Menai Bridge was one of those works. The Birmingham Junction Canal was another, and I am now employed on works to the amount of £60,000 or £70,000. I was called in to give an estimate for the proposed works on the Severn, and Mr. Williams and I went down the river from Gloucester to Stourport, and I made my own observations in addition to the information given me by Mr. Williams. I have an estimate of the whole cost of the works, including 10 per cent. upon the cost of the works for contingencies, but exclusive of the land to be taken, which I do not pretend to value. The amount of that estimate is £133,108 12*s.* 3*d.*, being £121,007 16*s.* 7*d.* for the total cost of the works, and £12,100 15*s.* 7*d.* for contingencies. I have made such a calculation that, if the work were offered to me, I should have no objection to undertake it at that contract, providing the supervision was such as I liked. Were I employed as an engineer to examine that estimate, I should say that it is a fair sum to give to any man to do the required work. The cutting required at Upton will cost £1656 17*s.* 6*d.*; the lock at Upton (including the building, the gates, and every thing necessary to complete it,) £6321 4*s.* 2*d.*; the weir at Upton, (including all that is necessary, rubble stone, &c.) £3887. [It was here understood that the odd shillings and pence should be left out to simplify the statement.] This would make the total expense at Upton £14,865. Worcester, cutting £1210, lock £6231, weir £2848; total £13,379. Bevere: cutting £1082, lock and coffer dam (which I think will be required there) £10,768, weir £1569; total £13,421. Holt Fleet: cutting £3347, lock £5863, weir £1658; total £10,869. Lincombe Hill: cutting £5126, locks and dams (not coffer-dams but embankments) £8072, weir £2016; total £15,214. Total of the five totals £67,750. The five lock-houses will cost £1250. This includes all the work except the equalisation and works below Upton. The total dredging will cost £18,141. Protecting the sides of the river, £33,866. These two items make £52,007. The three totals make £121,000. With the best judgment I can form, I think this is sufficient for the work. I have made estimates to the amount of millions.

Cross-examined by Mr. Austin.—The quantity to be dredged between Upton and Gloucester, including both branches of the river, is 311,000 yards, which I estimate at 1*s.* per yard. I believe that to be the full price, and I include the taking away and depositing the soil, the whole of which is proposed to be used in narrowing the river. There is no intention to take any away, except, perhaps, throwing a little into some of the deep holes, and putting some of the best gravel on the towing paths, which are very bad. This work, will come to £15,500, which is a very large proportion of the total cost of dredging, leaving only £3000 more to be expended on dredging between Upton and Stourport. It is proposed to face the channel with rubble stone, at an inclination of 3 to 1, extending from the bottom of the dredged channel to the height marked in the section to represent the spring-tide level. There will be 193,520 square yards of rubble stone facing between Upton and Gloucester, or about 132,000 cubic yards, at 3*s.* 6*d.* per square yard, or 5*s.* 3*d.* per cubic yard. The stone can be procured at the Red Stone Rock, at Lincombe Hill, and at Holt Fleet. The mode in which the facing is to be done, is first to set the dredging machine at work, and then to throw the stone promiscuously into the channel, marks being set up for the guidance of the men who discharge the cargoes of stone. The rubble stone facing was my suggestion, and Mr. Cubitt has adopted it. I cannot tell how much sand or how much gravel will have to be dredged above Upton, as the quantity of dredging is so very small that I did not consider it worth while to examine very minutely. It would be a little harder to dredge stones than gravel, but not much, because if the stones were large we should remove the buckets from the machine and replace them with claws, which would take up detached stones. I estimate the excavation at 10*d.* per yard, which includes the removal of the soil, placing it behind the stone walls, and sloping it from the top. We shall be driven to the plan of dropping in the stones for the weir till they rise to the surface, when they will be placed by hand, except where we make a cut, and then all the stones will be laid by hand. At the foot of the weirs it is proposed to have rubble stone, sloping at an angle of 3 to 1. We propose to make our weirs water-tight by having the sheet-piling jointed and grooved, and, as it will be driven comparatively dry, the swelling of the wood when it comes in contact with the water will be quite enough to make every joint water-tight. We do not resort to puddling. I have not made any estimate of the cost of the land which will be taken, nor for any compensation in case the drainage is affected. I have only estimated the cost of facing one side of the river at any place. This estimate has been in progress two months. I have not made any alteration in it from the first, saving to correct some little mistake respecting the quantities.

Re-examined by Serjeant Merewether.—The reason why I use stone instead of dwarf piling is because it is more durable than timber, and more proper to be used; but if it became a question, and it was deemed desirable to use timber in any particular part, then I should adopt timber. There are localities near the river where we can get stone very easily. The price I have stated is quite sufficient to cover any difference in the nature of the soil to be dredged. In constructing a weir we first put in piling. I have no reason to apprehend that the stone will be carried away, because there will be a great mass of it, placed at a considerable slope; I think the weirs will be quite strong enough to resist all pressure. I have not made any of these weirs myself, but I have taken drawings of some which have well answered the purpose for which they were designed. The walls are of the same description as those adopted by me in the river Dee, which is a rapid river. My cross-examination does not shake my conviction in the least, as to the strength of the wall.

Mr. Cubitt examined by Mr. Serjeant Merewether. The following are the principal items of his evidence:—Our plan will not affect the drainage below Upton at all, and will be the best with reference to expense. The dredging at Maisemore will be so small that the effect of it upon the Gloucester channel will be inappreciable. We shall dredge in the deep water channel. The plan proposed above Worcester has been adopted because in that district our object can be better and cheaper attained by it and with less injury to the surrounding lands. As an explanation of this, six inches of water going over a weir 600 feet long would take all the summer water in the Severn; 25 inches over a weir so constructed would make a good navigation and effect a good drainage of the land, and before injury could ensue the weir would become obsolete. We seek a channel of 45 feet from Upton to Diglis, with a rise at three inches per mile. The amount of dredging here would be upwards of 300,000 cubic yards, at 1*s.* per yard, which would be £15,000, which is the price of all the works at Upton. The lift between Worcester and Upton Bridge must be the sum of two lifts. If the two falls be brought to Worcester there must be two locks at the double fall, which would be more expense, in addition to the cost of £15,000 for dredging. I therefore think this is a sufficient reason why the weirs and locks should begin at Worcester. I apprehend there will be no difficulty whatever in the works answering their purpose when made. In putting the weirs across the river quite square it becomes a dead stop in proportion to the height and width of the weir to a portion of the section of the river, and backs up the water; but the quantity of water that falls over the weir is never of a longer sheet than the breadth of the weir, so that were the banks full there must be an obstruction. An oblique weir is the simplest, cheapest, and most efficient to dam up the river without injury. [To elucidate this, Mr. Cubitt produced a model of the proposed works and explained them in detail to the Committee, and also the scientific principles on which they were adopted.] I have considered the point of the sluices in the weir. I think them inexpedient. The flood gates would have no perceptible effect in such a case; and flood gates, as such, in the weirs would cost more than the weirs themselves. The weir is quite as capable of penning off the water without flood gates as with them.—If any works are put to improve Lord Sandys' drain it would not impede the navigation. My object has been to raise all the works, towing paths, &c., above the floods.—I do not intend to dredge away the quantity Mr. Provis stated at Maisemore shoal, or to do more to it than will be necessary to let the Maisemore boat pass. There is more in the Parliamentary sections than is necessary to be done, and so far there is a greater degree of safety.—I was first employed to make observations on this river by Mr. Lea, the Chairman of the Association at Worcester. I made my report to Lord Hatherton, the Chairman of the Committee of the Severn Association. I had met Mr. Williams professionally before. I was engaged with Mr. Rhodes in the plan of 1836; that was a plan involving the erection of weirs above and below Gloucester; the weir below Gloucester would have been in a portion of the river now avoided by the Gloucester and Berkeley Canal. The plans of the present day are the same amended; I approved of them in general, but not in all things. I have no doubt that we might get six feet of water by dredging up to Worcester, but it would be much more expensive. It is proposed to place a wall where we dredge. I have estimated for eight miles of walling and dredging; that will answer the double purpose of narrowing the river and securing the banks.

Mr. Cubitt cross-examined by Mr. Wortley.—Mr. Williams correctly described the mode of laying down the rubble stone. At one time I proposed to use dwarf piling in some places; and I still intend to do so, where I think it will be as cheap and efficient. In some respects it is preferable to stone, in others it is not so. I can't mention any part of the river in which I think it will be preferable. I do not propose to make the slopes of the banks perfect in all places, as Mr. Provis did, because I think there will not be stuff enough to do it. The channel of the Deerhurst shoal is rather straight; the deepest water is towards the left bank going down. It is not absolutely necessary to stone up to the high-water mark. The length of the dredging on the river between Upton and Gloucester upon my scheme, as marked on the sections, is between eight and nine miles. I should remark, that it is marked deeper than will be necessary for the navigation. I do not contemplate any works below the Gloucester and Berkeley Canal, nor below the entrance to the Gloucester and Hereford Canal. The continuous length of dredging in the sections, from Upton to Diglis is nine miles. We propose to start from Upton at a depth of 7 ft. 6 in.; and we do so because I don't think 6 feet sufficient. By the 6 feet spoken of as the depth we seek, I mean 6 feet above the lock sills. I save all the dredging there by penning the banks. Were we to dredge from Gloucester to Worcester to a width of 45 feet at the bottom, to the level of the lock sill of the Gloucester and Berkeley Canal, 5 feet in depth, with a slope of two to one, and rising 3 inches per mile, the quantity to be dredged would be 323,133 cubic yards. (Witness then answered a series of questions as to the volume of water that would flow in channels of different widths.) We shall scarcely affect the fall below Upton. We propose at Upton to form a close jointed waterproof weir, slanting, 600 feet long, with timber pilings driven into the river, 10 feet apart; behind this we propose to drop stones into the river, without masonry. The expense of having the lock at Diglis, instead of Upton, would be very much increased on account of the additional fall. In some places where we construct our weirs we widen the river, in which cases the cross sections would be as great or greater than at present. I measured that section across the river at right angles to the stream. The height of the water above the weir is 6 inches. I know by principle, and partly by practice, that when the water is 2 feet above the weir the boats will go over. The water, in coming to the weir, does not diminish its velocity, and no more water would pass over the weir in consequence of its being oblique than if it were right angled. I do not make a pond, and therefore I do not cause a deposit. If you do any thing to diminish the velocity of the water coming through the weir it will tend to form a deposit; but if it be so constructed that the water coming through can keep moving on with the same velocity, it will have no more tendency to form a deposit than before the weir was put in. If I were to carry out the works at once I do not intend to make any alteration in the length of the weir; and if I did so at all, it would be to meet the views of others rather than my own convictions. If the river be increased beyond its natural width it will be more liable to deposits. The expenses of general maintenance of the works can never cease while the works exist. The expense of the navigation of the Ayr and Caldwell is very considerable. We do not alter the natural surface of the water at Diglis locks to any extent; if the weir were placed above the entrance to the canal, vessels would have the same depth of water. The reason I have for not placing it higher up the stream is that it would lengthen the cut very much, take more land, and much reduce the water to what I may call the harbour of Worcester. The length to the harbour is 1000 yards; it would increase the length of the cut about nine chains. There would be great passing of vessels from all places at the point, and therefore I think there should be a good harbour. If the vessels coming at the same time had to wait for the lockage, it would be the best place to wait in, but there would be little or no waiting, as they would pass the lock in three or four minutes. At Bevere Island I propose to put the weir below the mouth of the Salwarp; Mr. Rhodes in his last plan has placed it in the same place. By putting a weir in a shallow stream we raise the water; but the instant it gets so much above the weir as to lose a fall, from that instant the weir is no obstruction. I have had but little experience in salmon rivers; I understand there are good salmon in the Severn, and I should be very sorry to do anything to destroy them; I have nothing to do with how far these works will affect the rights of piscary; I have considered how to form the weirs so as not to obstruct the salmon in passing up the river; the weirs will not afford any facility for taking the fish. The average yield of the river at low summer water is from 40 to 60,000 cubic feet per minute above the Avon; the quantity of course differs below the Avon.

By Mr. Lowndes.—I have not personally taken the levels of the drains on the river Severn; I received information from Mr. Williams, and a great deal from Mr. Rhodes; I don't know that Mr. Rhodes personally took the levels. I received the greatest information on this point from the documents. I examined the drain on Lord Sandys' property myself; if you proved there was an under-drain there it would not matter on atom. I consider the sole operation of a drain to be to take the water off the surface of the land; the effect of an under-drain is to take off that which gets below the surface of the land. If there is an under-ground drain it does not follow that the level must be the same as that of the open drain. I do not know whether there is an under-ground drain at this place, but I believe all the drains on Lord Sandys' property come into the Severn below the weir.—When a fresh comes down the river the surface of the river will remain nearly the same as before the weir was put in. The works will raise the water on the river at Salwarp perhaps four feet. The value of the land to be taken will be proved hereafter by other witnesses. If it should be proved that 2000 acres for instance would be injured in their drainage by the bill, there has been no estimate made of the amount of compensation for that. I can't give any opinion as to the permanency of any damage that might ensue. I admit that the consequences of imperfect drainage would be to effect the atmosphere of the district. The state of the towing paths is not good; they give way on both sides of the river. When they have given way, it is generally the case that the land is encroached upon for a fresh one, which they are entitled to do. If they are entitled by their Act to take 10 feet on the side of the river, and that falls in, I am of opinion they can take 10 feet more; notwithstanding this, I do not think it is imprudent in us to undertake their management.

Mr. Mc'Neil examined by Mr. Serjeant Merewether.—I am a civil engineer, and have been engaged in many extensive works for a period of 20 years. I have been present during the last few days of this enquiry. I have been engaged in works of a similar description to the present. Having heard the plan, I think it would effect the desired object. I think it would be best to dredge up to Upton. I think, also, that the weirs will effect Mr. Cubitt's object. With reference to expense, I think it is the best mode that could be adopted. I think the explanation given by Mr. Cubitt has been so clear, that nothing remains to be added to it.

Cross-examined by Mr. Austin.—I was called in on this business on Monday week. I had not made a previous examination of the river Severn. I never did so. I have been across it at Chepstow, but never practically examined it. I do not know any other river of a similar natural character. I under what circumstances, so awful a catastrophe would have occurred, of course not even those best acquainted with the subject could pretend to describe. Mr. Cottingham has caused about 150 wagon-loads of rubbish to be removed from the tower in order fully to ascertain its state, and there can be no doubt that the measures he intends to adopt will give full security. One great advantage, too, of his plans will be to expose the 52 stone columns of the tower (a remarkably fine piece of masonry) to the view of persons in the church. In the mean time, so imminent does he consider the danger, that he will not suffer the bells to be rung, and all attention to the other parts of the works is suspended until satisfactory reparation has been made. The restoration will now be effected at a comparatively trifling expense; had the discovery not thus timely taken place, the cost would have been enormous. It is worthy of remark that so little were these subjects understood only a comparatively short period ago, that the western front was declared to be secured for hundreds of years, and yet in six weeks only from the time of that declaration it was a mass of ruins.—*Hereford Journal.*

LIVERPOOL DOCKS.

It will be recollected that in the last February number of the Journal, we gave a letter of Mr. Hartley's, the Dock Surveyor, addressed to the Liverpool Dock Committee, in consequence of certain charges being brought against him by a Member of the Committee, whereupon a Sub-Committee was appointed to inquire into the charges. This Committee have lately made their report which is now before us, we are happy to announce, what we feel assured the whole of the profession were prepared for, that it completely vindicates Mr. Hartley from the charges. The report is too long for insertion in our Journal, but the following announcement we are sure will be all that is necessary for us to give.

"The sub-committee, having personally examined the accounts at the Dockyard, and the system of checks on labour and expenditure of stores, are unanimously of opinion, after a very strict investigation of the stock accounts, and careful examination of the books, which show in detail the expenses incurred in every department of work, and making allowance for the expense of the establishment and maintenance of a large stock, that the various works have been executed on very reasonable terms, and at lower rates than they could have been in any other way. The interests of the Dock Trust, in the conduct and management of the mechanical departments of the Surveyor's establishment, have been materially promoted by the system which has been pursued; and, as long as that system is kept up in the same orderly, vigorous, and efficient manner, no better system can be devised for the general benefit of the trust, the establishment being highly creditable to the Dock Surveyor, *whose indefatigable zeal, honour, and industry cannot be too highly commended.*"

Removal of Sunderland Light House.—At a late meeting of the Commissioners of the river Wear, the taking down of the Light House being discussed, as part of the plan of building the new North pier at the mouth of the harbour, Mr. Murray, the engineer, suggested the removal of the Light House, in its present entire state, to the eastern extremity of the new Pier, a distance of about 420 feet, so as to make it serve the double purpose of a stationary and a tide-light. Mr. Murray exhibited a model of the building, and after explaining how he proposed to effect this undertaking, the Board decided that he should proceed forthwith to remove it. This Light House was erected about 40 years ago, by the late Mr. Pickernell, then engineer to the Harbour Commissioners. It is wholly composed of stone; its form is octagonal, 15 feet in breadth across its base, 62 feet in height from the surface of the pier to the top of the cornice, where it is 9 feet in breadth across, and the top of the dome is 16 feet above the cornice, making a total height of 78 feet; and its calculated weight is 250 tons. Mr. Murray intends to cut through the masonry near its foundation, and insert whole timbers, one after another, through the building, and extending 7 feet beyond it. Above and at right angles to them, another tier of timbers is to be inserted in like manner, so as to make the cradle or base a square of 29 feet; and this cradle is to be supported upon bearers, with about 250 wheels of 6 inches diameter, intended to traverse on 6 lines of railway to be laid on the new Pier for that purpose. The shaft of the Light House is to be tied together with bands, and its eight sides are to be supported with timber braces from the cradle upwards to the cornice. The cradle is to be drawn and pushed forward by powerful screws, along the railway above mentioned, on the principle of Morton's patent slip for the repairing of vessels. However surprising the removal of such a building may appear to many, yet in New York, for some years past, large houses have been removed from their original situation to a considerable distance, without sustaining any injury. The immense block of granite, serving as the pedestal of the equestrian statue of Peter the Great, at St. Petersburgh, was conveyed four miles by land, and thirteen by water. Several Obelisks have likewise been transported at different times from Egypt to Europe; and lately, one was conveyed from Thebes, and erected by the French at Paris. But the fact that the Light House on our North Pier is composed of stones of comparatively small dimension, its great height, and small base, make the operation of removing it much more difficult than any thing of the sort ever attempted. We heartily wish the enterprising engineer every success in his bold and novel undertaking, which is to be carried into execution in the course of a few weeks from this date.—*Sunderland Herald.*

COMPETITION FOR THE MARSEILLES EXCHANGE.

The following conditions of competition for designing an Exchange at Marseilles, we have translated from *Revue Générale de L'Architecture.*

1st. The situation will be chosen in a *perimètre* commencing at the "Rue de la Prison," and proceeding up to the "Place de Justice," the Grand Rue as far as the Courts.

2nd. The competition designs must contain, not only the Exchange strictly so called, but also the Chamber and Tribunal of Commerce, the syndicat of the money-changers, the royal brokers, the merchant counsel, and all the necessary appendages to these, such as peristyle porticos, vestibules, vestries secretary's office, registry office, bureaux, counting houses, &c. &c. Also a dwelling place for the porter, a guard-house for a detachment, and a place to deposit cloaks, umbrellas, and walking sticks.

3rd. The great hall of the Exchange, including the interior porticos must contain at least 3000 persons, and consequently have a superficies of not less than 1000 square metres.

4th. The drawings must be done with care, the sections to be in a pale colour, the horizontal sections in Indian ink, and carmine for the vertical sections, yellow for the wood, Pussian blue for the iron, grey for the metallic roofs, and brick red for the tile roofs.

5th. Each design must be composed of the following separate pieces.

1. An explanatory and justifiable report.
2. A general plan of the whole.
3. A plan of the ground floors at one or two metres above the level of the great hall, and the same of the first floor.
4. Longitudinal and a transverse section through the interior of the edifice.
5. Front and back elevations.
6. Profiles and details of execution (this need not be paid so much attention to).
7. A descriptive device containing a scale of the works, and the cost after the current price of the country; the whole exactly and summarily expressed.

6th. As to the order of architecture, the best in whatever order it may happen to be chosen, and even the several orders may be blended, but keeping at the same time a tone of convenience, solidity, elegance, good taste, a noble simplicity, and a wise economy.

7th. The scale of the general plan to be, 2 millimetres to a metre, that of the sections and separate plans a centimetre to a metre, and that of the details of execution 5 centimetres to a metre.

8th. The competition is fixed at six months date from the 1st April. During the following fortnight the competitors to deposit their designs at the secretary's office, at the Chamber of Commerce, where they will receive a certain number according to the order of presentation, the names and address of the competitors must be enclosed in an envelope carefully closed, to which the same number will be affixed. Each competitor to have a receipt stating the formal deposition, the number of plans, and the particular number given them, but without indicating name or person.

9th. When the term for the preparation of the plans has expired, the designs will be submitted to the judgment of a committee chosen from the members of the Chamber of Commerce, and an equal number of artists. The decision will not be definitive until the sanction of competent authorities be given, and then the names only of the authors of the three best designs will be announced.

10th. The first design will receive the prize of 3000 francs (120*l.*), and then, without further remuneration or honours, will remain the property of the Chamber, who will have the right to alter it at their will, and to confide the execution to whom they please. The names of the other two authors of the second and third best designs will be honourably mentioned.

11th. Every design (No. 1 excepted), will be restored to their authors, as well as the sealed envelopes containing their names, on the production of the previously delivered receipts.

Marseilles, March 30, 1841.

CANAL STEAMER FITTED WITH MR. P. TAYLOR'S REVOLVING SCREW PROPELLERS.

On Wednesday the 5th of May, we had the pleasure of inspecting a new steam boat on the river Irwell, fitted by Messrs. Peter Taylor and Co., of Hollinwood, near Manchester, with steam engines and propellers of an entirely new construction, both inventions of Mr. Peter Taylor, and for which he has obtained patents. The vessel is 75 feet long and 10 feet wide, and built (with the exception of the gunwale and paddle-box,) entirely of iron. She appeared to perform very satisfactorily; at a speed varying according to the depth of water from about eight to nine miles per hour, which upon a confined water we believe has never been attained by any steam vessel. In noticing a trial some months ago of another vessel belonging to Messrs. Taylor and Co., which had then been newly fitted with similar propellers, we gave a description of the apparatus, which consists of a number of continuous curved vanes or segments of screws, or wings on two axes. In the instance now under notice five pairs are affixed upon one axis, and five pairs upon the other; the number being regulated by, and varied according to, the power of the steam engines and the extent of surface of the vanes or blades, which have the appearance of small windmill sails, and have been very appropriately named *revolving screw scullers*: each set consisting of five pairs are six feet in diameter. The vanes of one set work betwixt the vanes of the other in the same manner as the teeth of cog wheels; by this arrangement the two sets, although six feet in diameter, are together contained in a paddle-box (there being only one): it is 9 ft. 8 in. in width, and placed at the stern of the vessel; the smallness of the space occupied offering great convenience for passing locks.—The scullers are well protected from the banks or sides and bottom of the canal, with which it is almost impossible they can ever come in contact. The paddle-box occupies seven feet in length, and has the effect of extending the boat so much. The width or breadth is regulated by the width or breadth of the boat, which in the present instance is 10 feet outside. The two shafts or axes are placed at an equal distance from each other, as well as at equal distance from the sides of the boat or box containing them, and with which they run parallel; and as we have before observed, the shafts or axes are so arranged in respect to each other, that the vanes or oblique surfaces of the one can enter between the vanes of the other shaft or axis; thus obtaining a great extent of propelling surface within a very confined space. The axes are placed considerably above the water line, and the curved oblique vanes or scullers are affixed upon the shafts or axes in opposite directions, that is, they are affixed upon one shaft or axis in such a manner that they may be said to form parts of a right-handed screw, and upon the other shaft or axis, so that they may be said to form parts of a left-handed screw. This novel propelling apparatus is worked by a pair of *semi-rotatory steam engines*, also Mr. Taylor's invention. The steam boiler is of the same description as those used upon the railways. It is placed towards the stem of the vessel, and the steam engines close up to it. To one axis of the propelling apparatus is coupled a shaft, which runs lengthwise to the steam engines. The starting, reversing, and stopping apparatus is connected with the regulator of the steam engine, and affixed at the stern of the boat, within reach of the steerer, who manages the whole when necessary. This is a most simple and beautiful arrangement, the helmsman being altogether independent of the engineer. He can start, stop, or reverse the engines at his pleasure. The helm or rudder is placed in the usual position, and is immediately behind the propellers.

The vessel has been engaged during the last month on the Bridgewater Canal towing boats; at one time she towed six boats, their united cargo being equal to nearly 600 tons, at the rate of three miles per hour, and at another time she towed four fly boats equal to 60 tons, a distance of six miles in one hour 16 minutes.—*Manchester Times.*

BENEVOLENT INSTITUTIONS OF THE ENGINEERS.

Since the notice which we gave in our last, the promoters of the plans for giving relief to the members of the profession and workmen employed by them, have succeeded in organizing an institution for each of their respective objects. That for the relief of distressed engineers has received the countenance of the Institute of Civil Engineers, and the Society for the workmen goes on, receiving increased support from the mechanical engineers, who we trust will give every support to an object so well deserving; a subscription list is now open, it has been, we are happy to say, liberally signed by the masters.

KING'S COLLEGE.

We are glad to learn that the department in King's College hitherto devoted to engineering, and to the mechanical and manufacturing arts is about to be extended, so as to embrace also the principles and practice of architecture. The existing provision in King's College for the education of the engineer having also drawn thither students in architecture in search of instruction adapted to their pursuits, the desirableness of the proposed extension became evident. King's College is then likely to be the first collegiate establishment to undertake the preliminary education of the architect as such, as well as in literature and science generally, and we cannot doubt of its success in so doing, nor of the good that will be thereby effected both to the profession and to the public.

Monument in Westphalia.—A remarkable monumental structure is at present raising, or about to be raised, in that part of Westphalia where Arminius overthrew the Roman legions, commanded by Varus, to commemorate that event. The monument is to consist of a statue of the German hero, similar to the many images which may still be seen under the name of "Ermin Sæulen," in various parts of Germany, and which became, in the early periods of the Christian era, objects of idolatrous worship. The statue is to be of copper, 42 feet high, and to the point of the uplifted sword 75 feet! It is to be placed on a circular temple 90 feet in height, on the top of the hill Teut, in the Teutoburger forest. The monument promises to do honour to German art, and the idea of erecting such a work is a proof of the patriotic feeling of the Germans. The expenses are to be defrayed by subscription, and all the sovereigns of Germany have contributed.

SEVERN NAVIGATION IMPROVEMENT.

Abstract of the Engineering evidence for improving the River Severn, given before the Committee of the House of Commons, on the Bill, May 5, 6, 7, 10 11, & 12, 1841.

Mr. E. L. Williams, Engineer, was examined and stated that the fall in the Severn is slight compared with the Thames. The fall in the Thames from Abingdon to Henley is 2 feet per mile. The fall in the Severn in this district is about 9 inches per mile. On the Thames also there were the conflicting interests of millers and others who had private rights connected with the water which was not the case with the Severn. The operations on the Thames have been to the benefit of the navigation. The course of the Severn is comparatively straight, and its width comparatively uniform, which circumstances are favourable for our operations. I attribute the shoals of deposit to variations of width. There is little tide above Gloucester, and this will not affect us. Our first weir is below Upton. We propose there to make a lateral cut, with a lock in it with a lift of five or six feet. Between Upton and Gloucester below the lock we propose to equalize the area, or water-way of the river, by contracting it by embankments in certain parts and widening it in others. The effect of contracting it will be to preserve clear what we have dredged. We shall contract the area by decreasing the width and lining the banks with stone. I have experience of the natural way in which the water-way is preserved. The finest channel in the river is from Sandy Point to the Mythe Bridge near Tewkesbury, which preserves the water-way throughout from the quality of the sectional area. I infer that if we form the same results we shall produce the same effect. The average depth there at low summer water is from 10 to 12 feet throughout. I anticipate that the artificial banks will be principally confined to the district between the Mythe and the Haw Bridges. This space includes the Deerhurst and other shoals which we propose to dredge. I have here the sections of what we propose to do. The first shoal of importance we propose to dredge is at Gloucester, in the eastern channel alongside the Quay at Gloucester, extending from the lock of the Gloucester and Berkeley Canal to the other bridge. In fact we propose to dredge to a trifling extent from the Westgate Bridge to Sandhurst, a distance of two miles. In the western channel we propose to dredge sufficiently to allow canal boats to enter the Gloucester and Hereford Canal. We then come to Wainlode Hill; there is not much dredging to be done there. We then come to the Haw, which is laid down for dredging to a certain extent, but not requiring the shoal to be taken out. There is a section laid down for the other channel, and there is sufficient water for the purposes of navigation under one arch of Haw Bridge. We then come to Deerhurst, where the area is to be equalized and the channel dredged. At Sheplock we do the same thing: also at Lower Lode up to Cumberland, where similar operations are required. We then come to Bushley Reach and Saxon's Lode, where we dredge and equalize the area. Then we come to Upton, where we make our first lateral cut. There will be no interruption to the navigation while the cut is being made, and when the weir is being made the lock will be open. The lock will be 20 feet wide, 100 feet long, with 5 ft. 6 in. lift. We then place our weir obliquely to the current, about midway between the upper and lower entrance. The length of the weir is 600 feet. It will be constructed with sheet piling and rubble stonework. The height of the weir above the surface of the present bed of the river will be seven feet. The effect of this weir will not prejudicially affect the drainage of the surrounding district. I have surveyed the falls of the lowest drains in the district, and find the lowest will be above our permanent water line. This answer will apply to all the drains throughout our operations. I have taken the greatest pains to satisfy myself on these points. We do not raise the water there in any way; and I believe the effect of the works will be to expedite the passage of flood water and not to detain it, because we clean out the channel. Above Upton we do raise the level of the water in some places, but in all cases it will be below the drains. I have made a section of Lord Sandy's drain. I find there is a fall of 9 feet in the first 100 yards of the land drain. The drain itself is below the weir, and consequently cannot be affected by it. We then come to the shoal at Ryal Watering, and take a little off the top of it by dredging. At Hanley we do not dredge, as we shall get sufficient water from the pound to pass over. Dredging with simultaneously pounding back the water would produce a bad effect. At the Rhydd we take the top of the shoal off. At Clevelode, Pixham, and Kempsey, we do the same. These are the shoals mentioned as affected by dredging. We then come to the Ketch shoal, which is to be dredged. The Silver Ford shoal is to be dredged slightly. We then come to lock No. 2, which will be similar to the previous one, a cut with a lock in it, each of the same dimensions as the other, with a lift of 7 ft. 6 in. and a weir. The water is penned back sufficiently at Upton Bridge by the shoal: the height of the weir will be 11 ft. 6 in. from the bed of the river, the length 400 feet; it will also be placed at a sharp angle, and constructed in the same manner as the other; the piles are elm, oak, and fir. After the water has passed over the dam of sheet piling, it will fall on a dam of stone work, and we thus prevent a pool there; this will remove the obstructions immediately above. We have now passed Worcester and are come to Bevere Island, where is our third lock: the river there divides itself into two branches, which supersedes the necessity of an artificial cut, and we deal with it as such, placing a lock of the same dimensions in one branch and a weir in the other; the lift is 4 ft. 6 in., the length of the weir is 400 feet; it will be placed obliquely as the others; with some trifling dredging this is sufficient up to Holt, where we have another lock, No. 4. The length of the proposed cut is about a quarter of a mile on the Ombersley side, on Lord Sandys' property. I know of no damage that the estate can suffer by our taking that bit of ground. Our works will not be in sight of Ombersley House, which is a mile and a half to the left; the length and construction will be the same, the lift 4 ft. 6 in.; the locks will be built of brickwork; the length of the weir there will be 350 feet, the height 7 feet from the bed of the river; the obliquity is to give facility to the passing of the water, this will operate to prevent dredging except very slightly up to Lincombe Hill, where is our fifth and last cut:

Fig. 10, M is the Electric Detector, for detecting injury caused to the wires, either by contact with the pipe or with each other, fracture, or water.

m, is a small battery; 1 *m*, 2 *m*, are "feelers," in connection with the battery and detector. Whenever these feelers touch each other, an electric current passes from the battery and influences the index of the detector M, by turning it on its axis. J J are iron boxes which occur at short intervals along the line, each fitted with a screw lid, and so connected as to render them continuous with the tube C. The terminations of each length of wire rope one introduced into the box and each wire screwed with its fellow to a piece of wood fitted to the bottom of the box, so that the wire marked 1 is continuous throughout its length and always connected by the screw 1, by which it can be recognized at every box along the line. The openings by which the wires enter the box are hermetically sealed with composition; but a small tube passing through the box admits of a free communication of air from a distant reservoir. Suppose wire 1 to have become in partial contact with the tube, either by the metals touching or the presence of water: upon opening the box at which the wire is to be proved, the screw 1 must be taken out, and the feeler 1 m brought in contact with one end of the separated wires, the other feeler being kept in contact with the pipe. If this portion of the conducting wire is sound, the detector needle remains stationary; but upon removing the feeler, 1 m, to the other liberated end of wire, the detector index moves on its axis, and indicates on the graduated scale the degree of contact existing between that portion of the wire and the tube. Supposing the experiment to be tried again at the next box, and the contact proved to lie between the two boxes, the intervening faulty portion of wire is exchanged for the sound wire marked 0, (which is a spare wire introduced by such repairs) by this means the wire 1 is again restored to soundness; it is obvious that different portions of the spare wire, 0, may thus be employed to repair a damaged wire, at numerous short intervals along the line, without rendering it necessary to disturb the line generally; the minutest changes in the insulation of the wires from dampness, &c., can be detected by this valuable instrument, and corrected by blowing through the pipe a draught of dry air from the reservoir.

When a length of wire-rope has to be removed, in consequence of accidental injury, the connecting screws in the boxes at each end of the length are taken out, and one end of the wires to be removed is bound to the end of a fresh length of wire-rope conveniently wound upon a drum. The further end of the faulty length is then drawn out of the tube and wound upon an empty drum, as the new rope gradually takes its place. The screws again unite the ends of the wires, and the line is restored. The faulty length of wire, after undergoing examination and repair, is again fitted for use.

Each wire is separately covered with cotton and India-rubber solution, and the set of wires made into a rope, which is passed through a hot resinous varnish before being introduced into the tubes.

Fig. 11.

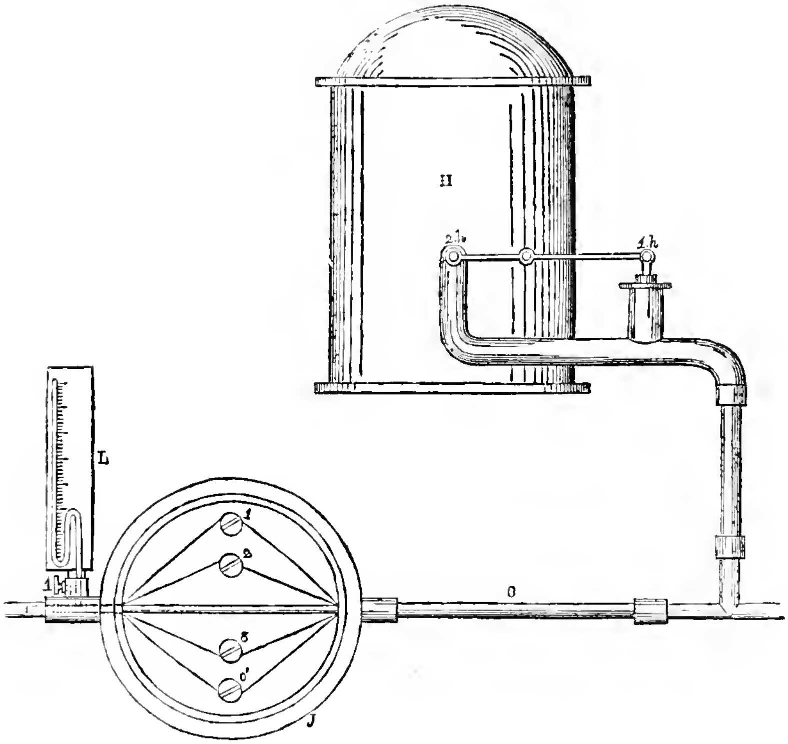

Fig. 11. Air-pressure apparatus, employed for excluding water from the tube, when carried underground; and for giving notice of defects in the tubing.

H is an air-pressure apparatus, or air reservoir, of convenient size, charged with dry air to any pressure. 1 *h* is a pressure balance, in the form of a lever; 2 *h* a valve communicating, by a minute opening, between the reservoir H and the protecting tube C. Suppose it to be found desirable to keep the interior of the tube under a pressure of two or three pounds (that being calculated as sufficient to exclude the greatest pressure of water to which the tube is liable), the balance 1 *h* must then be loaded to that amount; on any escape of air taking place from the tube, the lever arm, 1 *h*, would descend and open the valve 1 *h*, till the high-pressure reservoir had increased the pressure of the tube, which by raising the pressure-balance 1 *h*, would close the valve 2 *h*. A barometer, L, may indicate the change of pressure either in the reservoir or tube. The reservoir is supplied by an air-pump, when nearly exhausted by any leakage, which, under the light pressure of two or three pounds, should be very trifling. Should the barometer, however, indicate a sudden escape of air, attention must immediately be directed to the proving-boxes J, which occur at short intervals along the line.

In or near the box, conveniently connected with the tube, is a three-way stop-cock, to the pipe of which a portable barometer or detector, L, can immediately be applied. When the tube is faulty, upon turning the cock in one direction, the pressure on the barometer will remain steady, but in the other direction it will rapidly diminish, from the escape of the air. By proceeding with a similar experiment at other proving-boxes, the two boxes will be readily ascertained between which the escape of the air takes place; when the tube lying between the last proved points must be carefully examined to discover the faulty part.

THE ARTESIAN BORING AT PARIS.

In the Journal for April last, we gave an account of the successful operations in sinking the Artesian well at Grenelle; we are now enabled to furnish some farther detail of the geological formation through which the boring passed, from the observations of M. Mulot given in the *Revue Générale*, together with some additional information as to the size of the bore, and the geological character of the circumjacent country.

Table of the depths of the strata measured from the surface in metres and reduced to English feet.

Metres.	Feet.	
10	33	Alluvial formation, the former bed of the Seine.
41	134	Plastic clay and quartzose sand.
140	459	White chalk with black flints.
165	541	Gray chalk and flint.
506	1660	Gray chalk, very hard, with layers of micaceous clay.
546	1791	Blue clay, green clay, micaceous black clay, with fossils and iron pyrites.
547	1794	Argillaceous green sand.

Beyond here the sand continues and has not as yet been quite explored, it is in this stratum that the water is obtained.

The boring was commenced at a diameter of 0·51 metres (20 inches) and diminished by degrees as the tubes descended, the first four columns of tubing diminishing as just observed, to the depth of 145 metres (576 feet); at this point the diameter was 0·31 centim. (12 inches).

A 5th column of tubing goes down to 350 metres (1148 feet), with a diameter of 0·26 (10 inches.)

A 6th to 410 metres (1345 feet) diameter 0·21 ($8\frac{1}{4}$ inches.)

A 7th to 540 metres (1771 feet) diameter, 0·17 ($6\frac{3}{4}$ inches).

The last 7 metres (23 feet) are not tubed.

The fixing of the ascensional tube is always an operation very important and delicate, and will on this occasion in particular present serious difficulties. Indeed one would suppose that it was almost impossible to lower perpendicularly a tube 547 metres (1794 feet) high into the earth, but from M. Mulot's skill, of which he has given so many proofs during the work, we are completely assured of its final success.

The quality and kind of metal which composes the ascensional tube have been studied by persons interested in the construction of the well; for many tubes of this kind have been constructed of wrought iron, and have not answered the expectations of the parties interested. A remarkable instance may be cited which happened at Saint Cyr, near Tours, at Dr. Bretonneau's artesian well. The water there rises from the sand beneath the chalk, and was tubed with iron, yet every successive year the quantity of water was sensibly diminished, and at last gave only an insignificant supply. M. Bretonneau caused the tubing to be drawn up, and although it had at least a thickness of 8 millim. ($\frac{3}{10}$ of an inch) and was well preserved, yet at the joints of each pipe there was one, and sometimes several circular holes two and even three centim. diameter, (about an inch diameter,) of which the edges were perfectly sharp, as though they had been cut out by a pair of nippers. This phenomena was probably due to an electro-chemical action, and it shows that iron ought to be entirely rejected in the construction of ascensional tubes. Tubes of oak or elm are certainly those to which preference is always given; but the thickness which is indispensable for them, would diminish the interior diameter too much in the Grenelle well. Copper tubes of a thickness of two or three millim. (about $\frac{1}{10}$ of an inch), not only possess a sufficient resistance, but also the property of being indestructible. It is with these latter, therefore, that the Grenelle well is to be tubed.

Independently of the importance of M. Mulot's undertaking for the useful purposes to which it may be applied, it is also of great interest for the geological study of the strata through which it traverses with regard to the central heat of the globe. Taking as our starting point the constant temperature of the cellars of the Observatory, which are 28 metres (91 feet) deep, the temperature would present a uniform increase of a degree centigrade for every 32 metres (105 feet) in depth. The temperature of the water of this well has been calculated at about 27·6 Cent. (8·17 Fahr.)

The cretaceous formation, passed through by the well of Grenelle, has been deposited in successive layers in an immense basin, formed by the formations anterior to this part, of the secondary formation; the borders of the inferior strata of the chalk formation, crop out in many places, some on the edges of the basin and others a little below the soil; they not only receive the infiltrations of the rain water, but also those of rivers that flow over the exposed strata. A complete identity has been found to exist between specimens of brown free stone and green sand obtained in very different places, and very far one from another, and specimens from M. Mulot's boring. At Lisieux in Normandy, the inferior part of the cretaceous formation reposes on the Jura formation;—the limit of which formation extends towards Mans and La Flèche, and receives in this part considerable infiltrations from the Loire, which flows direct upon it N. E. of Angers. The Loire ought also to furnish water to the lower part of the formation near Saumur; the boundary then passes south of Paris by Loudun, Châtellerault, to the north of Bourges, and then to Sancerre. In all these different localities it receives the waters of the Vienne, Creuse, Indre, Cher and Loire; at Sancerre this limit takes a northeast direction passing near Auxerre, Joigny, and Troyes, and receiving the waters of the Yonne, Seine, Aube, and a great many other rivers of less importance. Near Troyes,* at Lusigny, and at the Abbey of Monster-Rancey, at four leagues south-east of Troyes, the brown free stone and the green sand crop out. In its northern direction through Sainte-Menehould this boundary receives the waters of the Aisne very considerably. Lastly, this formation forms the bottom of the tertiary formation of Belgium, where it receives other infiltrations that feed the Artesian wells of Picardy and Artois, &c.

All these waters filter freely enough through the sand of the cretaceous formations, and from thence pass and accumulate at the bottom of the basin, continuing to be in direct communication with the points of infiltration. As these points are so much elevated above Paris, the waters rise, and will rise still more in the Grenelle well when it is completely tubed, to a height which will be a measure of the amount of pressure exercised on the layer which forms as it were the roof of the bottom of the basin.

ON THE GIVING WAY OF EMBANKMENTS.

The following remarks on the giving way of embankments, by M. Colin, principal engineer of the bridges and embankments of one of the largest canals in France, are the results of many years practical acquaintance with the subject.

The first appearance presented by a slope that has given way is that of an alteration more or less complete of its primitive form, whether natural or artificial. On examining the facts which strike the eye of the observer it must be at once admitted that the cause of the fall of a mass of moving earth must have operated either at a certain depth, or near the surface of the slope; therefore it is requisite, in all cases, to distinguish the superficial slips of earth from those that have a deeper origin.

When a mass of homogeneous earth is composed of argillaceous matter, which is liable to give way, the strata may be more or less inclined to the horizon. When the slip occurs on a pre-existing surface, the following considerations will not be applicable; the slips of this kind are very rare, and are only accidental occurrences, which we should be careful not to confound with the general facts examined by M. Colin.

The mass of fallen earth whether natural or artificial, could not have been in a state of equilibrium in relation to the cohesion of its particles, which on the one hand tended to hold it together—and to gravity, which, on the other hand, tends to destroy the cohesive attraction. When this equilibrium is destroyed it must happen that the slope, or a part of it, will experience a spontaneous fall.

When by the action of the fall the moving mass is detached at such a depth that it preserves its central cohesion notwithstanding the fracture, which has destroyed the cohesion only on the surface of the slip, and notwithstanding that relative alteration in the angle of the strata which compose that mass,—in such case the cause of the slip must be pronounced to have proceeded from below, in contradistinction to that fall which occurs when the moving mass is detached nearer the surface, and when the cohesion of the mass is more or less destroyed by the action of external agents. It often happens, however, that both these kinds of slip occur at the same time.

This characteristic difference depends on the chemical nature of the soil, so that the same kind of slope may in one case experience a falling away from the surface alone, when in another case the cause of the slip may be more deeply seated.

There is another important difference between slips of earth proceeding from the surface and from below, which is, that the extent of the former is immediately known, while that of the latter may go on gradually increasing, according to the influence of rain, frost, and thaw. In every case, however, it is the action of gravity which causes the disturbance of the equilibrium; for the destruction of cohesion by the external agents is only an action eminently statical; the force of gravity alone causes the movement. It is therefore natural to infer, that as the principal cause of the destruction of the equilibrium is the same in all cases, the dynamical results must also be the same. Consequently the surfaces of slips, whether they proceed from below or from the superficies, ought, theoretically speaking, to be of the same kind, and to present, as regards their material points, a striking resemblance.

On examining with great care the general facts concerning these two kinds of spontaneous slips of earth, the angle of inclination of the falling earth, and that of the surface on which it falls, and comparing them with a great number of facts collected in various places, with different kinds of soil, and under different circumstances, by other engineers, as well as by M. Colin himself, he thinks he has established as a principle the following proposition:—

"When masses of earth nearly homogeneous, whether natural or artificial, are composed of such materials that the action of gravitation may, under the influence of certain physical circumstances, overcome the cohesion of their molecules, the results are spontaneous movements, which are called slips. These movements are independent of the height of the slopes on which they occur; they always present, nearly in the same degree, the character which appertains to them; lastly, and above all, the natural surface of separation, or the surface of the slip, has no pre-existence, and possesses a constant and regular form, which approaches more or less exactly, according to different circumstances, to a surface of a cycloidal shape, which brings the causes of its formation essentially within the domain of mechanical science."—*Inventors' Advocate.*

HEREFORD CATHEDRAL.

The public are already aware that very extensive improvements have for some time been going on in this beautiful edifice under the superintendence of Mr. Cottingham, the celebrated architect. We have already described the various restorations in the choir, Lady Chapel, &c., but all the interest in these (and it has been very great) is altogether lost in the discovery by the architect that the tower of the cathedral, with its immense superincumbent weight, is in imminent danger of falling, and crushing the mighty fabric in one general ruin. Before entering into a somewhat technical description (which may perhaps be understood only by a few) of the appearances that lead to this conclusion, we may observe, that we have examined the present state of the tower most minutely, and the fissures in the masonry at the angles of the Norman arches of the transepts are truly frightful. In some places the workmen may insert a piece of wood or any implement to the depth of two feet; and we particularly noticed that one of the stones forming the masonry had given way, not at the joining, but in the solid part itself, being literally split in two. It appears that some cracks in the chief wall of the tower led Mr. Cottingham to examine into the cause. He accordingly proceeded first to ascertain the state of the main piers below in the body of the church, and these he found to be all solid. He next explored the masonry of the unsightly piers under the Norman arches of the north and south transepts, and ascertained that the arch was quite independent of this enormous body of masonry; that is, that the Norman arch had "stuck firmly to its work," and that, as has long been suspected, the piers were no support whatever. Mr. Cottingham next examined the string course round the bell chamber, which supports the 52 solid stone columns above that chamber, and he found that this course (or wall, as we should call it) was rounded in the centre, and dipping down at the angles of the tower. This proved that the ancient Norman arches were still in their original position, and that the fractures which now exhibited themselves in every direction were occasioned by some defect in the main piers of the tower. On taking up the bell-ringers' floor, Mr. Cottingham found the stone groining (which was put up about the time of Edward IV.) also pressing upon the four angles of the tower. It is singular that the "pockets," or angular spaces of this groining, were filled up to the level of the floor with solid rubbish. On removing this, a most extraordinary failure in the masonry fully developed itself. At each end of the four angles was a hollow chamber running diagonally through the main wall, which, from the pressure of the enormous stone piers above alluded to, was crushing in in every direction. All the bond of the interior ashlering was ascertained to be broken, and the stones fractured into innumerable pieces; indeed, the failure is awful to contemplate, and we may congratulate the public that the discovery was made previously to any further pressure, which must have occasioned the total destruction of this magnificent tower, together with the choir, the transepts, and the eastern portion of the nave. When, or

* The specimens from Lusigny were presented by M. Volfardric, who observes that the height of the well above the level of the sea is 130 metres, whilst that at Paris is only 31 metres.

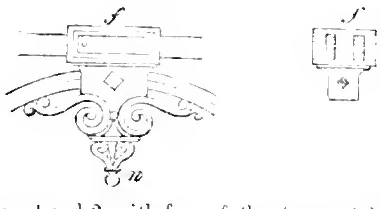
RAILWAY STATIONS.

The Revue Generale contains a description of several Railway Stations both in England and on the Continent, illustrated with details of their construction, from which we extract the following information relative to the Paris Station of the *Left Bank Versailles Railway*, situated near the barrier of Maine.

The terminus of the railway is on an embankment 23 feet high, which offers serious impediments to the construction of buildings, turn tables, and other works requiring solidity. The terminus consists of three ways with a platform on each side for the passengers on their arrival and departure. The whole of this was covered over with a semicircular roof of iron, which fell down soon after its construction, during a hurricane on the 16th of September last. The semicircular form without any stays forming direct angles is at all times a bad mode of constructing buildings, where they are subject to the powerful action of the wind, as its force impinging upon any part is transmitted through the whole, and when successive gusts of wind are continued, this transmission of the force becoming more and more formidable like a wave in a tempest, must in the end lead to the destruction of any building that is built of such slender materials as the one now before us. The roof possesses considerable ingenuity in its construction, for its lightness and elegance of its form, we shall therefore notwithstanding its failure, proceed to give some account of its construction.

Fig. 5.



The roof is of a semicircular form 161 feet long, and consists of 13 main ribs or arches placed 12 ft. 6 in. apart in the clear, 10 of which were 57 feet span, and three at the extreme end of the station 70 feet span. A section of the roof is represented in figs. 1 and 2, with four of the tangential curvilinear stays omitted. The main ribs spring from an upright cast iron base (fig. 2,) standing on the timber piles which carry the passengers promenade platforms, these piles are tied across the railway transversely at about 4 feet below the top of piles, or 3 feet below the surface of the rails by strong wrought iron ties, to prevent them spreading. The ribs are composed of 5 bars of wrought iron up to the top of the column, fig. 2, the two external bars ½ inch by inch, the two next ½ by 1½ inch, and the centre 1½ by 2 inches, all bolted together; above the column and up to about two-thirds the height they have only 4 bars, omitting the centre, and the remainder have only the 2 external bars. These ribs are strengthened by tangential curvilinear stays, consisting of wrought iron bars ¾ inch square placed diagonally and secured in the centre by the ornamental coupling *n*, fig. 5, and at each end by the pendant *x*, shown more in detail in fig. 6, and secured to the main rib. There are also similar tangential curvilinear stays springing from the same pendants at right angles to carry the purlin bars as shown in the lower part of fig. 3, for the support of the rafters and covering, the lower tangential stays abut upon the top of the wrought iron column 1½ inch diameter (fig. 2). The pendants (fig. 6.) consist of a cast iron baluster, the 2 bars of the main rib passing through the head (*a*), and also at right angles the purlin bar. The 4 ends of the tangential bars are secured in the holes at the 4 angles of the base *c*, which is hung up to the bars of the rib by a nut and screw bolt passing through the centre of the pendant; the d an *c'* shows the position of these holes, that in the centre receiving the bolt just described, and those at the 4 angles the tangential stays; the drop *e*, with the collar *d*, is fastened on to the top of the pendant and conceals the bolts, the bottom part of the baluster fits in with the conical shaped end (*b*) into the embrasure (*c*).

Fig. 6.

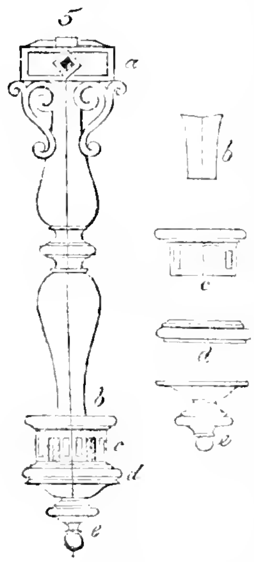


Fig. 7.

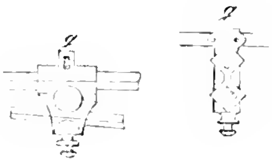

Fig 8.

The purlin bar and the curvilinear stays were secured by the coupling *g*, fig. 7, and fig. 8 shows the coupling of the purlin and the rafter *h*, which were of wrought bars 3 by ¾ inch placed 18 inches apart, as shown in fig. 4. The covering was of galvanized sheet iron laid with a folded seam similar to zinc.

The upper part of the roof was covered entirely by a skylight, laid to an angle of 25°, the lower part was supported by the light ornamental iron work shown in fig. 3, supported by the tangential stay bars.

We here give the weights of the principal parts.

Base of the column	5 lb.
Capital	9¼ lb.
Pendants of cast iron	26 lb.
Great S shaped guard of the lantern	36¼ lb.
The parts *m*	10½ lb.
n	7¾ lb.
o (cast iron)	7¼ lb.
p	3¾ lb.
h	¾ lb.

The total weight of the casting of the roof was 5 tons 6 cwt.

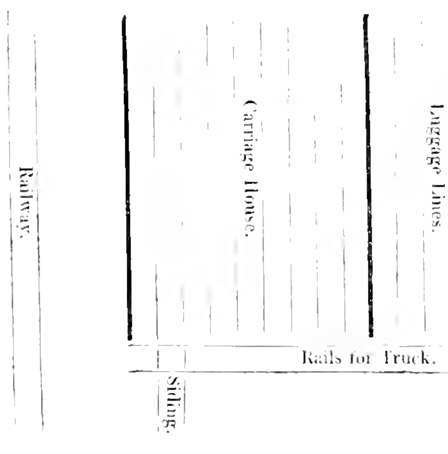
That of the other iron work 13 tons 5 cwt.

The total cost including painting and glazing was 25,000 francs, (1000*l*.), and as there were about 1000 square yards of surface, that gives 1*l*. per square yard covered, undoubtedly an exceedingly low price.

It will be seen from the preceding description what a great number of cast iron pendants and couplings compose this roofing, but at the same time that the different shapes are not numerous, and that the models are few. In wrought iron in order to obtain this variety of shape, it would have been requisite to have forged each piece separately, and to have had much manual labour. It will be further perceived that all the pieces are simply cut in lengths, without being re-forged or filed. The iron on coming from the forge, is bent cold according to the form required, and then fixed in the cast iron pendants by means of bolts, so that it is not necessary to employ iron of superior quality that can be worked hot: it is only necessary that it should not be cold short. It is this arrangement to which we principally wish to call attention, as it is the reason which has induced us to publish the preceding description, as an instance of an iron roof easily put together and composed of a minimum weight of cast and wrought iron. It will be seen that such work can be made at a distance and then put up on the spot. It is only necessary to send the pendants and couplings, and the bars of rough iron, which are to form the roof, and which can be cut up on the spot, and bent according to circumstances. As the coupling pieces are of cast iron, ornaments can be introduced in the casting, and an elegant appearance given without much expense. With these advantages had M. Fauconnier designed it with lines so as to have formed geometrical figures of fixed position, we have no hesitation in saying that it would have been a most remarkable work.

At the same station for the purpose of communicating between the main rails and the carriage house, which is parallel to them, a siding is carried from the main line to the front of the carriage house, as shown in fig. 9. The latter contains four lines of ways running from

Fig. 9.



from front to rear, and outside of it are five more lines of way for the luggage trucks. Along the front of the carriage house, and at right angles with the rails is a pair of rails laid to a gauge of 7 ft. 4 in., and 9 inches below the lines of way, upon which runs a carriage, shown in figs. 10 and 11. On the top of this carriage, and on a level with the

Fig. 10. Plan of Truck.

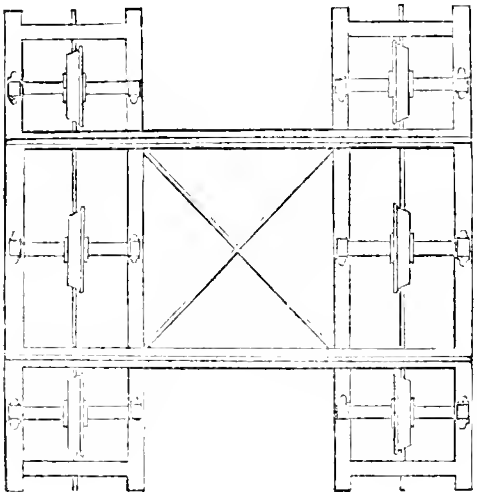


Fig. 11. Section of Truck.

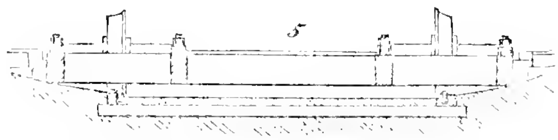
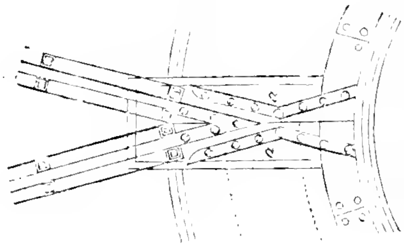


rails of the main line are corresponding rails supported on timber framing, which is suspended to the axles of six cast iron wheels, 20 inches diameter. These wheels run on the 7 ft. 4 in. gauge for the purpose of removing the carriage or truck which is put upon the frame to any pair of the reserve rails in the carriage-house. This saves the trouble and expense attendant upon turn tables opposite to each pair of rails.

Fig. 12.



The engine house is a polygonal building containing twelve lines of way, in the middle of which is a turn table communicating with the whole. The construction of the points is shown in the annexed figure 12.

Glass Cloth Weaving.—A most ingenious artist, a Mr. Barker, from Ossett-street-side, is now exhibiting the process of this novel species of manufacture, in a room in the Philosophical Hall, Halifax. He has lately forwarded a most splendid apron, and a pair of slippers, to her Majesty the Queen, which have been most graciously received, with the strongest approbation. We have seen some very beautiful specimens of the ingenious inventor's skill, and consider them as splendid novelties. We particularly noticed a piece of waistcoating, two and three quarters yards long, and half a yard in width, which he states to be the first of the kind he has been able to bring to any degree of perfection, and has been woven in Huddersfield. It is beautifully figured like damask or fancy work. One remarkable circumstance in glass cloth is that it will stand washing. We were shown a piece of pure white, which has six times undergone that process. We hope the ingenious and persevering man who has already spent two years and a half in bringing his invention to a state fit to meet the public eye, will reap his reward for his invention.—*Halifax Guardian.*

ON THE ECONOMY OF FUEL IN LOCOMOTIVES CONSEQUENT TO EXPANSION AS PRODUCED BY THE COVER OF THE SLIDE VALVE.

Sir—With a view to economy of fuel, locomotives are now generally constructed so that the slide valve shall have what engineers call "cover on the steam side," the effect of which is, that steam is admitted to the cylinder during only a part of the stroke of the piston, and during a part of the remainder that steam by expanding to occupy a greater volume propels the piston; which expanding increases the work performed by a given quantity of steam to an extent depending on the ratio of that part of the stroke, during which the steam is admitted to the cylinder, and that part of it during which the steam is expanding; and as the consumption of fuel is dependent on the work performed by a given quantity of steam, an analytic investigation of the cover of the slide valve is the object of the following.

In the figure* let F′ G, represent the connecting rod, F′ E the engine crank, E A′ the eccentric crank, F E the engine crank when the piston commences its stroke, and E A the corresponding position of the eccentric crank, B C, D C valve levers. Put E A′ $= a$, E F′ $= d$, cover of valve $= c$, lead of valve $= l$, B C $=$ D C. To diminish complication neglect the radiation of the eccentric rod and connecting rod, which may be done without sensible error, since their length is great in proportion to the lengths of the cranks.

Draw L E perpendicular to E B, and any angle L E A has its sine proportional to the distance that the valve is from its position when L E A $= o$. When the piston is commencing its stroke the valve is open, the quantity (l), and therefore it has travelled the quantity $(l + c)$ from its position when L E A $= o$; hence $a \times$ sin. L E A $= l + c$

$\therefore$ sin. L E A $= \frac{l + c}{a}$, and cos. L E A $=$

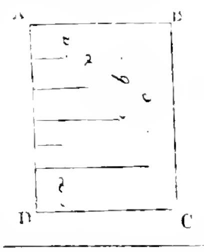
$$\sqrt{\left(1 - \frac{(l+c)^2}{a^2}\right)}$$

Again, if the engine crank travels over any angle (φ) from its position, F E the descent or progress (y) of the piston is equal to $d \times$ versin φ, $\therefore$ cos. $\varphi = 1 - \frac{y}{d}$, and sin $\phi = \sqrt{\left(\frac{2y}{d} - \frac{y^2}{d^2}\right)}$. The travel (x) of the valve corresponding to the travel (y) of the piston, is equal to $(a$ sin. (L E A $+ \varphi) - a$ sin. L E A), $\therefore \frac{x}{a} =$ sin. L E A cos. $\varphi +$ cos. L E A sin. $\varphi -$ sin. L E A, and by substituting for the functions of the angles their values found above, and reducing we get

$$x^2 + 2x(l+c)\frac{y}{d} = a^2\frac{2y}{d} - a^2\frac{y^2}{d^2} - (l+c)^2\frac{2y}{d},$$

an equation expressing the relation of (x) and (y) in terms of known quantities.

When the piston begins its stroke the valve is a little open, and steam continues to enter until the valve in its retrograde motion shuts the passage; expansion then commences and continues until the eduction passage is opened. When the eduction passage is opened on one side of the piston it is shut on the other, which gives rise to the compression of steam on the educted side of the piston, and this compression continues until the valve opens for the lead of the next stroke.



In figure let A B C D be a steam cylinder, stroke $=$ A D $= 2d$, $a' =$ distance from commencement of stroke to commencement of expansion, $b =$ distance from commencement of stroke to end of expansion; $c' =$ distance from commencement of stroke to position of piston when the valve opens for the lead of next stroke. To find by the above equation the travel of the valve corresponding to the travel (a') of the piston substitute $x = -l$, for the travel corresponding to (b) $x = -(l + c)$, and

* The figure is not quite correct; the line should be drawn [illegible] and not from f' to a'.

for the same in relation to (c') $x = -(l + 2c)$. And we have

$$x = -l \text{ and } y = a' = \frac{d(a^2 - lc - c^2) + d\sqrt{(a^2 - lc - c^2)^2 - a^2 l^2}}{a^2} =$$

$$d(1 - lc - c^2) + d\sqrt{\left\{(1 - lc - c^2)^2 - l^2\right\}}. \quad \text{When } a = 1$$

$$x = -(l + c) \quad y = b = \frac{a^2 d + d\sqrt{a^4 - a^2 (l + c)^2}}{a^2} = d + d\sqrt{1 - (l + c)^2}$$

$$x = -(l + 2c) \quad y = c' =$$

$$\frac{d\left\{a^2 + lc + c^2\right\} + d\sqrt{\left\{(a^2 + lc + c^2)^2 - a^2 (l + 2c)^2\right\}}}{a^2} =$$

$$d(1 + cl + c^2) + d\sqrt{\left\{(1 + cl + c^2)^2 - (l + 2c)^2\right\}}$$

Having now found the values of $(a'$ b and $c')$, we must next find the effect gained by the expansion of the steam from $(a'$ to $b)$, and the effect lost by the compression of the steam from $(b$ to $c')$. But expansion may take place in two ways, the operations of which are quite distinct, first, the cylinder may remain of the same volume and the steam be increased in pressure before entering them; or, the cylinders may be enlarged and the pressure of the steam be constant, which is the plan virtually adopted in locomotives; for those of them that do not work by expansion when properly constructed, are so made that their cylinders are not capable of consuming a greater volume of steam than the boiler can furnish of the greatest safe pressure.

The eduction passage being shut by the time that the piston arrives at the end of (b), saves, or at least prevents from flying to the atmosphere a quantity of steam of a pressure (t), that fills $(2d - b)$ of the cylinders, which at a pressure (p) would fill $\frac{(2d - b)t}{h}$ of the cylinders hence when the steam is cut off at (a'), there is only admitted so much fresh steam as fills $(a' - \frac{(2d - b)t}{h})$ and since the quantity of fresh steam admitted must (whatever the expansion is) be constant, we have $s\,(a' - \frac{(2d - b)t}{p}) = 2d \times 1$, $\therefore s = \frac{2dp}{a'p - 2dt + bt}$, (s) being the area of the piston.

Again in figure let (x) be any portion of the stroke greater than (a), and less than (b), and let p' be the pressure into which the steam has expanded at the end of (x) then $x : a' :: p : p'$, $\therefore p' = \frac{ap}{x}$ $\therefore$ effective working pressure $= \frac{ap}{x} - t$.

$\because$ differential of work performed $= d$ efficiency $= s\,(\frac{ap}{x} - t)\,dx$,

$\therefore$ efficiency in part (b) of the stroke $= s\,ap\,(\log \frac{b}{a} + 1) - s\,t\,b$.

Again, for the effect of compression caused by the shutting of the eduction passage let (x) (measuring from D C) be any portion of the stroke between $(b$ and $c)$, and (p') the pressure, to which the confined steam has been compressed, then $x : 2d - b :: t : p'$ $\therefore p' = \frac{(2d - b)t}{x}$, $\therefore$ effective working pressure $= \frac{(2d - b)t}{x} - t$ $\therefore d$ efficiency $= \left(\frac{(2d - b)t}{x} - t\right) s\,dx$, $\therefore$ whole effect of compression $=$

$$s\,t\,(2d - b)\left\{\log. \frac{2d - b}{2d - c} - 1\right\} + s\,(2d - c)\,(p + t.)$$

By deducting the effect of compression from the efficiency of the part (b) of the stroke, we have whole work performed $=$

$$s\,a'p\left(\log. \frac{b}{a'} + 1\right) - s\,t\,b - s\,t\,(2d - b)\left\{\log. \frac{2d - b}{2d - c} - 1\right\}$$

$- s\,(2d - c)\,(p + t)$. Put $2d = 1$, $t = 1$ and (p) is then expressed in multiples of (t). $\therefore$ whole work performed $=$

$$s\,a'p\left(\log. \frac{b}{a'} + 1 - s\,b - s\,(1 - b)\left\{\log. \frac{1 - b}{1 - c} - 1\right\}\right)$$

$- s\,(1 - c)\,(p + 1)$.

$$\text{But } s = \frac{p}{a'p - 1 + b}$$

$\therefore$ Whole work performed $= \frac{p}{a'p + b - 1}$ multiplied into

$$\left\{a'p \log. \frac{b}{a'} - (l - b) \log. \frac{1 - b}{1 - c} + a'p - 2b - p + pc + c.\right\}$$

An expression for the work performed by a unit of volume of steam, formed of known quantities, or rather of quantities which become known when (l) the lead, and (c) the cover of the valve are given.

Let the safety valve be so loaded that (p) is equal to (s), and let the lead (l) of the slide valve be nothing, and the cover (c) be nothing. Then $a' = 1$, $b = 1$, $c' = 0$, $\therefore$ whole work performed $= p - 1 = 4$, which is exactly what another mode of proceeding gives for when the valve has no cover and no lead, the work performed is evidently $= 2d\,(p - t)\,s$. But $2d = 1$, $t = 1$, and when the valve gives no expansion $s = 1$, therefore work performed $= p - 1 = 4$.

Again, let the lead (l) be equal to $\frac{1}{6}$ of the breadth of the port, and the cover (c) equal to $\frac{1}{4}$ of the breadth of the port. And then
$a' = 0{\cdot}888$ $b = 0{\cdot}9545$ $c' = 0{\cdot}992$ $\therefore$ whole work performed $= 4{\cdot}2378$.

Again, let $l = \frac{1}{6}$ breadth of port, $c = \frac{1}{2}$ breadth of port, and then
$a' = 0{\cdot}656$ $b = 0{\cdot}873$ $c' = 0{\cdot}99$ $\therefore$ whole work performed $= 4{\cdot}8966$.

Again, let $l = \frac{1}{6}$ breadth of port, $c = \frac{3}{4}$ breadth of port, and then
$a' = 0{\cdot}2881$ $b = 0{\cdot}7$ $c' = 0{\cdot}975$ $\therefore$ whole work performed $= 7{\cdot}1$.

Again, $l = \frac{1}{100}$ breadth of port, $c = \frac{3}{4}$ breadth of port, and then
$a' = 0{\cdot}43$ $b = 0{\cdot}825$ $c' = 0{\cdot}999$ $\therefore$ whole work performed $= 1{\cdot}97$.

Hence the following conclusions:—In a locomotive in which the stroke of the cylinder is 18 inches, and breadth of port $1\frac{1}{2}$ inches, if the work it performs with a ton of coke when the valve has no cover be called 1; then by giving the valve $\frac{1}{4}$ of an inch of lead, and $\frac{3}{8}$ of an inch of cover, the steam will be cut off at 15·98 inches from commencement of stroke, and the work performed by a ton of coke will be 1·0591.

Again, by giving the valve $\frac{1}{4}$ of an inch of lead, and $\frac{3}{4}$ of an inch of cover, the steam will be cut off at 11·8 inches from commencement of stroke, and the work performed by a ton of coke will be 1·2211.

Again, by giving the valve $\frac{1}{4}$ of an inch of lead and $1\frac{1}{8}$ inches of cover, the steam will be cut off at 5·2 inches from commencement of stroke, and the work performed by a ton of coke will be 1·75.

Again, by giving the valve $\frac{1}{100}$ of the breadth of the port of lead, and $1\frac{1}{8}$ inches of cover, the steam will be cut off at $7\frac{5}{8}$ inches from commencement of stroke, and the work performed by a ton of coke will be 1·242.

In the two last examples the cover of the valve is the same, but in the latter the lead is much less than in the former, which has diminished the efficiency of a ton of coke from 1·75 to 1·242, or nearly in the ratio of 3 to 2; and if the lead was still a little less the advantage gained by the cover would be altogether neutralized. Hence it appears that the lead is an important feature in the construction of the slide valve, and might be a good subject of enquiry as to what relation it ought to bear to the cover so as not to interfere with the operation of expansion.

I am, Sir, your obedient servant,

J. G. LAWRIE.

Cartsdyke Foundry, Greenock,
June 27, 1841.

N.B.—Should you consider this letter worthy of insertion in your Journal, I shall probably request insertion of another in continuation of the same subject, in which the lead will come under consideration.

J. G. L.

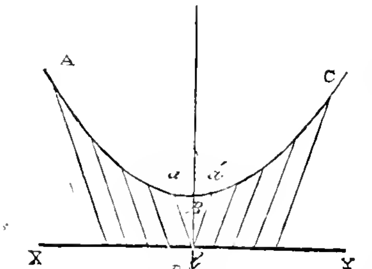
REMARKS ON MR. DREDGE'S SUSPENSION BRIDGE.

SIR—Feeling some interest in the subject of suspension bridges, I was gratified to find in a recent number of your instructive publication, a description of Mr. Dredge's newly invented suspension bridge, represented as offering such superior advantages, in all the essential particulars of strength, durability, and economy of construction. At the same time, however, I was somewhat disappointed when, having perused the article in question, I found that no attempt had been made to demonstrate the possession of such desirable qualities, by a reference to those well known principles and laws which govern the forces to which a suspension bridge is subject, and not having subsequently seen in the Journal or other publications, any such investigation of the subject, I am induced to forward to you the few remarks which follow, in the hope that you may think them deserving of a place in your forthcoming number.

The two characteristic features of Mr. Dredge's bridge appear to be the unequal thickness of the chains which taper from the middle point of the curve to its extremities, and the inclined position of the suspension rods.

A chain whose thickness is equal throughout being suspended from its extremities, assumes the form of a curve which has received the name of the Catenarian curve; the tension to which the chain is subject by its own weight, varies as the secant of the angle made by the tangent on any point, with a horizontal line, or, which is the same thing, as the secant of the angle contained by the tangent and ordinate. It is obvious, therefore, that the tension will be least at the lowest point of the curve, and increase towards the points of attachment, where it will be a maximum. In a chain of equal thickness its strength cannot therefore be proportionate to the stress to which it is subject, and it therefore naturally occurs that the chain should not be of equal thickness throughout, but be increased in sectional area from the lowest point of the curve to the highest. By mathematical analysis, the form of chain has been determined whose sectional area is always proportional to the tension; and a chain constructed upon this principle has, I believe, been actually adopted for the large suspension bridge erecting over the Avon by Mr. Brunel.

The idea of a chain of varying thickness is not therefore *new*, and as regards Mr. Dredge's bridge, the utility of the form of chain he has adopted appears to depend upon whether the sectional area varies as the tension at each point. Considering the chain in the first instance, as simply affected by its own weight, this point would be determined by comparing its form with that in which it is known the sectional area varies as the tension. I have not at this moment with me the means of making the comparison, but it is evident that if the two forms are identical, there is no *novelty* in this part of the invention, and if they are not, Mr. Dredge has proposed a form which is inferior to one that would always be employed when rendered proper from attendant circumstances. Except in large bridges it has not, however, been considered desirable to vary the thickness of the chain according to the tension, as the difference of thickness at different points is found too inconsiderable to merit attention. It seems, therefore, extremely probable that Mr. Dredge by varying the thickness of his chain in a very rapid ratio has far exceeded the increased thickness required by the tension.



Abstracting now for the sake of argument, the effect produced by the weight of the chain itself, and regarding only that occasioned by the tensions of the rods, it will be observed that these tensions are much increased by the inclined positions which the rods are made to assume. This is illustrated in the figure. A B C is the chain, X Y the horizontal platform, and *a b*, *a' b*, &c. the suspension bars. Let us suppose that the tension of the bars has been adjusted so as to be equal for all, and that the weight of the platform is known. If it be homogeneous in its structure, the centre of gravity will be at *b*, and the weight may be conceived as a force B D, acting in a vertical direction through this point. Each of the pairs of forces acting along the rods *a b*, *a' b*, &c., will have a resultant acting in the direction D B, opposite to that in which gravity acts. These resultants will also be equal to one another, and, supposing the platform suspended from two chains, their sum will be a force equal in magnitude (though opposite in direction) to half the force B D, the weight of the platform. Hence if this weight be given, we obtain the resultant of each pair of forces acting along oppositely inclined rods, by dividing half this weight by half the number of rods attached to one chain. Let the angle made by the rods with the vertical be θ, w half the weight of the platform, and n the number of rods, then the resultant of each pair of forces $= \frac{w}{\frac{1}{2} n}$.

And b the tension of each rod is $\frac{1}{2} \times \frac{w}{\frac{1}{2} n} \times \frac{1}{\cos. \theta} = \frac{w}{n \cos. \theta}$. Hence $b \propto \frac{1}{\cos. \theta} \propto \sec. \theta$, and is consequently least when $\sec. \theta$ is least, *i. e.* when $\sec. \theta = 1$, or the rods are vertical. This arrangement, then, appears disadvantageous, since it not only requires that the rods should be made of increased size to resist the increased tension to which they are exposed, but subjects also the chain to increased pressure from the rods in the ratio of $\sec. \theta : 1$.

Although the forces acting upon the two halves of the chain are inclined in opposite direction, it will be observed that the two halves are precisely similar, for if we imagine one-half to revolve round the axis B D, till the plane in which it is situated, coincides with the plane of the other half, the suspension rods of the two halves will exactly coincide, and consequently as the forces produced by them are equal, coincident in direction, and have similar points of application, the curves produced will be identical in all respects. Being produced by equal and parallel forces uniformly distributed along the curve, they belong to a Catenary whose ordinate is at right angles to the directions of the rods. Hence the tension caused by the action of the rods varies according to the law already stated, and if it be required to equalize the sectional area and tension of the chain, it must be constructed of the form already determined for the Catenarian Curve. Whether, then, we consider the effect of the weight of the chain itself, or the pressures produced by the suspension rods, the chain should be constructed upon precisely the same principles as in the ordinary suspension bridges. For these reasons I cannot but regard the plan proposed by Mr. Dredge as inferior to the ordinary method of construction, and I have accordingly, a contrary opinion having been maintained in your pages, ventured to offer these remarks to the consideration of your readers.

I am, Sir, your's obediently,

G. F. F.

Sandon Bury, July 11, 1841.

MR. PARKES' NEW THEORY OF THE PERCUSSIVE ACTION OF STEAM.

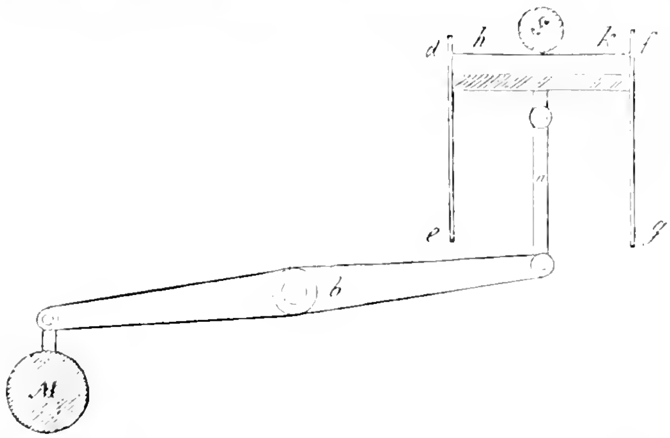
In this highly enlightened age, when long established theories crumble to dust under the all-searching glance of modern science, and the discoveries of our fathers, eclipsed by the surpassing splendour of the productions of modern genius, hide their diminished heads, it would perhaps be a mark of weakness of intellect to express astonishment at any new doctrine, however contrary it may be to our preconceived notions, or apparently so to the fundamental laws of nature. If, then, we were not surprised, at least our interest was excited in a high degree by the perusal of Mr. Josiah Parkes' Paper "on the Action of Steam in Cornish Single Pumping Engines," published in the Transactions of the Institution of Civil Engineers, Vol. 3, Part 4, wherein he developes, or rather announces a new principle of Action of Steam in Cornish Engines, which seemed at the first glance to point out a means of increasing almost indefinitely the dynamic effect of steam in steam engines; though why he considers it to operate in these engines only we know not—we are of opinion, that, if it obtains in them, it should obtain *à fortiori* in Locomotives, where the density and velocity of the steam entering the cylinder are so much greater. This new Principle is denominated by its discoverer the *Percussive Action of Steam*, and is announced in the following words, page 268:

"Steam, in its action on the piston of an engine, has hitherto been considered as simply exerting elastic force."

"Steam, however, possesses another important property, equally inherent in its nature with pressure and expansibility. This property is the velocity and consequent momentum due to steam of high elasticity; a force which comes into play under the peculiar conditions of a Cornish engine. The velocity of steam, in passing from a dense into a rarer medium, is immense; and the momentum of this steam must be very considerable. On the sudden and free communication effected between the cylinder and boiler of a Cornish engine, the steam in the cylinder receives an instantaneous action, proportionate, in amount, to the velocity of the entering steam, and this action, by the property of fluids, is transmitted to the surface of the piston. This action, thus transmitted to the piston, and due to the communication suddenly established between the highly elastic steam in the boiler, and the steam in the cylinder, may be likened, I conceive with great propriety, to the force of percussion; by which term I propose to distinguish it from the action of the steam's simple elastic force."

This force is illustrated in a note at the foot of the page by a comparison with the Pile-driving Machine and Hydraulic Ram; we think the following illustration much more appropriate.

Let *d e f g* in the annexed diagram represent the section of a cylinder, in which the piston *p* can move air-tight, let the latter be connected by a link *a* to one end of the vibrating beam *b*, a mass M being



suspended at the other end; further, let *h k* represent an inflexible circular plate fitting air-tight into the cylinder, but supposed to have no weight, and let there be a space *c* between this plate and the piston *p* filled with air of a given density.

The piston *p* being near the top of the cylinder, the circumstances are analogous to those of the Cornish single-acting engine just before the commencement of the working stroke, the air in the space *c* above the piston representing the cushion of steam against which the piston is brought to rest at the end of the return stroke, the beam *b* the balanced portion of the moving parts of the machinery, and the mass M the unbalanced portion.

In order to form an idea of the manner in which the momentum of the steam, admitted suddenly above the piston at the beginning of the stroke, is transferred to the latter, and thus increases the effect above what is due to the simple elastic force of the steam, let a mass S (say equal to the mass of steam admitted in the stroke) impinge against the plate *h k* with a given velocity. The result of this impact is, obviously, that the mass S loses a portion of its velocity, and consequently of its momentum, which is transferred to the air contained in the space *c*, which in its turn, communicates the chief part of this momentum to the piston *p*, the beam *b* and the suspended mass M. If the mass S be supposed to strike the plate *h k* with a velocity equal to that of the steam at its entrance into the cylinder of the Cornish engine, its percussive effect may be assumed to be the same as that of the latter, though it will in reality be greater on account of the *simultaneous* action of the whole mass, whereas the mass of steam arrives in the cylinder *gradually*. The interposition of the air *c* is essential to the perfect conformity of the two cases, for the entering steam no sooner passes the contracted orifice of the throttle-valve, where it impinges, as it were, against the steam already in the cylinder, than it expands and loses the greater part of its velocity, at the same time compressing the steam with which it mingles.

The necessity of adopting this theory (of the Percussive Action of Steam) was forced upon Mr. Parkes by his inability to discover, in the simple elastic force of the steam employed, an amount of power adequate to accomplish the actual duty ascertained to have been performed by several of the Pumping Engines in Cornwall, the facts observed admitting of no question. This is, in our opinion, the only valid argument brought forward by the author in its favour, though he has adduced several others in corroboration, which, however, require the co-existence of the former to give them weight, and even so they are but of a negative character, amounting in substance to this: since the amount of power due to the steam's elasticity alone is less than the amount of work done, an additional quantity of power must be derived from other source; and whence can it be derived but from the instantaneous action transmitted to the piston, on effecting the sudden communication between the steam in the cylinder and that in the boiler.

Assuming the data furnished by experiment to be correct, (and we have no reason *à priori* to doubt their accuracy), the above reasoning appears to be conclusive, at least in so far as the additional power required to realize the observed dynamic effect must be sought in some property of steam distinct from its elastic force; and its Momentum, or rather Inertia, is the only property which suggests itself as capable of supplying any additional amount of power.

Admitting, therefore, the inadequacy of the simple elastic force of the steam to accomplish the work actually performed, and assuming the deficiency of power to be supplied by the Steam's Percussive Action, the next step naturally, is to examine into the causes and effects of this action.

The cause is obvious, and is almost sufficiently explained in the illustration which we have given above. A mass of dense steam passes through the throttle valve at a great velocity, the chief part of which it loses by the time it comes to act by its elastic force upon the surface of the piston. This mass of steam must, therefore, in losing its velocity, impart its momentum to some other body or bodies, through the medium of which it may afterwards be utilized in increasing the dynamic effect of the steam. The body which receives the shock of the entering steam, and transmits its momentum to the moving parts of the engine, is the steam cushion represented in the illustration by the air *c*, and the entering steam by the mass S. It is this imparting of its momentum which is called the Percussive Action of the steam.

In investigating the effects of this action, our object is to ascertain the amount of momentum transmitted thereby to the piston and other pieces of machinery connected with it, and we looked in vain to Mr. Parkes' work for assistance in this inquiry: there is, indeed, an article (page 269), headed: *Determination of the quantity of Percussive Action*, which commences with the statement that "the dynamic effect, or quantity of action, due to percussion, is discoverable, and assignable for each example: but the only method employed by the author for its determination is that of elimination, that is, by deducting from the total dynamic effect of the steam found in the quantity of work done, the amount due to its elastic force, including expansion, the remainder, which is the deficiency of power according to the ordinary theory, being attributed to the percussive action. In a note at the foot of the same page Mr. Parkes says: "It forms no part of my task to investigate the abstract question of the quantity of this species of force to be obtained from steam; my present purpose is confined to the determination of the effect attributable to it in the three engines subjected to analysis." It is a pity he did not make it part of his task to investigate, not *the abstract question of the quantity of this species of force to be obtained from steam*, but *the practical question* of the quantity which the steam would afford in the three cases under consideration. This inquiry would, doubtless, have been full of difficulties, should the result not turn out to be equal to *o*, which we much suspect would be the case if the investigation were based on the laws of percussion as laid down in the treatises on Mechanics; and if the new principle is to be established in opposition to these laws, it is necessary first to demonstrate their fallacy; but that this is not the view of the case taken by the author is evident by his merely comparing the percussive action of the steam to the shock of a solid body, without intimating in any way that the laws laid down for solid bodies do not obtain equally with regard to steam. He overlooks, however, the important consideration that the shock of the entering steam is not received immediately by the piston, but by the steam previously occupying the space above it, and likewise that the reaction is necessarily equal to the force of impact.

By reason of this latter condition the entering steam can only part with its momentum as fast as the steam in the cylinder is capable, *by its simple elastic force*, to oppose a resistance, or reaction, equal to the force of percussion. The latter is therefore always strictly measured by the elasticity of the steam in the cylinder, the dynamic effect of which thus includes that due to the Percussive Action. If, then, the Indicator diagram exhibits a faithful representation of the elastic force of the steam as it varies from the commencement to the termination of the stroke of the piston, it must necessarily furnish us with the means of determining the whole amount of dynamic effect which can be obtained therefrom. It may also be observed that the effect of the Percussion is transmitted, "by the property of fluids," to the Indicator piston as well as to the working piston, so that, even if there were a Percussive force which acted on the latter in addition to the elastic force of the steam, its influence, being felt by the former also, would be indicated in the diagram by an additional elevation of the pencil.

The above discussion convinced us, as it may also some of our readers, and perhaps Mr. Parkes himself among others, that the difference observed between the amount of power due to the elastic force of the steam and the duty actually performed by the engines subjected to analysis cannot be attributed to the Percussive Action of the steam; and, as there appears to be no other source of power to which it can be ascribed, we are compelled to conclude that the supposed difference does not exist in fact, and consequently that either the experimental data, or the calculations based upon them, are erroneous.

We have said above that we had no reason *à priori* to doubt the accuracy of the observations, and we will therefore now examine into the details of Mr. Parkes' calculations relating to the Huel Towan engine, with the view of discovering whether the discrepancy observed between the power developed by the simple elastic force of the steam and the actual work done be not attributable, either wholly or in part, to some error in his deductions from the data furnished by observation.

Mr. Parkes says (page 261): "The absolute resistance consists of the weight which performs the return stroke, plus the value of engine and pitwork friction, and of the elasticity of the uncondensed steam." To this should be added, for each forcing pump, the weight of a column of water whose base is equal to the sectional area of the plunger and altitude to the mean height of the bottom of the plunger above the level of the water in the cistern whence it is drawn, and for each lifting pump, the weight of the whole column lifted, from the level of the water in the cistern; and we should deduct the amount of assistance, though small, given by the atmospheric pressure on the top of the piston rod.

We are not informed of the value of any of these quantities, except the last, from direct experiment, but we know that the weight which performs the return stroke is necessarily slightly in excess of that of the average column of water raised, augmented by the friction of the water and machinery, and the difference between the atmospheric pressure and that of the steam, during the return stroke, on the area of the piston rod; and the excess (which is necessary to set the engine in motion with its load of water) is counterbalanced at the end of the stroke by the cushion of steam which brings the engine to rest.

Mr. Parkes substitutes for this weight, in his calculations, the water load, which, he says, can alone be termed a positively ascertained quantity; but in computing this load he commits two errors, which, however, compensate each other. He calls the mean diameter of the pumps 14·625 inches, instead of 14·968, which renders it necessary to assume a cubic foot of water to weigh 65·47 lb., instead of 62·5 lb., in order to make the water load equal to 6866641 lb., in which he agrees with Mr. Henwood, by whom the experiment was made. It is permitted, in calculating the effective resistance on the piston, to use the total height of the column of water, since it is equal to the sum of the average heights mentioned above; so that the absolute resistance will be equal to the weight of the total column of water raised, *plus* the friction of the water in the pipes, twice the friction of the machinery, and the elasticity of the uncondensed steam, *minus* the difference between the pressure of the steam during the return stroke, and that of the uncondensed steam during the working stroke, on the area of the piston rod. The diameter of the piston being 80 inches, and that of the piston rod 7 inches, the area of the former minus that of the latter, or the effective area of the piston, is equal to 4988·08 square inches, and the resistance on the piston due to the water load is consequently 11·01 lb. per square inch. (Mr. Henwood by some mistake made it only 10·2 lb. per square inch, which he also called the whole resistance of the engines). The elasticity of the uncondensed steam is estimated at 1·25 lb. per square inch, and that of the steam in the cylinder during the return stroke appears, by Mr. Henwood's indicator diagram, to have been about 6·4 lb. The difference between these two last quantities, reduced in the ratio of the area of the piston rod to the effective area of the piston, becomes 0·04; and we find the whole resistance per square inch of the piston (assuming with Mr. Parkes that the frictions, the actual amount of which we have no means of ascertaining, cause a pressure of 5·75 lb. per square inch) equal to

$$11·01 + 5·75 + 1·25 - 0·04 = 17·87 \text{lb}.$$

We think, with Mr. Parkes, that this amount is by no means exaggerated, but more likely the reverse, particularly in the evaluation of the frictions, and must therefore conclude that the error, if any, must be in the calculation of the power from the indicator diagram. Now we have satisfied ourselves that the mean elasticity indicated by the diagram would not produce sufficient power, so that we have no alternative left but to prove the diagram false or to confess ourselves unable to account for the facts observed by Mr. Henwood.

If we admit the pressures to have been as shown in the diagram, and that the equilibrium value was closed when the piston was 9 inches from the end of the return stroke, we must either suppose the unreasonably large space of 68·059 cubic feet to have existed below the piston at the bottom of its stroke, or, (if we allow thirty cubic feet,) we must assume a waste of 7·1 per cent. of the water expended. On the latter hypothesis, the volume of steam of 6·4 lb. pressure discharged from the cylinder every stroke was 352·886 cubic feet, which is the capacity of the space below the piston when the equilibrium valve is closed, and the volume remaining above the piston was $25·979+c$, calling c the capacity of the space above the piston when at the top of its stroke, or the volume of the steam-cushion. The whole quantity of steam in the cylinder of this elasticity is therefore equal to $378·865+c$, and its relative volume 3668. The space it occupied before the equilibrium valve was opened was $316·393+c$, its elasticity was 7 lb. per square inch, and its relative volume 3377, so that we can find the value of c from the following proportion,

$$32·472 : 291 :: 316·393+c : 3377,$$

whence

$$c = 30·438 \text{ cub. ft.}$$

The absolute volume of the steam which formed the cushion was, before compression, 56·417, and its relative volume 3668; after compression its absolute volume was 30·438, which makes its relative volume 1979, and its elastic force 12·48 lb. instead of 10·7, as shown by the diagram. Mr. Parkes gives 9·176 cubic feet as the value of c, which would evidently increase the difference between the calculated and the observed pressure of the steam-cushion.

The volume of steam of 7 lb. pressure in the cylinder just before opening the equilibrium valve is 376·831 cubic feet, and the volume occupied by the same steam when the piston had described one fourth of its stroke, and the admission valve was quite shut, was 117·036 cub. ft., so that the relative volume of the steam was then $3377 \times \frac{117·036}{376·831} = 1049$, and its elasticity 21·87 lb. per square inch; according to the indicator diagram it was only 20·4 lb.

We have no means of testing the correctness of the pressures marked by the indicator during the period when the admission valve was open, but the above calculation suffices to prove that the diagram is far from furnishing an exact measure of the steam's elastic force at least in the instance quoted, and that if the whole, or nearly the whole, of the water expended passed through the engine in the form of steam, it was sufficient to produce, by its simple elastic force, a dynamic effect equal to the work actually performed, particularly if the volume of the steam-cushion was only 9·176 cubic feet as stated by Mr. Parkes, and which accords with Mr. Henwood's datum of the volume of steam used per stroke.

Mr. Parkes has rendered some part of his paper rather difficult to understand by an ambiguity of expression relating to the expansion of the steam, accompanied in one place by an apparent contradiction in the facts. He says (page 264), "it is evident that the effect of a given weight of water as steam, consumed during a stroke, will be the same, whether that steam be regarded as having been all enclosed between the piston and cylinder cover, before the piston were permitted to move, when it would expand nearly uniformly from the beginning to the end of the stroke; or, whether it be considered as having been admitted during a portion of the stroke, at some pressure greater than the resistance, and then expanded through the remainder of the stroke."

What the author meant by this we cannot guess; taken literally, it is obviously false, and that it was not intended to be understood so, appears by the calculation of the effective power in the sequel. He continues:

"But, the value of expansion consists, virtually, in the quantity of action derived from the steam, after *it forms an equilibrium with the resistance*.....By tracing it, first, through the space of the cylinder, where *it would barely balance the resistance*; and secondly, through the space during which *it suffered expansion below that pressure*, a true measure of the respective and total quantities of action developed by it, expansively and unexpansively, will be obtained."

The expressions in italics imply that the expansive is separated from the unexpansive part of the stroke at the point where the pressure of the steam is equal to that of the resistance; but the numbers quoted in the next page prove that such was not the author's meaning, for he says, "when the piston of the Huel Towan engine had passed through 50·7 out of 120 inches, which was its total length of stroke, the steam's elastic force and the resistance counterpoised each other." Now we are informed that the resistance was 18·01 lb. on the square inch, and the indicator diagram shows a pressure between 13 and 14 lb. at the point mentioned; but in the diagram of the steam's action at page 294, a pressure of 18 lb. is marked at that point, and the steam and resistance are said to be in equilibrio. We are unable to account for this discrepancy.

A series of well-conducted experiments with Cornish single-acting engines would not only be very interesting with regard to the working of these engines, concerning which so much doubt is still entertained, but would doubtless throw a great deal of light on the general theory of the steam-engine, since they afford facilities for making observations which double-acting engines do not admit of.

A New Line of Atlantic Steamers.—The *St. John's N. B., Herald* informs us that the English Government is about contracting for an additional line of steamers to the North American colonies, which will give a weekly communication with England. The new line will be likely to run direct to St. John's, such being Sir William Colebrook's wish, while the present line will continue to run to Halifax. We presume the new line will be extended from St. John's to this port.—*New York Evening Post.*

BRONZE GATES.

Fig. 1.—Elevation of Gate.

Fig. 4.—Section.

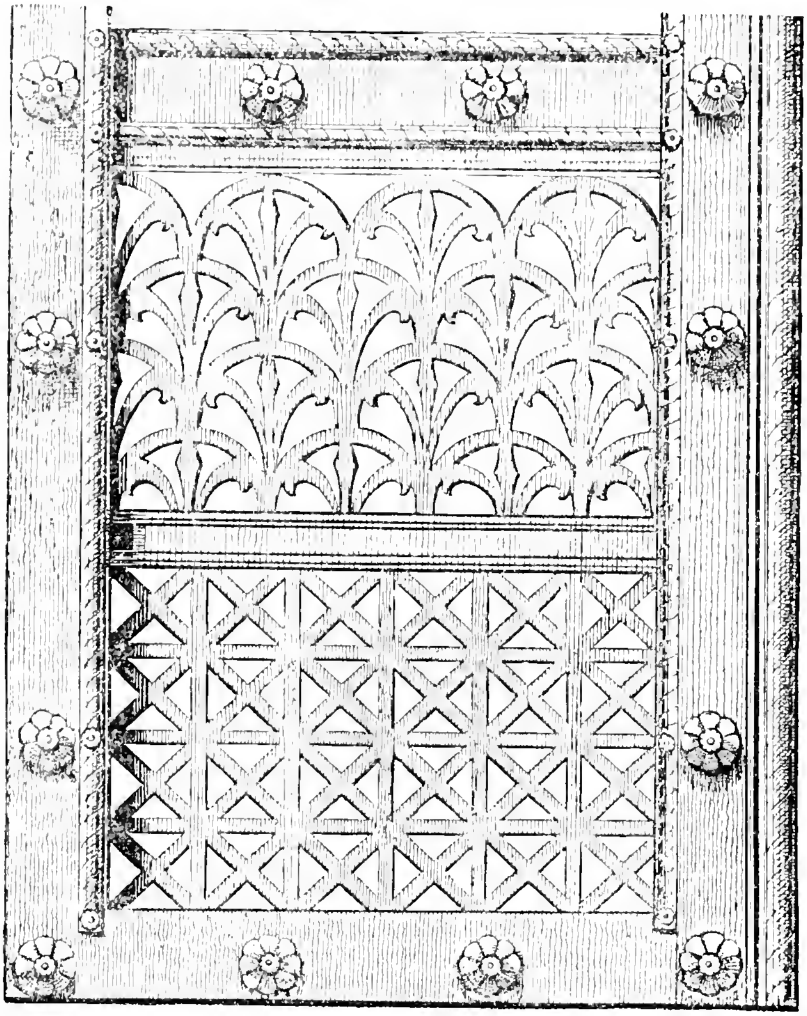


Fig. 3.—Elevation.

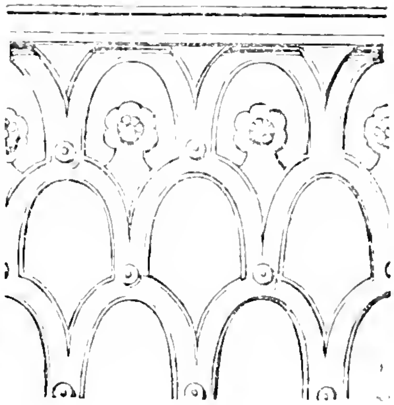

Fig. 5.

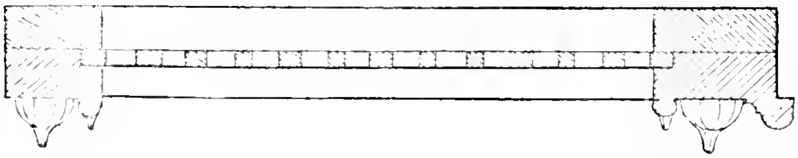
Fig. 2.—Plan of Gate.



The "*Revue Générale*" intends to give a series of designs of bronze gates selected from the best examples to be found in France, some of which we propose occasionally to give in the Journal. The annexed engravings represent the celebrated bronze gates of the Cathedral of St. Mark, at Venice.

Fig. 1 is a double panel of one of the gates: two styles and two cross rails, ornamented with projecting nailheads and torus mouldings enclose the principal panel, which is divided into two open compartments by a horizontal rail; the lower part is an exact copy of ancient cross-barred work, and the upper presents an imitation of the *imbrications* often made use of by the ancients; the hollow formed by each of the semicircles is occupied with a kind of fleur-de-lis, such as is generally depicted during the middle ages. The ensemble of this composition is original, and perfectly answers the object proposed.

A horizontal section (fig. 2) shows the arrangement of the different parts of this gate, the thickness of the panels, and the projection of the mouldings and rails which ornament it.

Fig. 3, is a fragment of another panel of the same church, which also exhibits Roman imbrications; in the upper row the artist has introduced some detached flower ornaments, which have a good effect. Fig. 4 is a vertical section of this fragment.

Numerous lion's heads, formerly gilt, are placed in the imbrications which decorate this gate, one is represented in fig. 5. The style of sculpture would serve to point out the age of the gates, were we not aware that they were cast in the 11th century, when St. Mark's was finished.

The annexed designs may be arranged in a variety of ways, so as to form some excellent examples for iron gates, railings, &c., either by repeating the same panel, or taking two panels of one design and one panel of the other, or *vice versa*. Likewise by omitting any part of the ornaments, or all, or introducing others, and the same framework may be applied either vertically or horizontally.

CANDIDUS'S NOTE-BOOK.

FASCICULUS XXIX.

"I must have liberty
Withal, as large a charter as the winds,
To blow on whom I please."

I. CAMPBELL's Vitruvius Britannicus contains a design for a church, by himself,—"an original invention," as he calls it,—which is nothing more than an Ionic prostyle, pseudo-peripteral along its sides, so far tolerably Grecian as to its plan, but a mere parody of Grecian architecture, as to style. The east end has a large Venetian window, which is the only one in the building, but he says, it would give sufficient light to the whole interior; and if so, it is a pity the hint has never been taken by any one else for structures of that class, instead of cutting up and crowding their designs with a multiplicity of windows, that become so many blemishes, as is the case with St. Martin's Church. In all the various styles of pointed architecture, windows are principal and almost indispensable features, they and doorways being the chief source of decoration, and of character; whereas they are so much at variance with either the Grecian or the Roman style, if intended to be kept up with tolerably consistency, as to be hardly admissible, more especially where the general idea is affected to be borrowed from that of an ancient temple, whither it be a peristylar or merely a prostyle one. Its windows detract very materially from the design of St. Pancras' Church; and when it is viewed obliquely, the flank of the building produces a harsh and disagreeable contrast with the portico—which last is not disfigured, as too frequently happens with any apertures of the kind. That there is authority for windows in ancient structures, is undeniable, because those of St. Pancras are copied from the same edifice as the order itself, and the ornamental details. But then, the application of such features is altogether different from what it is in the original precedent. In the last there are only three at one end of the exterior; in the professed copy there is a range along each side, besides a series of smaller ones below, which gives an air of insignificance to the whole. Were there no other objection against them, it is no small one that they quite contradict the portico, indicating as they do not only that the interior is divided into two floors, but that the ceiling of the lower one or ground floor, is not half so high as the doors! Without entering the church, we may guess that there is in reality no such division, but that the lower windows, are merely intended to admit light beneath the galleries. The question then becomes, what occasion can there be for windows just there, provided the interior be otherwise sufficiently lighted, as it certainly might be? What occasion in fact for side windows at all—unless indeed they can be made to contribute advantageously to external effect—when they might be dispensed with altogether, and a building of the kind—a single spacious room—be lighted entirely from the ceiling, in almost any way that would best suit the particular design?—If, for instance, there is a dome, let the light proceed chiefly, if not exclusively, from that part of the ceiling plan, instead of the concave of the dome being in comparative gloom and darkness, as is the case at St. Paul's. One advantage attending the exclusion of side windows—which except in the Gothic style are more injurious than conducive to effect—would be that the walls being solid, noise from the street would be obstructed. Whether smart Sunday bonnets in the seats under the galleries would be seen to so much advantage as at present, is a different consideration—doubtless a most important one in itself. The galleries themselves are a nuisance; and never have I met with an architect who did not cordially agree with me on that point. The pew-system is not much better, though mightily in favour with

"A loyal Church, that keeps the rich and poor
Duly apart, nor blends the lord and boor.
'Tis sweet to witness *pews*, nor mean, nor scant,
For those who pay,—*free seats* for those who can't," &c.

These lines are from a clever poem which has just issued from Albemarle-street—hitherto considered the seat of High-Church orthodoxy, and conservatism!

II. In regard to the church I have just been speaking of (St. Pancras,) I cannot help thinking that the design would have been very materially improved, had the two caryatic wings, been placed at the west instead of the east end; so as to combine with the portico, and form an extended façade. A very striking composition might have been so produced, one no less distinguished by picturesque variety than by its richness. Those wings would have balanced the tower above, and given a pyramidical outline to the whole structure as viewed in front. Neither would it have been the least recommendation of such arrangement, that the wings would have served to screen the insipid side elevations. It would however have been further desirable that instead of being merely stuck on to the body of the edifice, as at present, they should be made to unite with it symmetrically, for at present the upper line of the cornice ranges with no other line, but falls about midway of the windows.

III. Caryatides or *anthropostyle* supports to an entablature, as they may very properly be described, entirely upset the *old-women* critics' fudge as to the different orders being proportioned after the human figure, their proportions being more robust than those of the "manly Doric." Whether these columnar ladies were matrons or virgins, is a point I leave to be settled by the more curious,—and indeed, I almost wonder that no one should as yet have given us some learned twaddle in regard to it;—but it is certain that they are by no means of that maypole appearance which those dames must have exhibited, who stood for models of Ionic and Corinthian columns. After all it is possible that the Greeks borrowed the idea of Caryatides from Holland, for they are most indisputably very Dutch built, and to all appearance brawny enough to perform the office put upon them, without flinching.

IV. If for no better one, it is for this last reason that I do not object to the use of Caryatides, as being disagreeable to the feelings. Thank heaven! my feelings are not quite so refined and super-refined as to be shocked at beholding ladies of stone, bearing a burden they seem quite able to support. I should as soon think of expressing my sympathy for the Cardinal Virtues which are frequently turned out of doors, and doomed to keep watch on the outside of a building in all weathers, while the Cardinal Vices, perhaps, are enjoying themselves very snugly within.—As soon should I think of being mawkishy sentimental, and compassionating some poor devil of a Neptune who is compelled to stand as a sentinel on such a ticklish situation as the top of a pediment, to be there roasted in a broiling sun. It is wonderful how vastly sentimental many people can be, provided the display of outrageously fine feelings costs them nothing! Many a one who would almost pretend to snivel at "Patience on a monument smiling at grief," would drive over a poor old apple-woman and her stall, as unconcernedly as if she were a mere stock and stone. And yet the Apple-woman is a more perfect image of patience, than all the "Patiences" ever sculptured, were there one upon every hypocritical monument that has been erected.

V. Panegyric, as Swift observes, "is all pork, with very little variety of sauce: for there is no inventing terms of art, beyond our ideas; and when our ideas are exhausted, terms of art must be so too." This last remark certainly holds good, in regard to those writers and critics who repeat what they have picked up in praise of Palladio and Jones, pretty much as a parrot would repeat a pater-noster. They would fain insist upon our believing that those worthies possessed every architectural virtue and excellence; but to dwell upon their merits, or to examine the beauties of their edifices one by one, assigning to each its due value, is more than they care to attempt,—for reasons perhaps, well known to themselves, and not difficult to be divined by those who are not arrant gulls. Very quickly indeed are their ideas of art exhausted, for after they have uttered some stale commonplace, or vapid truism they are completely aground. It may be questioned whether "the celebrated Inigo Jones" would consider Goldicutt's publication of Heriot's Hospital, particularly complimentary, since the account of it is dispatched in less than a page and a half, without any thing being said in regard to the structure itself. Yet its beauties certainly require to be carefully pointed out, for they are of a kind quite invisible to unprejudiced eyes. Not so, however, the defects, they being glaring enough. The entrance tower might be supposed to have been intended as a whimsical burlesque on modern applications of the ancient orders; and the whole is no better than an architectural hotchpotch—an unintelligible, Babel-like jargon of styles jumbled up together. Still, for aught I can tell, the Doric entrance and Corinthian patchwork above it, may be precisely that part of the design which finds most admirers. The great charm after all, I suspect, lies in the name of Inigo Jones: take away that, and few persons would be able to discern any beauty or grandeur in it whatever.

VI. In the "Magasin Pittoresque" it is said that the windmill, built by him at Chesterton in Warwickshire, does Jones no less honour than the palace of *Blenheim*"! It is a wonder the writer did not favour us with the information that Inigo Jones was the father of the equally "celebrated" Tom Jones, of whom there is a tolerably well written life by one Mr. Henry Fielding, an author not very much inferior to some of the second-rate geniusses of our own enlightened age.

HISTORY OF DECORATIVE SCULPTURE IN FRANCE.

By ALBERT LENOIR, Architect.

(Translated for the Civil Engineer and Architect's Journal, from the Revue Générale de l'Architecture.)

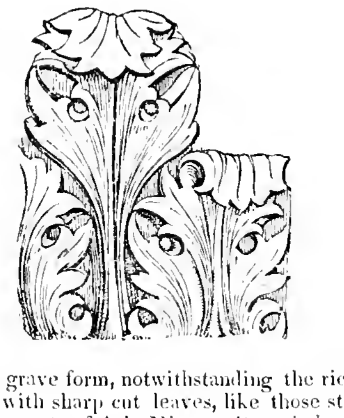
GAULISH PERIOD.

In the earliest ages men, in however rude a condition, have always been fond of decorating their dwellings, an impulse to which the Celts and the Gauls gave way, and of which we find many evidences in their monuments. On the coasts of Britany, and on the sides of Druidic monuments, we see rude sculptures of rays and spirals so combined as to produce something of a decoration. On the well known peulvan or rough obelisk of Kervéaton in Finisterre, we find the head of a bull represented in such a way as to enable us to comprehend the outline. All other monuments which preceded the civilization of Gaul by the Greeks and Romans, except those of the Druids, having perished, we are deprived of the opportunity of describing the mode of ornamentation adopted by the Aborigines.

GREEK PERIOD.

The Phoceans, as is shown by the remains preserved in the Museum of Marseilles, brought into Gaul the elements of Asiatic art, which they used with taste. In 1773 M. Grosson, an inhabitant of that city, published a quarto volume,* in which are engravings of many ancient monuments, found within the boundaries of the old colony. Notwithstanding the mediocrity of the representations, we can easily recognize on some of the tombs, decorated with bas reliefs and inscriptions, how completely they had succeeded in imparting a classic taste, the crowns of olive leaves, and wreaths of flowers and foliage boast the same elegance as on the coasts of Attica or the Peloponnesus, Caria or Ionia. On the borders of the territory of the Greek colony, in a place called Le Bas Vernègues, near the Pont Royal, on the road from Aix to Lambesc, is to be seen a temple of the Corinthian order, evidently of a Greek character, both as regards its general composition and the style of its mouldings and ornaments, as may be judged by the following engraving.

Fig. 1—Leaves of the capital of Vernègues.



The capital of a grave form, notwithstanding the richness of its details, is decorated with sharp cut leaves, like those still to be seen at Athens, and on the coasts of Asia Minor. It reminds us of the foliage used in the decoration of the capitals of Pompeia, sculptured in the Hellenic school. In the temple of Vernègues, the bases of the columns, the mouldings of the pedestal, and the proportions of the architraves have evidently been designed and executed by Greeks.

The influence of the Asiatic colony was not limited to the bounds of the Marseillese territory, but was felt throughout Gaul, and thus it is we find at Vienne in Dauphiny, and at St. Remy-en-Provence, the ancient Glanum, traces of oriental art, as readily to be recognized there as in the fragments of the Phocean metropolis.

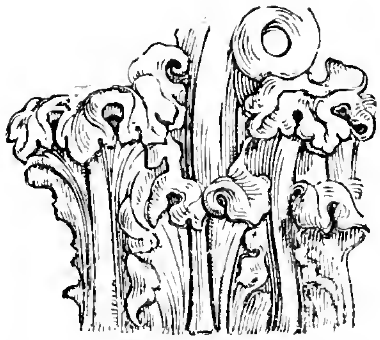
When Gaul came under the power of the Romans the Greek spirit still survived, as we may see in the case of the two cities just mentioned. At Vienne, the capitals of the temple of Augustus and Livia, were executed on the Greek plan, as may be ascertained by the finely executed sharp leaves, and in the Museum of Vienne, formed in the cella of the temple may be recognized more than one fragment which shows the Greek chisel.†

* Recueil des Antiquités et Monumens Marseillais, 1 vol. 4to., Marseille, 1773.

† The reader may consult *Antiquites de Vienne*. 1 vol. in folio, by M. Reg, Director of the Museum of Vienne.

The tomb of St. Remy, raised for a Roman personage, as the inscription, figures and bas relief show, was also of Greek workmanship, this we can trace in the fragment of a capital represented in the following engraving, and further proved by the Greek contour of the mouldings.

Fig. 2—Leaves of the capital of St. Remy.



The capitals surmount the columns, decorating the upper part of the tomb; the sculpture of them is broad and well massed.

The triumphal arch at Orange is a monument cotemporary with the first victories of the Romans in southern Gaul, in it we trace something Greek, every detail serving to remind us, in some degree, of that school. The composition of the mouldings of the entablature, and particularly those at the top of the architrave bring to mind the profiles seen in the ancient edifices of Asia Minor; a cavetto is seen surmounting a line of ova, reposing on a string of pearls, a detail completely Ionian.* The modillions, decorating the principal cornice of the arch, have a remarkable peculiarity which is met with in the octagonal monument at Athens called the Tower of the Winds, and as we shall hereafter see reproduced in the Maison Carrée at Nimes, an edifice of a later date than that on which we are now treating. These modillions are sculptured in an inverse way from those which decorate all the ancient entablatures, the larger part, instead of resting against the cornice so as to form a console, is on the contrary near the outer edge of the corona, a very rational arrangement by the bye if we consider this part of the decoration as being derived from a wood building, and as the expression of the pendent extremities of the rafters, supporting the tiles. The resemblance between this entablature at Orange, and the Athenian edifice, which as it is described by Vitruvius,† must be of ancient date, comes in confirmation of the influence exercised by Greece on architecture and its details in southern Gaul. A specimen of the Greek palmetto is to be found in the midst of the foliage of the upper ogee of the impost of the Arch at Orange. The coffres, decorating the arches are executed with more delicacy than in any Italian monuments, particularly in the double arches, where we observe a happy arrangement which adds to the finish of the execution. In general, the Roman monuments of southern France show in their ornamentation a lightness of touch which may be attributed to the Greek school as introduced by the Phocean colony.

We have already shown what Hellenic elements are observable in the tomb of St. Remy: the same we have to notice in the triumphal arch of that town, particularly in the double arches decorated with arabesques. The archivolts of this monument, as well as those of the triumphal arch of Orange, are decorated with foliage and fruits, taken from the produce of the country, an interesting ornament as it makes us acquainted with the state of culture at that date.‡

ROMAN PERIOD.

Out of Provence we perceive a considerable change in the style of ancient architecture, approaching to the Roman forms, of which Nimes, one of the richest cities of Europe in antiquities, affords many examples, having been for a long time opulent enough to construct fine buildings. Augustus gave walls to Nimes, as is attested by an inscription on the gate, still bearing his name. The Corinthian capitals of the pilasters of this gate are executed with breadth, and remind us of the style at that period adopted at Rome. To the same emperor is attributed a portico which decorated the fountain of the Baths, the fragments of which are preserved on the site of the Temple of Diana. In the Maison Carrée are two of the finest bases ever sculptured by

‡ See the introductory plates to the History of France, by Jorand, Jouffray and E. Brecon.

the ancients, also parts of the fountain.* At the temple of Diana are to be seen many fragments of richly ornamented double mouldings, which decorated the lower part of the great pedestal or stylobate in the centre of the Baths. They are beautifully executed. Neither must we omit the long marble frieze of the stylobate of the fountain preserved in the Maison Carrée.

The temple of Nimes, known by the vulgar name of the Maison Carrée, and built in honour of the grandsons of Augustus, was executed by skilful artists; the capitals, in the Roman manner are broadly modelled, but we can see here, as well as on the frieze, abundant proofs of a difference in the skill of the several workmen employed. The modillions of this temple, as we have already mentioned, exhibit the same peculiarity as those on the Triumphal Arch at Orange, but being deeper cut, they are evidently imitations. The great gallery or colonnade around the temple, forming the sacred boundary, shows the same style of sculpture as the temple itself, but with less luxuriancy in the details: the frieze was formed of garlands, fruits and flowers, bound with floating ribands.

Antoninus, who was a native of Nimes, adorned that city with many important buildings. To him are attributed a temple and a basilica dedicated to Plautina; and the fragments of sculpture collected in the Museum, apparently belonging to this golden age of art, fully bear out their claims. Among these may be remarked the eagles supporting the olive garlands; and a frieze composed of ox sculls, supporting garlands of fruit.

Vienne, the rich Museum of which is formed in the temple of Augustus and Livia, possesses more than one fragment of the best ages of Roman art.† Here are to be seen the cornice, frieze and architrave of a beautiful entablature, on the frieze of which is particularly to be remarked the rosette which serves to unite the bends of the foliage. The cornice is less remarkable, showing as it does in its modillions evident symptoms of the decline of the arts, first, because their form is that of a console en talon, little in harmony with the richness of the other members; second, because these modillions are all decorated differently, which is contrary to the strict rules of the best periods of art. It is singular that among all the remains of ancient art those of France alone should be found to present these departures from the general rule, an exception which we shall have occasion to remark both during the history of the Roman period, and of the middle ages, in which this variety of form became the parent of riches to a new style. In the Museum is also to be seen a beautiful piece of monumental sculpture, forming a frieze, and consisting principally of an eagle attacking a serpent. It seems to belong to the time of Septimus Severus.

Arles, a city of little importance before the time of Constantine, rapidly increased under the reign of that prince, and became to a certain extent, the Gallic Rome. Extensive buildings, still in existence, serve to show its splendour, but art was no longer what it was under the Antonines, the theatre, capitol, amphitheatre, and great cemetery or elyseum, show by the bad taste of their details, and the transposition of the principal members of the styles, how complete was the decadence. The capitol, of which a part is still to be seen in the Men's Square, consists of a ruin composed of two columns, crowned with an entablature and the fragment of a pediment; the ornamental sculpture is neglected, the frieze being composed of scrolls without character, while in the capitals, the bad proportions of the leaves indicate the period of ignorance at which the monument was erected. The theatre exhibits greater signs of decadence than even the capitol, the entablature of the lower story presenting the greatest anomalies, the sculptors have placed a frieze decorated with triglyphs and rosettes immediately above the capitals, where the architrave ought to be; then come a frieze in bad taste, and a badly proportioned cornice. In the Museum at Arles is preserved part of a marble entablature, which appears also to belong to the time of Constantine; the modillions varying every two and two in their decoration, which we have already pointed out as contrary to the principles of classic antiquity.

The walls of the city of Sens, of which the destruction, going on even now, presents numerous details of ancient architecture, placed by the Romans themselves on hasty foundations made in the time of the Emperor Julian, have afforded several cases analogous to those we have mentioned under the head of Arles.

The city of Autun, celebrated in Gaulish history and the capital of a province, has preserved some remarkable monuments. Those in the best condition are two gates attributed to Constantine, who was a great patron of the town. These two military constructions are in good style, both as regards the architecture and the ornamental sculpture, notwithstanding the well known general decadence of art which prevailed under the first Christian emperor. In the same city an ancient entablature of the Gallo-Roman epoch, which affords an example unique in France, of modillions sculptured on the angle of the corona. The ornamental details of this fragment show one of the last periods of Roman art in Gaul; we can however recognize the fertile imagination of the native artists, in the variety of *motifs* in the sculpture, which change the form and character of each modillion.

A triumphal arch of large proportions is formed in the walls of the city of Rheims, and is now known as the Gate of Mars. The construction has been attributed to Cesar by some modern writers, although there is nothing to give any foundation to this notion. An examination of the sculptural details of this edifice is enough to prevent its being assigned to any period anterior to the Lower Empire, and perhaps it ought rightly to be placed in the time of the emperor Julian, who fought often enough in the East of Gaul to obtain triumphal honours in a provincial city. In this monument the sculpture is of most uncommon barbarism, the foliage being scarcely of a recognizable form; the capitals out of proportion surmount heavy and badly chiselled columns, and the mouldings of disagreeable figure are made heavier by ornaments of which the model is a large hole in the midst of a shapeless leaf.

HISTORICAL SKETCH ON THE USE OF BRONZE IN WORKS OF ART.

By Cesar Daly, Architect.

(Translated for the Civil Engineer and Architect's Journal, from the Revue Generale de l'Architecture.)

(Continued from page 219.)

The exertions of the Italian artists excited general emulation throughout Europe; and in a very short time every country used bronze for the decoration of its public edifices, and to transmit to posterity the deeds of its kings and great captains. Italy erected statues to the Medici and the Farnese, Spain to Philip III, Russia to Peter the Great, Sweden to Gustavus Adolphus, and England to Charles Ist. Much might be said with regard to the progress of this art, but we consider ourselves obliged on account of the extent of the subject to limit it to the history of bronze in France.

It was under Louis 14th, that this art made rapid progress through the enlightened endeavours of the two brothers Keller, whose principal master pieces are yet to be seen adorning the royal palaces of Versailles and the Tuileries. In 1699, Balthazar Keller cast in one piece the equestrian statue of Louis 14th, modeled by Girardon. This colossal mass was more than seven yards high, and yet weighed only 26,072 kil. (57,50 lb.) It seemed however as if the art of founding had only attained this state of perfection soon to fall into decadence; the equestrian statue of Louis 15th, cast by Gor in one piece, from the model of Bouchardon, and afterwards raised on the Place de la Concorde, was only 5·40 m. (17 ft. 9 in.) in height, while its weight was 29,370 kil. (64,775 lb.) During the revolutionary crisis, the only bronze work was limited to cannon; but under the Empire, bronze was again appealed to, to take its place among the other arts in representing the military triumphs of the French. Unfortunately the art had been too long neglected to allow of success, and some of the first essays were not prosperous, the statue of Desaix was a complete failure, and the Column of the Place Vendôme is far from being a master-piece of founding.

According to M. Payen, to whom we are indebted for the following details, the execution of the Desaix statue was put up to contract, and it was undertaken for 100,000f. (£4,000), a price in which the bronze was not included. The contractor gave up his bargain to a bell-founder, and he knowing nothing of the fashioning of such great works, and calculating upon the basis of his ordinary limited operations, engaged to do it for 20,000f. (£800); but in order to economize as much as possible, he required that the sculptor should be forbidden from superintending the moulding. The most difficult hollows were filled up, in order to avoid the trouble they would occasion; an attempt was made to mould in sand with frames, furnaces were erected, and an ill-constructed scaffolding, and after many useless arrangements and expenses, the bronze was let out, and having burst the moulds, ran about. Thus the operation completely failed, a good deal of the bronze was lost, and it was necessary to begin again. The founder then tried to cast the monument in pieces, but not arranging his moulds well, nor securing a uniform mixture of the metal, the pieces produced were dissimilar. He managed however to fit them together, but all the proportions of the figure were altered, and as these defects could not be remedied by the chisel, a most wretched monument was produced.

When the Column in the Place Vendôme was erected, the same faults were repeated; a bargain was made with an ironfounder, who had never been engaged in bronze work, he however had the temerity to undertake the moulding and finishing at one franc per kilo. (9*d.* per 2 lb.) The government on the other side undertook to deliver to him in guns, taken from the Russians and Austrians during the campaign of 1805, the quantity of bronze necessary for the completion of this enormous monument. The founder used a furnace he had for casting iron, but not being aware of the phenomena of bronze casting, and urged by his vanity to attempt in the first instance the casting of several of the great pieces of the base of the column, he encountered several defeats. Each time he necessarily altered the alloy by oxidizing the tin, lead and zinc, which metals so oxidized passed into the scoriæ or were carried off by the current of warm air. He did not perceive this cause of continual loss, and continued to produce the bas reliefs; but it may be readily conceived that they contained more copper than the bronze of the guns. When the founder had got two thirds through the column, he found out that he had got no more metal, and being, according to contract, responsible for the metal delivered to him, he was at once ruined. In this lamentable situation he tried to melt up the white metal obtained from the reduction of the scoriæ, and a large quantity of refuse metal which he had bought up at a low price. The bas reliefs which he obtained from the mixture of all these materials were marked with blotches and lead spots, their colour from a dirty grey became quite black; the authorities refused to receive work so defective, and put his foundry under sequestration. He succeeded, after much petitioning, in obtaining a committee to examine his accounts, which was composed of two chemists, two architects, two mechanical engineers, and two founders, with an auditor of the Council of State for the chairman. The weight of each piece delivered by the founder was known; specimens were taken from them, and the proportional parts weighed, from which was made an ingot representing the mean composition of the whole column. It was then found by analysis that it contained:

Copper	89·440
Tin	7·200
Lead	3·343
Silver, zinc, iron	0·017
	100

The committee then took specimens of bronze from the guns remaining in the government stores, and an ingot was formed to represent as nearly as possible the mean composition. The analysis of this ingot gave the following proportions:

Copper	89·360
Tin	10·040
Lead	0·102
Silver, zinc, iron, loss	0·498
	100

It was further known, that the law in France had fixed the composition of gun metal at 90 parts of copper and 10 of tin per cwt., but that this law was never well executed, and during the revolution scarcely attended to at all; it was also known that these foreign guns were of a more complicated and baser alloy than the French. Taking all these circumstances into consideration the committee were of opinion that the founder had produced an alloy, if not superior, at least equal, to that which had been given to him; and that they considered that he could not be charged with fraud in his contract. The chemical operations further explained the whole proceeding: by making separate analyses of the specimens of the great bas reliefs, the shaft, and the capital, it was found that the first had only 0·06 alloy per quintal; the second, particularly towards the upper part, and the third contained as much as 0·21. It was therefore evident that the founder not knowing how to manage bronze, had refined his alloy by several times remelting, and consequently diminished the total weight, and that to make up for this loss, he was obliged to put into the last castings the white metal extracted from the scoriæ. Thus he had given bronze of too good alloy in the beginning, which had obliged him at last to make the alloy too low. The moulding of the several bas reliefs was so badly executed, that the chaser employed to go over them, removed by chiseling or filing, a weight of bronze equal to 70,000 kils. (7 tons), which were given to him, besides a sum of 300,000f. (£12,000) paid down.

It was certainly hard to pay so dearly for experience, but fortunately it was profitable; not however that all the subsequent bronze works in France have been more successful, for the founders had to submit to several severe checks, and were obliged to study the processes, and proportions necessary to form a good alloy. Thus when in 1817 Lemot was employed to cast the equestrian statue of Henry 4th, now on the Pont Neuf, he at least took the precaution to take specimens from three bronze statues of Keller at Versailles, which were the best, with regard to casting, green colour, and the grain. The following is the result of his analysis.

	No. 1.	2.	3.	Mean.
Copper	91·3	91·68	91·22	91·4
Tin	1·	2·32	1·78	1·7
Zinc	6·09	4·93	5·57	5·53
Lead	1·61	1·07	1·43	1·37
	100·	100·	100·	100·

Lemot thought that he had gained experience enough from these analyses, but he did not escape from serious difficulties during the casting. Wishing to make use of the furnace, which had been built for casting the equestrian statue of Louis 15th, formerly in the Place de la Concorde, but the furnace not having sufficient draught for the fusion of Keller's alloy, in which there was more copper than in that of the statue of Louis 15th, he was obliged after several trials to make great changes, and still the casting did not perfectly succeed. The body of the king had several hollows in it, and the belly of the horse failed, a hole so large having been formed that it was obliged to be filled up; further 14,000 kilo. (14 tons) of oxidized rubbish was sold off.

Casting in bronze, although presenting only slight difficulties in the manufacture of objects of small dimensions, has always required greater responsibility when it is required to form considerable masses, perfectly homogeneous. The component metals are deficient in energetic affinity for each other, when in fusion tend to separate in the order of their densities, and, when the less fusible begin to solidify, the others in a liquid state, rise up towards the top, where the easy oxidation of a component part of the alloy always causes the risk of refining the metal. Besides these great obstacles, others are encountered in calculating the several component parts of the bronze, where it is wished to obtain precisely the required quantity of metal for the object to be cast, also in the preparation of the model, the construction of the furnace, and the disposition of the moulds. These and other difficulties explain how many abortive attempts sometimes preceded in former days the casting of a large work in bronze. They point out why Falconnet was 15 years casting the equestrian statue of Peter the Great, which figures on an immense monolithic pedestal at St. Petersburg; why the Kellers were 9 years casting the statue of Louis 14th; why Bouchardon and his successor Pigalle took 8 years for that of Louis 15th, on the Place de la Concorde; why the statue of Desaix, and we may almost say the Column of the Place Vendôme, failed, and why the great equestrian statues we have mentioned did not come perfect out of their moulds. The statue of Peter the Great was obliged to be begun again from the knees of the Czar and the breast of the horse, to the top of the statue. Bouchardon had much trouble in restoring the delicate forms of the horse in his beautiful equestrian statue of Louis 15th, which were badly produced in the lower part, and we have related the difficulties encountered by Lemot and Piggiani in casting the statue of Henry the 4th, difficulties which lasted four years. We cannot better finish this essay than by mentioning those which have just been surmounted in casting the various parts of the July Column, and for the better effecting this we shall compare it with the Column of the Place Vendôme, which is the only one having any analogy to it. The Vendôme Column is only coated with bronze, and the largest pieces are only five yards in extent, while each of its tambours is composed of six pieces, and the whole cost of the column in specie and metal provided by the state was 2 millions (£80,000). The July column on the other hand is entirely of bronze, and each tambour is in one piece, the base of the column extends about 16 yards, and the capital at the most extended place has the enormous dimension of 26 metres, 85 feet. This column however only cost 1,172,000 francs (£46,880).

Inequalities in the thickness of the parts constitute one of the great difficulties of casting, because the thin parts cooling rapidly, and the thick parts slowly, the shrinking of the former taking place sooner than that of the latter is apt to split the metal. It may be also conceived that the shrinking of a large object is so much more than that of a small one, as its dimensions are greater, and the necessity for taking this into consideration causes a fresh difficulty in the construction of the mould, which must be calculated so as to provide for the contingency. It is easy in the same way to conceive that the least motion of the mould, during the operation, will cause the required thickness to be exceeded. These considerations will explain the difficulties which had to be surmounted in casting the several parts of the Column of July, and as to the statue we cannot do better than republish an extract from the report of M. Hericarb de Thury, made to the *Société d'Encouragement*, on the improvements introduced by M. Soyez in the moulding of bronze sculptures.

"This statue 4·25 m. (14 feet) in height, supported on the toe, and bending forward, presented great difficulties in the moulding, and still greater in the casting, as the solidity of the statue depended on the extreme lightness of the upper parts, and the strength of the leg on which it is supported. Had the old methods been resorted to, the figure would most probably have failed, or have been tried in several pieces; because the upper part being very thin would cool down immediately, while the lower part cooling more slowly, would have contracted on itself, leaving at the ancles an opening of about 25 millimetres (an inch), the metal contracting from 12 to 14 millimetres per metre (½ an inch) and the statue would undoubtedly have been lost. To obviate these difficulties, M. Soyez determined upon casting it head downwards, by which he diminished the danger, I say diminished, for in this posture, the mould must have yielded, or the leg broken above the ancle. To provide for this, M. Soyez placed on each side of the foot a branch of copper 6·6 met. (26 in.) broad, finishing in a strong head, so as to force the foot to contract on the knee. Further these branches were so managed as to be rather thinner than the leg. Full success crowned the trial of this bold and ingenious innovation, the casting of this admirable statue succeeded in every detail, being perhaps the first time that a figure of this importance was cast without any defect. The thickness of the statue is from 4 to 5 millimetres (a sixth to a fifth of an inch) in the upper part, except the wings, which are only 2 millimetres. The supporting leg is 55 millimetres (2¼ inches) thick, beginning from the ancle, and progressively diminishes in thickness up to the thigh."

The monument of July undoubtedly marks a new era in the history of the art of bronze casting, and places France in the first rank in its pursuit, and in order to do justice to M. Soyez, we must mention some of the improvements effected by him. This artist has got rid of the use of iron as a means of consolidating isolated parts of figures, and particularly in supporting members; he casts these parts full by turning the figure upside down, which is an important innovation. He gets over the resistance of the sand of the mould on the contraction of the metal, not only by the weight of the mould, but by the progressive tenacity of the bronze while cooling. This tenacity, which may be considered as proportional to the area of the section of the part so cast, is increased at pleasure by accessary parts placed in the mould according as they are wanted. It is thus that the Genius of Liberty was cast, having as it were a second shapeless leg placed parallel to that which supports the figure, and intended to become at the period of contraction, auxiliary to the statuary leg to which it was united by the two extremities. Thus also was cast the bent back leg of the horse of Charles Emmanuel of Savoy. In order to prevent this leg from breaking in the ham when cooling, the foot was united to the thigh by a strong tenon, which was afterwards chiselled away.

ENGINEERING WORKS OF THE ANCIENTS, No. 7.

WORKS OF HERCULES.

Besides the performance of the Egyptian Hercules already mentioned, Diodorus Siculus, Book 4th, gives an account of several works of the Greek Hercules. Not to speak of the operations attributed to him at the Straits of Gibraltar, there were two hydraulic works in Greece said to have been executed by him. The large champain country about Tempe being all over a stagnant lake, he cut trenches through the lower grounds, and through these trenches drained all the water out of the lake, by which means were reclaimed all the pleasant fields of Thessaly as far as the River Peneus. In Beotia he did quite the contrary, for to punish the Minyœ it is related that he caused a river to overflow the whole country, and turn it into a standing pool. In his passage of the Alps from Gaul, an expedition in which he was the predecessor of Hannibal and Napoleon, he levelled and opened the rough and difficult ways to make way for his army and carriages. In Italy Hercules performed some remarkable works about the Lake Avernus, for whereas the lake extended as far as the sea, Hercules is said by casting up earth, to have stopped up its current, and to have made the way near the sea, called the Herculean way.—In Sicily to express his good wishes for the inhabitants, he caused a pond or tank to be sunk near the city of the Agrineans, four furlongs in compass, which he called after his own name.—In Greece Hercules had the further merit of having diverted the River Achelous into another channel which he had dug for it. This irrigated a considerable part of the country, and was done to please the Calydonians. It gave rise to the poetical fable that Hercules fought with Achelous transformed into the shape of a bull, and in the conflict cut off one of his horns and gave it to the Etolians. This they call Amalthea's horn, in which the poets feign that there grows all manner of summer fruit, as grapes, apples, and such like, not the only time by the bye that engineers have filled the horn of plenty.

DEDALUS—ENGINEERING FESTIVALS.

Diodorus gives a long account of Dedalus, from which we have made the following extracts. Dedalus was an Athenian of the family of the Erechthidæ, being the son of Hymetion, son of Eupalamus, son of Erechtheus, King of Athens. He was extraordinarily ingenious, and very studious in the art of architecture, an excellent statuary and engraver upon stone, and improved those arts with many notable inventions. Dedalus was obliged to flee to Crete for the murder of his nephew Talus, who was killed by him out of envy. To Dedalus is attributed the invention of sails for ships. After leaving Crete he staid with Cocalus and the Sicilians, in whose country Diodorus, a native, says that works of his were to be seen in that day.

While on the subject of Dedalus we must not omit what the Biographie Universelle says on the subject of festivals established in his honour. When the Plateans returned to their native city, 311 B.C., after an exile of sixty years, they instituted an annual festival called Dedalia, which every sixtieth year was celebrated with extraordinary magnificence. All the trees cut down were made into statues called Dædala. The name of Dedalia was also given to a Theban fete in honour of the reconciliation effected between Jupiter and Juno by Cithero.

TALUS.

Talus is sometimes called Atalus, Calus, and Acalus; he was the nephew of Dedalus, as before mentioned, and murdered by him. Being the son of Dedalus's sister, and but a young boy, he was bred up with his uncle to learn his trade. Talus for ingenuity exceeded his uncle, and invented the potter's wheel; he got likewise a serpent's jaw bone, and with it sawed a little piece of wood asunder, then in imitation of the tooth in the jaw, he made the like in iron, and so he found out an instrument for sawing the greatest pieces of timber. He invented likewise the turner's lathe and many other tools.

PROMETHEUS—CRETAN HERCULES—VESTA—MINERVA—VULCAN.

Prometheus is according to some the first who stole fire from the gods, and bestowed it upon men (Book 5th), but the truth is he found out the way how to strike fire out of flint or stone. The Idæi Dactyli are also said to have found out the use of fire. They discovered the nature of iron and brass to the inhabitants of the Antisapterians, near the mountain Berecynthus, and taught the manner of working it, and because they were the first discoverers of many things of great use and advantage to mankind, they were adored and worshipped as gods. One of them they say was called Hercules, a person of great renown. After them were nine Curetes who invented swords and helmets.—Vesta invented the building of houses, and upon this account almost every body sets up her statue in their houses, and adores her with divine honours.—Minerva was the introducer of architecture, and also according to our chronicler of the use of garments, so that architecture and tailoring according to him boast one common parent. Vulcan they say found out the working of iron, brass, silver and gold, and all other metals that require forging by fire; and the general use of fire in all other cases was found out by him.

XERXES—AGRIGENTUM—PHEAX—THEMISTOCLES—DIVERSION OF THE NILE.

The Eleventh Book of Diodorus, is on Greek history, he mentions Xerxes throwing a bridge over the Hellespont, and cutting a canal through Mount Athos.

The Agrigentines in Sicily having acquired great spoil by the defeat of the Carthaginians, took the greater part of the prisoners into the public service, and employed them in cutting and hewing stone. They not only set them to build the largest of the temples, but made water courses and sewers underground, so great and wide, that though the work itself was contemptible, yet when done and seen was worthy of admiration. The overseer and master of the work was one Pheax, an excellent artificer, from whom these conduits were called Pheaces. The Agrigentines likewise formed a tank for fish, at great cost and expense, seven furlongs in compass, and twenty cubits deep. This by neglect of succeeding ages, filled up with mud, and at last through length of time turned wholly into dry ground; but the soil being very fat and rich, it was planted, and yielded the city a large revenue.

Themistocles has the merit of projecting and carrying into effect the construction of a haven at the Pyræus, by which the naval power of Athens was greatly increased. The account of his negociations with the assembly of the people is of much interest in an historical sense, but not immediately relating to the end we have in view, we are compelled to omit it.

In the 21st chapter is mentioned the diversion of the Nile during the war between the Persians and Egyptians.

BLOCKING UP OF THE EURIPUS.

In his 13th Book our historian describes the measures taken by the inhabitants of Eubœa on their revolt from the Athenians. This island being separated from the continent only by the narrow strait of the Euripus, they solicited the Beotians to assist them in stopping it up, in order that they might receive assistance against any attacks from the Athenians who were masters of the sea. To this the Beotians agreed, and all the cities set upon the work, and every one strove with diligence to perfect it, all the citizens, foreigners and strangers being set to work. The mole began at Chalcis in Eubœa on one side, and at Aulis in Beotia on the other, that being the narrowest part. In these straits the sea was very boisterous and rough, but after this work much more unquiet and raging, the passage being made so very straight and narrow, that only one ship could pass through. There were forts built on both sides upon the extremities of the moles, and wooden bridges made over the currents for communication.

CARTHAGINIAN ENGINEERING.

Our author gives an account of several sieges by the Carthaginians in Sicily, who appear from his account to have been as skilful as the Greeks in military warfare. At the siege of Himera in Sicily, Hannibal the elder (Book 13th), undermined the walls, supporting them with great pieces of timber, which being set a-fire, a great part of the walls suddenly fell down.

In the 20th Book, in the account of the expedition of Agathocles into Africa, there is a description which mentions, the country as well irrigated and supplied with canals and sluices.

MACEDONIAN GOLD MINES.

Philip, King of Macedon, (Book 16th), having taken Crenidas, and called it Philippi, so improved the gold mines in those parts, which before were but inconsiderable and obscure, that by building of houses for the works he advanced them to bring in a yearly revenue of above a thousand talents.

ALEXANDER THE GREAT.

The siege of Tyre by Alexander the Great, recounted in the 16th Book, required the execution of works on a very great scale. Alexander demolished Old Tyre, as it was then called, and with the stones carried by many thousands of men, raised a mole two hundred feet in breadth across the sea, which by the help of the inhabitants of the neighbouring cities, who were impressed for the purpose, was speedily carried out a considerable way. This mole was afterwards injured by a violent storm, when Alexander caused it to be repaired with trees laden with earth, and so again brought it near the city. By this and many other operations he was able to take the city, after a gallant defence, in which the inhabitants displayed much ability.

In the memorandum books of Alexander examined after his death, (Book 18th), were found heads of six colossal plans, among which were the following,—that a plain and easy road should be made straight along the sea coast of Africa to the Pillars of Hercules, that six magnificent temples should be built, and that arsenals and ports should be made in places convenient for the great navy he contemplated. These things, although highly approved by the Macedonians, yet because they seemed things beyond all measure impracticable, were desired to be laid aside.

INUNDATIONS.

During the Seleucian war, (Book 19th), the Macedonians under Eumenes encamped on the banks of the Tigris, about three hundred furlongs from Babylon, Seleucus occupying the river with a flotilla of small vessels. The Seleucians, having sailed to an old water course, cut down the banks at a part where it had been filled up from length of time, upon this the Macedonian camp was surrounded with water, and all the tract of ground overflowed, so that the army was in great danger of being utterly lost. At last removing a great part of his army in flat bottom boats, he caused all the Macedonians to repass the river, and then for the purpose of recovering his carriages and baggage, by the direction of one of the native inhabitants, he set about cleansing such another like place, by which the water might be easily diverted, and the ground all round about drained dry. When Seleucus perceived this he granted a truce, and the works were suspended.

In the same book is the account of the natural inundation, by which the city of Rhodes was so much injured. Rhodes being built in the form of a theatre, and the rain very heavy, the water ran for the most part into one place, and the lower parts of the city were presently filled with water, for the winter being looked upon as over, no care had been taken to cleanse the channels and sewers, and the pipes likewise in the walls were choked up, so that the water stood several feet deep, until part of the city wall breaking down, the pressure was suddenly relieved.

PILEWORK.

In a mention of the Cimmerian Bosphorus in Book 20th, it is related that the king's palace was surrounded with the river Thasis, and that there was a road to it through the fens, guarded with forts and towers of timber, raised upon pillars over the water.

DEMETRIUS POLIORCETES.

We find in the 20th Book a long account of the siege of Rhodes by the celebrated Demetrius, who among other works made extensive mines under the city walls, which being told to the Rhodians, by a deserter, the Rhodians made a deep trench along the walls, which was now ready to be tumbled down, and forthwith fell to countermining, and at length met the enemy under ground, and so prevented the mine from proceeding any farther.

MR. MUSHET'S PAPERS ON IRON AND STEEL.—No. 3.

Sir—The opinions adopted by Drs. Ure and Karsten respecting the quantity of carbon in iron, namely, assigning to white cast iron a larger proportion than to gray, and taking the manifestation of the graphite fracture in the latter as a certain sign that the quantity of carbon in the metal is on the decrease, appear to me so much at variance with, and subversive of, all that practical men have understood and believed upon this subject, that it is my intention, with your permission, to make a few remarks upon the matter, in order to ascertain, by an examination of facts, how far they are borne out by the appearances which we every day see exhibited on the scale of manufacture, and in the manipulation of the metallurgical department of the laboratory.

I hope your readers will not consider I have travelled out of my way to make any gratuitous observations on Dr. Ure's most elaborate work further than the necessity of the case required, seeing his views of the subject are at direct variance with my table of the proportions of charcoal used in the fusion, and in forming the various qualities of iron and steel so frequently referred to in these letters.

As a prelude to the subject, and with a view to enable your readers to arrive at a more clear understanding of the points at issue, I shall define and class the distinct characteristics which cast iron assumes. Nothing can be more marked in the page of metallurgy than those divisions in the progressive stages of this metal:

1st. Steel-grained cast-iron, or crude steel.
2nd. White cast iron.
3rd. Gray cast iron.

In the absence of chemical analyses, but grounded upon numerous direct and comparative experiments, I have considered steel-grained cast iron to contain from 1 to $1\frac{1}{2}$ per cent., the white cast iron from $1\frac{1}{2}$ to $2\frac{1}{2}$ per cent., and gray cast iron from $2\frac{1}{2}$ to 4, or, when richly carburetted, to $4\frac{1}{2}$ or 5 per cent.

Steel-grained cast iron is rarely to be met with at the blast furnaces in this country: decided traces of it are occasionally to be found in the commencement of a blast, particularly should the furnace be started with too heavy a charge; a high temperature being required to maintain its fluidity, it either sets on the bottom of the furnace, to be cleared off afterwards by an alloy of gray iron, or it escapes with the white iron when the furnace is tapped. At this juncture, which, when steel-grained iron is produced, is always one of difficulty in the affairs of the furnace, should the iron which has been obtained be examined, it will be found possessed of a white fracture, frequently mixed with a portion of the steel-grained iron.

Calcareous ores, however, afford the steel-grained cast iron more as a natural product; the supposed alloy of the metal of lime with the iron produced from those ores, renders the white cast iron more lively and fluid than the gray, and becomes in some measure a substitute for carbon in maintaining a considerable degree of fluidity, when the metal is at any time passing into the steel-grained quality, so as it may be run out of the furnace in quantity, and with a comparatively clean cinder.

Castings made of such iron possess a degree of strength quite unknown in the general operations of the foundry; they will beat up like soft steel, and acquire by hammering a permanent flexure like malleable iron; but, as far as my information and experience go, all attempts hitherto to remelt it have failed.

Rare as this peculiar state of the metal may appear to the iron maker of this country, yet the whole of his metallic produce, in passing through the furnace, must have, in the first instance, been subjected to this process of steelification, before it absorbed enough of carbon to constitute it white cast iron. It may, however, be produced at any time artificially, by exposing white cast iron, particularly of that quality that merges on the steel-grained, in an open or covered furnace for some time to the action of a red heat, the time of exposure to be commensurate to the thickness of the iron employed. This operation has the effect of discharging the white or lamellar fracture, and substituting in its place one of a grayish colour, very dense, and minutely steel-grained, the process itself being one of decarbonization, and which, from its colour and softness under the file, ought not to be taken, as it sometimes is, for a manifestation of an increased quantity of carbon in the iron.

2ndly, as white cast iron occupies a position between steel-grained and graphite or gray iron, and is frequently found merging in both, it of course possesses a variety of quality and character greater than either of the other two, so as to render the details of experiments made with this variety of the metal subject to greater uncertainty than with the graphite or steel-grained.

Dr. Ure has assigned no definite quantity of carbon to the steel-grained iron, but that, in his estimation, it possesses a notable proportion, may be gathered from what follows: he assigns to white cast iron a maximum dose of 5¼ per cent., and further states that with a proportion of 4½ per cent. it still retains its white or lamellar fracture. So that in the absence of more correct data, it may be inferred that when the change to steel-grained iron has taken place, the iron has lost 1 per cent. and still retains about 3½ per cent. of carbon, so that as it regards carbon, the iron is in the same situation with good foundry iron, but observe the difference when this theory is tested by practice—the foundry iron will melt in an air furnace, and come out as fluid as water, while the steel-grained iron, under the same circumstances would not melt at all, but pass rapidly into the state of malleable iron.

3rdly, graphite or gray cast iron first makes its appearance by small dark specks inserted on the fracture of the white iron, and at this stage it is said to be mottled when those specks cover the entire surface, and receive, from the addition of more carbon, some degree of lustre, the iron is said to be bright gray; as the fracture becomes more open, and the colour darker, it is called dark gray iron; and when uniformly open throughout with a smooth surface, it is called best foundry iron.

Hitherto it had been supposed and believed that white cast iron contained a much less quantity of carbon—that the change of fracture from white to gray was in consequence of the iron absorbing or becoming united with a large share of that substance—that whatever carbon white iron contained, the graphite was so much in addition, and never considered as a symptom of its abatement.

Dr. Ure, however, holds a contrary opinion; according to him, the greatest quantity of carbon which can be united to the metal is in the state of white iron, and may be to the extent of 5¼ per cent, as the iron becomes more gray by the addition of carbonaceous matter in the furnace, the quantity of carbon in it diminishes inversely to 3½ or 4 per cent. This I confess is a paradox of difficult solution, as it involves, to a certain extent, the operation of substracting during a process of repeated additions.

Independent of this, the new theory is to me abundantly perplexing, as the student has to deal with carbon in a considerable variety of states with which he had not been formerly familiar. We have "free carbon, residuum of plumbago and carbon, graphite or plumbago, combined carbon, carbon unaltered, carbon in mechanical mixture, carbon in a state of alteration, &c." The most of this is new and strange to me, but I may inquire whether Dr. Ure ever separated carbon from cast iron by mechanical means that were not magnetic.

Were the new theory true, we should be obliged to abandon the old legitimate conclusion that iron and steel were fusible in proportion to the carbon they contained, but now inversely, seeing white pig iron, which is said to contain the most carbon, is much more infusible than gray iron.

The process of refining pig iron for the manufacture of bar iron, would, under Dr. Ure's system, be no longer a decarbonating operation, but the reverse; for when the gray pig iron introduced into the furnace, had acquired the white or lamellar fracture, it would be found to have absorbed or taken up $1\frac{83}{100}$ of carbon in addition, being the difference between 3½, the utmost that forge iron may be supposed to contain, and 5¼, the quantity assigned to white iron, and this during an operation of the most severe decarbonization with which we are acquainted.

In like manner, suppose a founder was to charge his air-furnace with 2000 lb. or any other quantity of gray pig iron, which is known to contain 3½ per cent. of carbon by repeated fusions, accompanied with a considerable loss of iron, it would at last become possessed of the white or lamellar fracture, and have acquired nearly 2 per cent. more of carbon while passing through a repetition of consecutive fusions. To believe this for one moment appears to me the climax of absurdity.

Again, in the blast furnace a comparatively limited quantity of coke only is necessary merely to fuse the charge, and cause the whole to flow in one common slag, without any portion of the iron being separated. More coke, that is carbon, is added, separation takes place, the iron becomes white, and partakes of the lammelated fracture, and may at that period be supposed to contain the maximum dose of 5¼ per cent. of carbon. The manufacturer, aiming at a more profitable result, adds more and more carbon in the furnace, until he has attained his object as to quality; but, according to the new doctrine, while he has been adding carbon in the furnace, it has been uniformly diminishing in the pig iron.

The pig iron maker might naturally put the following questions: if white pig iron absorbs 5¼ per cent. of the fuel by weight, how is it that this augmentation is not felt in the yield of our ores, but quite the contrary, whereas, when the furnace is making gray iron, the yield from our ores is considerably better?

The operator in the laboratory may be apt to doubt and inquire how it is that, after obtaining his metallic result in white cast iron, and with a fine gloss, he can at any time, by the addition of charcoal, augment the produce of his ore from 1 to 3 per cent. This fact has been known and acted upon by myself for at least 10 years, so that when carburetted results have been obtained beyond the range of the blast furnace, an allowance has been made in the yield of the ore for their extra dose of carbon.

The steel iron maker of Hindostan might well call in question the truth of the new theory upon the most solid and philosophic grounds; for were it so that white cast iron contained more carbon than gray iron, he would decidedly make white iron in preference, for he could do it for for one third of its present cost for charcoal; but he has continued for ages to make gray iron, for the best of all reasons, viz., that his customers can, with gray iron, convert into steel a greater quantity of malleable iron than they can with white.*

On the same grounds I make no doubt that Agricola understood the secret of making iron like the East Indian (gray cast iron), for the purpose of converting, by steeping therein his malleable iron, into steel, and on the same principle, namely, that of its possessing more carbon to communicate to the iron.

I shall, for the present, furnish no further objection to the theory of Drs. Ure and Karsten, but conclude by stating the following facts as being finally conclusive against it:—quantities of gray cast iron, white cast iron, and steel-grained cast iron, were reduced to powder so small as to pass a sieve containing 900 holes in the square inch of its surface, my purpose being to form a species of metallic charcoal to be used in the reduction of an ore of iron, confident that that iron which contained the greatest proportion of carbon would revive from the ore the greatest per centage of iron. A micaceous ore was used in preference, from its presenting more surface to the iron, and which contained 70 per cent. of iron; with the powder made from gray iron 40 per cent. was on the average obtained from the ore, besides making good the weight of the original quantity of iron introduced into the crucible, whereas, when the same experiment was carried into effect with the white and steel-grained iron, not only was there no yield obtained from the ore, but the original iron had sustained a loss varying from 4 to 8 per cent.

I will now make a few final remarks upon the subject of the alleged quantity of carbon contained in steel, on which subject I find my opinions as widely different from those of Drs. Karsten and Ure as upon the proportion which they allege is contained in white cast iron, and which has been aluded to at large in my former communications on this subject.

Dr. Karsten, whom Dr. Ure quotes upon most occasions on the subject of iron and steel, says that he has found the proportions of carbon in steel vary from 1¼ to 2¾ per cent.; now in noticing this latter proportion, I have no hesitation in saying that 2¾ per cent. of carbon united with iron would not form steel at all, but white cast iron. Again, it is said that the proportion in blistered steel reaches, sometimes, but never exceeds, 1¾ per cent., so that we are led to infer that some sort of steels contains 1 per cent. more carbon than that which is said to be contained in steel of cementation. According to my knowledge and view of the matter, steel of any sort united with 1¾ per cent. of carbon, would not at any degree of heat extend under the hammer, or be applied to any useful purpose. 1¾ per cent. would be

* See my Papers on Iron and Steel, page 670.

nearly equal to $\frac{1}{77}$ part the weight of the iron; now $\frac{1}{60}$ part the weight of iron of charcoal fused with Swedish charcoal bar iron on the scale of manufacture, affords cast steel of a very high quality, which requires careful working at a low red heat to convert it into form; any increase of charcoal beyond this proportion would entirely destroy its ductility, either cold or hot. Should an adequate allowance be made for the waste which the charcoal must unavoidably undergo in the crucible, before the affinity is established between it and the bar iron, and for the moisture which, in common with all charcoal, it contains, probably not more than $\frac{1}{3}$ of its weight becomes united to the iron in the process of fusion.

In proof that Dr. Karsten's estimate of the proportions of carbon forming steel is excessive, I refer to the celebrated Bergman's analysis of Swedish steel iron and steel. According to him, the proportion of carbon in steel is (or $\frac{1}{200}$ part) - - ·50
Carbon originally in the iron - ·12

Taken up by the iron in passing into the state of steel, equal $\frac{1}{263}$ part; a proportion very different from those furnished by Dr. Karsten, which range from $\frac{1}{36}$ to $\frac{1}{68}$ - - ·38

A still less proportion of carbon was found in the laborious analyses of four specimens of French steel iron performed by M. Vauquelin, and which seems to have carried the dose of carbon to the opposite extreme.

*Specimen No. 1,	contained of carbon	- -	·110789
Do. 2	do.	- -	·00683
Do. 3	do.	- -	·00789
Do. 4	do.	- -	·00643

I also subjoin a very accurate and interesting analysis made by Mr. Tennant at Glasgow, and inserted in the 6th volume of the transactions of the British Association, of cast steel made from Danamora iron, which, in point of proportion, coincides with my view of the matter:

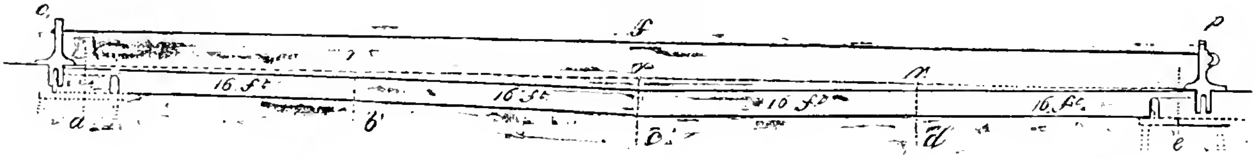
Iron - - - - -	99·288
Manganese - - - - -	·190
Carbon - - - - -	·388
Loss - - - - -	·134
	100· parts.

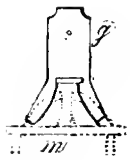
This proportion is equal to $\frac{1}{260}$ part the weight of the steel, and exhibits in a most striking point of view, the minute proportion of carbon which communicates to iron the varied and enduring properties of steel, without which, or some equally powerful substitute, arts and manufactures would soon become stationary.

Your's, &c.,
Coleford, June 17. D. Mushet.

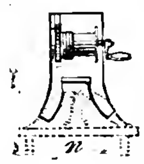
P.S. When Dr. Ure revises the article upon the assay of iron ores, I should recommend him to substitute some other glass or flux for flint glass, as it would be inconvenient and perplexing for the juvenile assayist to have to deal with a button of iron over-riding one of lead, the former containing a little lead, and the latter some iron.

PLATE LAYERS GAUGE LINE.





f, four lengths of 16 feet rails, with the set-ups at *o* and *p*.
o, *p*, the set-ups on the rail with the line fixed, and showing the reel at *p*.
g, *b*, ditto across the ditto.
m, *n*, section of chairs and rail, with the instrument placed.
r, *r*, *r*, top of rail when corrected.



Sir—I take the liberty of handing to you the annexed rough sketch of a plate-layer's line, &c., for the purpose of enabling the plate-layer to keep nearly a correct gradient on the surface of the rails, between two correct heights, at the distance of four or five 16 feet rails. If you think this of any use, or worthy of insertion in your widely circulated Journal, it is at your service, at the same time I beg to say that I am not aware of its ever being applied, but from the best consideration I am able to give on its utility, I am persuaded that it may be applied to advantage, more particularly on railways like the Great North of England, which has so many favourable positions for a great distance in a straight line.

The instrument can be made very portable, and of a light construction, readily fixed on the cheeks of the joint chairs, at any distance required, by merely placing the claws of each set-up on them, no other fastening being required.

One of the set-ups (or gauge) is furnished with a reel and ratch, so that when the line is wound tight, it will be kept from slacking; the line must be made fast to the other 'set-up,' and at equal distance from the top of the rail with the other. When the points at *a* and *e*, (sketch *f*) are connected, the instrument may be then fixed on these places; when the intermediate blocks, &c., at *b*, *c*, and *d*, may be beat up to the proper height, by gauging from the line to the top of rail, (as per dotted line at *f*, *r*;) the line may be so arranged as to stretch from the points *a* and *e*, on the surface of the rail, and the intermediate rails then brought up to the line, so that no gauging would be required, but I believe the first process would answer the best.

Your obedient servant,
M. Q.

York, June 13, 1841.

If you refer to page 181, I wish you to correct an error in the weight of chairs, &c., the following is the correct statement, and should have been inserted:—

Joint chair	- -	40 lb. each.
Middle	- -	30 „
Check	- -	41 „

M. Q.

CHIMNEY FLUES.

Sir—According to the new Act, chimney flues are, in future, not to be less than 14 inches by 9 inches, or (if cylindrical,) 12 inches diameter. Is this meant to apply to the whole extent of the flue? for if so, all chimney-pots, &c., of less diameter are at once condemned; as far as such unsightly terminations are concerned, that will however be no loss; but as experience has proved that when flues exceed a certain size, contraction becomes necessary, at the top at least, to ensure a good draught, if that is henceforth not to be permitted, the fire-places, in order to contain fire enough to rarify the greater column of air that will thus be exposed to its influence, must be enlarged to an inconvenient extent.

Your opinion on the proper construction of the Act, will oblige your obedient servant,

A Subscriber.

N.B. According to Tredgold on this subject, flues seldom ought to be more than 8 or 9 inches in diameter, indeed frequently much less; and when climbing boys are no longer permitted, there can be no objection whatever to making them of any size that the particular case may require; and indeed there never was any objection, since there is no necessity, even now, for using so barbarous a mode of sweeping as is about to be forbidden by law.

[We are of opinion that the Act does not apply to chimney-pots—a chimney-pot is not a flue—the flue terminates with the brick shaft.—Editor.]

* See Mushet on Iron and Steel, and the quarto edition of Nicholson's Journal.

ON THE BUILDING MATERIALS OF THE UNITED STATES OF NORTH AMERICA.

By David Stevenson, Civil Engineer, Edinburgh.

Read before the Society of Arts for Scotland in Session 1841.

There is, perhaps, nothing connected with the useful arts, which has a greater share in forming the characteristic appearance of a country, than the materials which it produces, and of which its public works are necessarily constructed. I use the word *materials* in the technical sense in which it is employed by engineers and architects, to denote the several productions of the mineral and vegetable kingdoms which are used in the construction of engineering and architectural works; and we have only to look around us for a moment, to be at once convinced how much these, in their almost endless variety, affect the appearance, as well as modify the structure, of the public works of every-country.

A good illustration of the truth of this observation presents itself, when we compare the circumstances of Scotland and England in this respect; the former being what may be termed a *stone*, and the latter a *brick* country. To what circumstance can the far-famed beauty of the Scottish metropolis be more reasonably attributed, than to the great abundance of beautiful sandstone afforded by the quarries in its immediate vicinity, to which its street architecture and public buildings are so greatly indebted for their striking appearance. This remark applies, as we are well aware, not only to Edinburgh, but to many other towns in Scotland; while our less highly-favoured neighbours in the south, from the scarcity of good coloured building stone in some districts, and the total want of it in others, are reduced to the necessity of using brick for their dwelling-houses, and in many instances for their public buildings. So generally acknowledged are the fine qualities of the stone from many of the Scotch quarries, that it is exported to a considerable extent. To London itself, indeed, a large quantity of stone is annually sent from Craigleith in Mid-Lothian, which is the largest, and probably the finest sandstone quarry in the world, and of which the dwelling-houses in the New Town of Edinburgh, and most of the public buildings, were in a great measure built.

Many similar illustrations may be found, even in matters of much smaller importance than that to which I have just alluded. In Great Britain, for example, with the exception of some districts in England, the roofs of houses are very generally covered with slates, the greater part of which are supplied by the extensive slate quarries of Bangor in North Wales, and Easdale, Balachulish, and others, on the west coast of Scotland. But Holland has not the advantage of a like supply, and consequently the houses in that country are invariably covered with tiles; and if we extend our observations still further, to Canada and the United States, we there find that the want of more suitable materials for roofing, and the great quantities of fine timber with which those countries abound, have induced the inhabitants to cover their dwelling-houses with wood cut into thin pieces called "shingles," while the spires of the churches, which rise from all the principal towns on the banks of the St. Lawrence, are covered with highly polished tin.

Another of the many illustrations that may be given, appears in the construction of roads—a most important branch of engineering. The roads in this country are now invariably macadamized, as materials hard enough for forming them advantageously on that principle are very generally met with throughout the length and breadth of the island. In France, on the other hand, the want of hard materials renders Macadamizing not so applicable; and consequently, it has not by any means been generally introduced in that country, many of the principal roads being still *pitched* or paved with large stones. In Holland, owing to the scarcity of stones of every description, most of the roads are paved with small well-burned bricks, called "clinkers," which are set in sand, and present an exceedingly smooth surface; while in America and Russia, we find long stretches of "corduroy road," constructed entirely of timber—the produce of their extensive forests, which forms a species of highway by no means so well calculated as any of the others alluded to, for extending communication or promoting the comfort of the traveller; as the painful experience of every one who has travelled on them can abundantly testify.

The materials of every country may therefore be regarded as a subject of great interest connected with its history, and this consideration has induced me to offer a few remarks on the materials employed in the construction of the public works of the United States, in the belief that they may not be uninteresting to the members of a society which has for its object the promotion of the useful arts.

Iron is pretty abundant in North America, and it is worked in several parts of the United States. The only iron-works which I had an opportunity of visiting in the course of a late tour in that country, were those in the neighbourhood of Pittsburg, on the river Ohio, which are said to be the most extensive in America. At this place, the workmen were engaged in the manufacture of pig iron and plate-rails for railroads. The use of plate-rails, however, has been very limited, and as no other description of rail has been manufactured in the country, it has been the practice to import both the rails and chairs for the greater part of the American railroads from Britain, as well as the iron used for some other purposes. The government of the United States, indeed, in order to facilitate the progress of railways, do not exact the duty on iron rails and chairs imported from this country. It may safely be said, that the manufacture of iron in the United States, and what is more closely connected with the subject of this paper, its application to engineering works, are still in their infancy, at least when we regard the great extent and perfection to which these arts have been brought in Britain; and my observations on the materials of the country will therefore be confined to those of masonry and carpentry, as these are in some degree peculiar to the country, and any remarks regarding them will of course be more interesting.

Brick is the building material which is now invariably used in the construction of dwelling-houses in the towns of the United States. Timber is still pretty generally used for houses in the country; but of late years the erection of wooden structures, from their liability to take fire, has been prohibited in the neighbourhood of towns. Clay suitable for brick-making is found in great quantities, which is a fortunate circumstance for the inhabitants; and the bricks, which are burned with wood, and manufactured in other respects like those in this country, generally cost about 6½ dollars or 26s. a thousand.

Experience in our own and in many other countries, has proved that brick is well suited for house-building; but experience has also shown that it is by no means so well adapted as stone for engineering operations generally; and to some works it is with us considered wholly inapplicable. Marble and granite, of which I shall afterwards have occasion more particularly to speak, occur in the northern parts of the United States; but stone easily accessible to the quarrier, and fitted for building purposes, is very rarely to be met with, and the American engineers have therefore been obliged, as is the case in all countries, to adapt the structure of the works to the materials they possess; and in making this adaptation, they appear to have violated many of the established rules of engineering as practised in this country. The scarcity of stone, and the unsuitableness of brick for hydraulic purposes, for example, has forced them to construct most of the locks and aqueducts on the lines of their great canals wholly of timber, with which the country abounds; and that material, ill adapted as it may seem to such a purpose and situation, where it is not only exposed to the constant tear and wear occasioned by the lockage of vessels, but also to the destructive effects of alternate immersion in water and exposure to the atmosphere, has nevertheless been found in practice to form a very good substitute for the more durable materials used for such works in Europe.

Stone.—The quarries of the United States, taking into consideration the great extent of the country and the number of its public works, are, as I have already hinted, few in number; and, generally speaking, the workings are on a small scale. They afford granite and marble, and their produce is almost exclusively applied to facing public buildings, forming stairs, window and door lintels, and to other architectural purposes.

Granite is worked in the northern part of the country at Quincey in the state of Massachusetts, and at Singsing in the state of New York, and also in New Hampshire. The Quincey granite is of a fine gray colour, and can be quarried in large blocks. It has been used a good deal in Boston and the neighbouring country for architectural works. It has also been employed for railway blocks on some of the lines of railway in the neighbourhood of Boston, and in the construction of the only two graving docks which exist in the United States, the one at Boston, and the other at Norfolk in Virginia, the latter at a distance of upwards of 500 miles from the quarries; and these, so far as I am aware, are the only engineering works of any consequence in America in which granite has been employed.

The Singsing granite, which is of a dark gray or bluish colour, is quarried on the banks of the Hudson, about 25 miles from the town of New York, at which place it has been pretty generally used for some time for stairs and lintels, and has lately been introduced for facing buildings. The Astor hotel, the largest in America, and perhaps in the world, which is one of the very few stone buildings in New York, is built of this granite.

In the neighbourhood of Boston, and also Philadelphia, a species of soap-stone is found, which is quarried to some extent, and used in situations exposed to high temperatures instead of fire-brick.

Marble. To the marble quarries, however, the Americans look for their principal supply of materials. These are more numerous, and are more widely distributed than the others I have mentioned, although they also are confined to the northern states. The principal marble quarries are in the states of Pennsylvania, Massachusetts, and Vermont. I visited some of them when in the country, and had also the advantage of receiving much information regarding them, as well as the materials of the United States generally, from Mr. Strickland, architect, at Philadelphia, and from Mr. John Struthers, marble-cutter, of the same place, to whom I am indebted for the specimens of marbles and woods which I had the pleasure of laying before the Society.*

The marble quarries in Pennsylvania are situate in the valley of the river Schuylkill, and are from thirteen to twenty miles distant from Philadelphia. They produce white, blue, black, and variegated marbles. Limestone is found resting on the marble, and is blasted off with gunpowder, and burned for making mortar. In some of the quarries which I visited, the beds of marble dipped from north to south at an inclination of 60° with the horizon, and they were worked at considerable disadvantage. In one quarry the men were working a bed of white marble 14 feet in thickness, at a depth of 120 feet below the natural surface of the ground. The blocks, some of which weighed 12 tons, were raised to the surface by means of a rudely-constructed horse-gin, there being no road to the bottom of the quarry, or rather pit, from which they are taken, by which even a man could conveniently, or safely, descend or ascend, without the use of a rope to prevent his falling headlong to the bottom. In this respect the American marble quarries reminded me of the celebrated sandstone pits of the ancient city of Caen in Normandy, which are not only remarkable as having produced the materials for the old London Bridge, but as presenting a mode of working very similar to that pursued in the coal-pits of this country; the blocks, being excavated at a great depth under the ground, are conveyed in subterranean passages to shafts, through which they are raised to the surface by horse power, as in the American quarries. The price of the American marble varies according to its quality and kind. The carriage of the materials, owing to the badness of the roads, forms a very expensive item in all the public works, and is, of course, regulated by the distance of transport; but the white marble costs about 4s. 10d., and the blue about 4s. per cubic foot at the quarries, and although this may seem a very moderate price for marble, which in this country costs from 15s. to 2l. a cubic foot, still, when used instead of stone throughout the whole thickness of the wall of a dwelling-house, or the pier of a bridge, it becomes, even at the lower price I have mentioned, a costly material.

The Massachusetts quarries, which are at a place called Stockbridge, produce white and blue marbles, and the Vermont quarries, which are near Lake Champlain, furnish black and white marbles.

Those I have enumerated are the principal quarries in the United States; but from the circumstances of their being so much confined to particular localities, and the manner in which they are worked, it is evident that their produce cannot be applied by any means to the general wants of the country; and consequently, excepting in the case of buildings on which a good deal of money is to be expended, it is but little employed, the cost of the material itself, and the expense of carriage, being very considerable.

The marbles of the United States, according to the account of many intelligent Americans with whom I conversed on the subject, are not suited for sculpture or very fine ornamental works, or even, indeed, for the capitals of columns, which require superior workmanship; and the marble used for the capitals of all the fine buildings throughout the country is imported from Carara in Italy, whence a very large quantity is annually exported to America. For similar purposes black marble is also imported into the States from Ireland. If, however, I might form a judgment from the quality of some of the specimens which I procured, I should think that were the American quarries efficiently worked, there could be very little necessity for applying either to Italy or Ireland for so great an annual supply. Those buildings which are constructed of the whitest description of American marble carefully selected for the purpose, such as the Capitol and the President's house at Washington, the Bank of the United States, the Mint, and other public buildings at Philadelphia, and the monument erected to the memory of Washington at Baltimore, have certainly a most imposing and gorgeous appearance, owing to the fineness and beauty of the material. But the buildings which are constructed of the blue or unselected marble, such, for example, as the State Capitol at Albany, or the Town-House at New York, have a bloated and dingy look, and the general effect produced by the marbles in these buildings is greatly inferior to that of some of the sandstones from Craigleith and other British quarries.

The white marble retains its purity of colour much longer in the United States than it would do in this country, owing to the clearness of the atmosphere and the absence of smoke, the use of anthracite coal, which produces no smoke during combustion, being common in most of the towns. These circumstances may also account for the seemingly permanent vividness of the various colours, such as red, white, brown, yellow, and green, with which, according to the taste, or rather want of taste, of the occupiers, the exteriors of the brick houses in New York, and many other towns in the United States, are generally painted.

Timber.—I must now make haste to speak of the materials of carpentry, the other department regarding which I proposed to offer a few remarks.

The forests, to the British eye, are perhaps the most interesting features in the United States, and to them the Americans are indebted for the greater part of the materials of which their public works are constructed. These forests are understood to have originally extended, with little exception, from the sea-coast to the confines of the extensive prairies of the western states: but the effects of cultivation can now be traced as far as the foot of the Alleghany Mountains, the greater part of the land between them and the ocean having been cleared and brought into cultivation. It is much to be regretted that the early settlers, in clearing this country, were not directed by a systematic plan of operations, so as to have left some relics of the natural produce of the soil, which would have sheltered the fields and enlivened the face of the country, while at the same time they might, by cultivation, have been made to serve the more important object of promoting the growth of timber. Large tracts of country, however, which were formerly thickly covered with the finest timber, are now almost without a single shrub, every thing having fallen before the woodman's axe; and in this indiscriminate massacre there can be no doubt that many millions of noble trees have been left to rot, or, what is scarcely to be less regretted, have been consumed as firewood. This work of general destruction is still going forward in the western states, in which cultivation is gradually extending; and the formation of some laws regulating the clearing of land, and enforcing an obligation on every settler to save a quantity of timber, which might perhaps be made to bear a certain proportion to every acre of land which is cleared, is a subject which I should conceive to be not unworthy of the attention of the American Government, and one which is intimately connected with the future prosperity of the country. But should population and cultivation continue to increase in the same ratio, and the clearing of land be conducted in the same indiscriminate manner as hitherto, another hundred years may see the United States a *treeless* country. The same remarks apply, in some measure, to our own provinces of Upper and Lower Canada, in many parts of which the clearing of the land has shorn the country of its foliage, and nothing now remains but blackened and weather-beaten trunks.

The progress of population and agriculture, however, has not as yet been able entirely to change the natural appearance of the country. Many large forests and much valuable timber still remain both in Canada, and in the United States: the Alleghany Mountains, as well as other large tracts of country towards the north and west, which are yet uninhabited, being still covered with dense and unexplored forests.

The timber trade of the United States and of Canada, from the quantity of wood which is required for home consumption and exportation, is a source of employment and emolument to a great mass of the population. It is carried on to a greater or less extent on all American rivers, but the Mississippi and the St. Lawrence are more especially famous for it. The chief raftsmen, under whose direction the timber expeditions on these rivers are conducted, are generally persons of great intelligence, and often of considerable wealth. Sometimes these men, for the purpose of obtaining wood, purchase a piece of land, which they sell after it has been cleared; but more generally they purchase only the timber from the proprietors of the land on which it grows. The chief raftsman and his detachment of workmen repair to the forest about the month of November, and are occupied during the whole of the winter months in felling trees, dressing them into logs, and dragging them with teams of oxen on the hardened snow, with which the country is then covered, to the nearest stream. They live during this period in temporary wooden huts. About the middle of May, when the ice leaves the rivers, the logs of timber that have been prepared and hauled down during winter, are launched into the stream, and being formed into rafts, are floated to their destination. The rafts are furnished with masts and sails, and are steered by means of long oars, which project in front, as well as behind them; wooden houses are built on them for the accommodation of the crews and their families. I have several times, in the course of the trips

* These specimens are now in the museum of the Society of Arts.

which I made on the St. Lawrence, counted upwards of thirty men working the steering oars of the large rafts on that river, from which some idea may be formed of the number of their inhabitants. Those rafts are brought down the American rivers from distances varying from one hundred to twelve hundred miles, and six months are often occupied in making the passage. When it is at all possible, they moor them during the night in the still water at the edge of the river, but when this cannot be done, they continue their perilous voyage in the dark, exhibiting lights at each corner of the raft to warn vessels of their approach to them. The St. Lawrence rafts vary from 40,000 to 300,000 square feet, or from about one to no less than seven acres in surface, and some of them contain as much as £5000 worth of timber. If not managed with great skill, these unwieldy specimens of naval architecture are apt to go to pieces in descending the rapids, and it not unfrequently happens that the labour of one, and sometimes two seasons is in this way lost in a moment. An old and experienced raftsman, with whom I had some conversation on board of one of the St. Lawrence steamers, informed me that he, on one occasion, lost £2500 by one raft which grounded in descending a rapid and broke up. He said the safest size for a raft was from 40,000 to 50,000 square feet, or about one acre, and that five men were required to work a raft of that size.

The species of forest trees indigenous to different countries is an interesting subject connected with vegetable physiology. There are said to be about thirty forest trees indigenous to Great Britain, which attain the height of thirty feet; and in France there are about the same number. But according to the best authorities, there are no less than 140 species which attain a similar height indigenous to the United States.

To notice each of these numerous species, whose timber is employed by the Americans in the arts, even if I were able to do so, would greatly exceed the limits to which I am restricted by the nature of the present communication, and I shall therefore only make a few remarks regarding those timbers which are most highly prized and most extensively used in the ship carpentry and public works of the country.

The first which I shall notice is the Live Oak (*Quercus virens*), so named because it is an evergreen, its leaves lasting during several years and being partially renewed every spring. It grows only in the southern states, and is one of the most valuable of the American timbers. The duty imposed by our government on wood from the United States, prevents its importation into Britain, and as live oak grows only in the United States and is not found in Canada, it consequently never reaches this country as an article of commerce; the whole produce being consumed by the Americans themselves in shipbuilding. Its specific gravity is equal to, and in some cases greater than, that of water, and it is used along with white oak and cedar for the principal timbers of vessels. The climate, according to an American authority,* becomes mild enough for its growth near Norfolk in Virginia, though at that place it is less multiplied and less vigorous than in more southerly latitudes. From Norfolk it spreads along the coast for a distance of 1500 or 1800 miles, extending beyond the mouths of the Mississippi. The sea air seems essential to its existence, for it is rarely found in the forests upon the mainland, and never more than fifteen or twenty miles from the shore. It is most abundant, most fully developed, and of the best quality, about the bays and creeks and on the numerous fertile islands which lie scattered for several hundred miles along the coast. The live oak is generally forty or fifty feet in height, and from one to two feet in diameter, but it is sometimes much larger, and its trunk is often undivided for eighteen or twenty feet. There can be little doubt, from its great density and durability, that this is one of the finest species of oak that exists, surpassing even that for which Great Britain is so famous. Its cultivation has been tried in this country without success; but could it be imported, it would be found admirably suited for the construction of lock-gates and other engineering works, for which hard and durable timber is required, and for which English or African oak is generally used.

The White Oak (*Quercus alba*) is the species of which so much is imported into this country. It is known by the name of "American oak," but it is a very different and much inferior wood to the live oak of the United States which I have just described. It is also much more widely distributed, and occurs in much greater quantity, than the live oak. It is very common throughout the northern states and in Canada, from whence it is exported to this country. It attains an elevation of seventy or eighty feet, with a diameter of six or seven feet. It is known by the whiteness of its bark, from which it derives its name, and from a few of its leaves remaining on the branches in a withered state throughout the winter. The wood is of a reddish colour, and in that respect is very similar to English oak. But it is generally acknowledged to be greatly inferior to it in strength and durability. It is very straight in the fibre, however, and can be got in pieces of great length and considerable scantling—properties which, for certain purposes, make it preferable to the British oak. It is much used in ship-building, and also for the transverse sleepers of railways. There are many other oaks in the United States, but the two I have mentioned are those most in use.

The pines are perhaps the next woods in importance to the oaks. The species of those are also very numerous, and I shall only mention one or two of the most important of them.

The White, or Weymouth Pine (*Pinus strobus*), is widely distributed both in the United States and in Canada, and is exported to Britain in great quantities from the latter country. It is the tallest tree of the American forest, having been known, according to Michaux, to attain the height of 180 feet. The wood has not much strength, but it is free from knots, and is easily wrought. It is very extensively employed in the erection of bridges, particularly *frame* and *lattice* bridges, a construction peculiar to the United States, and very generally adopted in that country, which I have described in detail elsewhere.* For this purpose it is well fitted, on account of its lightness and rigidity, and also because it is found to be less apt to *warp* or *cast* on exposure to the atmosphere than most other timbers of the country. It is much used for the interior fittings of houses, and for the masts and spars of vessels.

The Yellow Pine (*Pinus mitis* or *variabilis*) occurs only in the southern and middle states, and is not found in Canada, and therefore does not reach this country, the wood known by that name in Britain being the *Pinus resinosa*. It attains the height of 50 or 60 feet, with a diameter of 2 or 3 feet, and is the timber which the Americans employ in greatest quantity for the masts, yards, booms, and bowsprits of their vessels. A large quantity of it is annually consumed for this purpose in the building-yards of New York, Philadelphia, and Baltimore.

The Red Pine (*Pinus resinosa*) is the only other of the pine species that is much used. It occurs in great plenty in the northern and middle states, and in Canada, from whence it is exported in great quantity to this country, and it is known to us by the name of "American yellow pine." It attains the height of 70 to 80 feet, with a diameter of two feet, and is remarkable for the uniform size of its trunk for two-thirds of its height. Its name is derived from the redness of its bark. The wood, owing to the resinous matter it contains, is heavy; and is highly esteemed for naval architecture, more especially for decks of vessels, both in this country and in America.

The Locust (*Robinia pseud-acacia*), from the beauty of its foliage and the excellent qualities of its timber, is justly held in great esteem in America. It abounds in the middle states, and in some situations attains the height of seventy feet, with a diameter of four feet. The wood of the locust tree is of a greenish yellow colour, marked with brown veins, not unlike the laburnum of this country. It is a close-grained, hard, and compact wood, and is of great strength. It is used, along with live oak and cedar, for the upper timbers of vessels, and is almost invariably used for treenails, to which it is well adapted. It is also employed in some parts of the country as transverse sleepers for railways. Its growth being chiefly confined to the United States, it is not imported into Britain. It is one of the very few trees that are planted by the Americans, and may be seen forming hedge-rows in the highly cultivated parts of Pennsylvania.

The Red Cedar (*Juniperus Virginiana*) is another valuable wood, the growth of which is confined to the United States. In situations where the soil is favourable it grows to the height of 40 or 50 feet, with a diameter of 12 or 13 inches. This wood is of a bright red colour; it is odorous, compact, fine-grained, and very light, and is used, as already stated, in ship-building, along with live oak and locust to compensate for their weight. It is considered one of the most durable woods of the United States, and being less affected by heat or moisture than almost any other, it is much employed for railway sleepers. I remember, in travelling on some of the railways, to have been most pleasantly regaled for miles together, with the aroma of the newly laid sleepers of this wood. It is now, however, becoming too scarce and valuable to be used for this purpose.

The White Cedar (*Cupressus thyoides*) and the Arbor Vitæ (*Thuja occidentalis*) are employed for sleepers and other purposes to which the red cedar is applied, but the latter is preferred when it can be obtained.

The only other tree which I shall notice is the Sugar Maple (*Acer saccharinum*) which occurs in great abundance in Canada and the

* The Sylva Americana, by J. D. Browne. Boston, 1832.

* Stevenson's Sketch of the Civil Engineering of North America. London: John Weale, 1838.

northern states. It attains the height of 50 or 60 feet, and is from 12 to 18 inches in diameter. The wood of this tree is soft, and when exposed to moisture it soon decays. It is very close-grained, and when cut in certain directions is remarkably beautiful, its fibres, owing to their peculiar arrangement, producing a surface variegated with undulations and spots. It is also susceptible of a very high polish. These qualities tend to render it a valuable acquisition to the list of American woods for ornamental purposes, for which it is very generally employed, and is well known in this country by the name of "Bird's Eye Maple." The wood of the Red-flowering Maple (*Acer rubrum*) is also employed for ornamental purposes, and is generally known by the name of "Curled Maple." The cabins of almost all American-built vessels are lined with these woods, or with mahogany inlaid with them, and they are also much used for making the finer parts of the furniture of houses.

The property of the sugar maple, however, from which it derives its name, is of perhaps more importance in a commercial point of view than its use as timber. I allude to its property of distilling a rich sap, from which sugar is largely manufactured throughout the United States. From two to four pounds of sugar can be extracted annually from each tree without hurting its growth. I had an opportunity of making some inquiries regarding this simple process when on the banks of the river Ohio, where I saw it in progress. One or two holes are bored with an augur, at the height of about two feet from the ground, and into them wooden tubes, formed of the branch of some soft-hearted tree hollowed out, are inserted. The sap oozing from the maple flows through the tubes, and is collected in troughs. It is then boiled until a syrup is formed of sufficient strength to become solid on cooling, when it is run into moulds and is ready for use.

Such is a brief notice of some of the principal timbers of the United States, which, from their great abundance and variety, are suitable for almost every purpose connected with the arts, and thus serve in some degree to compensate for the want of stone, while at the same time they afford great advantages for the prosecution of every branch of carpentry, an art which has been brought to great perfection in that country. Many ingenious constructions have been devised to render timber applicable to all the purposes of civil architecture, and in no branch of engineering is this more strikingly exemplified than in bridge-building. Excepting a few small rubble arches of inconsiderable span, there is not a stone bridge in the whole of the United States or Canada. But many wooden bridges have been constructed. Several of them, as is well known, are upwards of a mile and a quarter in length, and the celebrated Schuylkill Bridge at Philadelphia, which was burnt about two years ago, but was in existence when I visited the country, consisted of a single timber arch of no less than 320 feet span. Canal locks and aqueducts, weirs, quays, breakwaters, and all manner of engineering works have there been erected, in which wood is the material chiefly employed; so that if we characterize Scotland as a stone and England as a brick country, we may, notwithstanding its granite and marble, safely characterize the United States as a country of timber. I shall only, in conclusion, very briefly allude to the appearance of the American forests, of which so much has been written and said; and on this subject I may remark, that it is quite possible to travel a great distance without meeting with a single tree of very large dimensions; but the traveller, I think, cannot fail very soon to discover that the average size of the trees is far above what is to be met with in this country. I measured many trees, varying from 15 to 20 feet in circumference, and the largest which I had an opportunity of actually measuring was a Button-wood tree (*Platanus occidentalis*) on the banks of Lake Erie, which I found to be 21 feet in circumference. I saw many trees, however, in travelling through the American forests, which evidently far exceeded that size, and which my situation, as a passenger in a public conveyance, prevented me from measuring.

M. Michaux, who has written on the forest trees of America, in speaking of their great size, states, that on a small island in the Ohio, fifteen miles above the river Muskingum, there was a button-wood tree, which, at five feet from the ground, measured 40 ft. 4 in. in circumference. He mentions having met with a tree of the same species on the right bank of the Ohio, thirty-six miles above Marietta, whose base was swollen in an extraordinary manner; at four feet from the ground it measured 47 feet in circumference, giving a diameter of no less than 15 feet 8 inches; and another of nearly as great dimensions is mentioned by him as existing in Genessee; but these trees had perhaps been swollen to this enormous size from the effects of some disease. He also measured two trunks of white or Weymouth pine, on the river Kennebec, in a healthy state, one of which was 154 feet long and 54 inches in diameter, and the other was 142 feet long, and 44 inches in diameter, at three feet from the ground. M. Michaux also measured a white pine which was 6 feet in diameter, and had reached probably the greatest height attained by the species, its top being 180 feet from the ground. It is difficult for an inhabitant of our island, without having seen the American forests, to credit the statements which have been made by various authors, as to the existence of these gigantic trees of 180 feet in height (being about 40 feet higher than Melville's monument in St. Andrew Square, in Edinburgh): but such trees undoubtedly do exist. Mr. James Macnab of the Royal Botanic Garden, in a paper on the local distribution of different species of trees in the native forests of America,* mentions having measured numerous specimens of the *Pinus strobus* in Canada, which averaged 16 feet in circumference, and 160 feet in height: and one specimen which had been blown down, and of which the top had been broken off, measured 88 feet in length, and even at this height was 15 inches in diameter.

The ascent of the sap in trees is a subject which has long occupied the attention of physiologists. Some difference of opinion, however, exists regarding it, and hitherto it is believed no very definite conclusions have been arrived at;—and although not strictly connected with the subject of this paper, I may be excused for remarking, that the quantity of sap required to sustain such enormous trees as these I have been describing, and the source and nature of the power by which a supply of fluid is raised and kept up, at the great height of 180 feet from the ground, are inquiries which, could they be satisfactorily solved, would form most interesting and instructive additions to our knowledge regarding vegetable physiology.

Edinburgh, February, 1841.

* Agricultural Journal for 1835.

ON THE SYSTEM OF WARMING BUILDINGS BY HOT WATER.

A Reply to Mr. Perkins's "Answer" (in the Journal for June last, p. 201,) to the Report presented to the Manchester Assurance Company. By John Davies, and George Vardon Ryder.

Mr. Perkins declaims against our "unfair report;" and charges us with "errors and misstatements," with "manifest absurdity," with "unjust and absurd experiments," "conducted with any view rather than that of candid investigation." Such charges are easily made on either side of a discussion, and are most generally resorted to by those who are least warranted in applying them. We shall presently show how unmerited and irrelevant such charges are in reference to us; and we trust that we shall be enabled to satisfy every disinterested reader, that Mr. Perkins has, in order to conceal the weakness of his defence, indulged his feelings in this kind of phraseology, which, from the facility with which he uses it, seems to be quite natural to him. It usually happens, as in this case, that the use of such language leaves every thing untainted but the reputation of him who utters it; while it forfeits every claim upon an opponent for any greater courtesy of expression in reply than the example would suggest, or the nature of the objections appear calculated to excite.

Our directions, as the reader of the preceding pamphlets will remember, were "to inquire into the *nature of the accidents which have* recently *occurred* from the use of the hot water apparatus; and to institute a personal investigation into some of the cases referred to; and to make such experiments as might tend to satisfy our minds as to the *causes* of the *accidents which had occurred*" from the use of the apparatus as it has been erected in Manchester, and *not* as it may have been since improved by the Patentee; for the latter being unknown until very "recently," that is to say, until our Report had appeared, it was impossible for us to notice.

We had to investigate the abuses, as well as the uses of the apparatus, as hitherto put up in this town and neighbourhood; for, if the abuses were likely to be of frequent, or even occasional occurrence, if they could arise from ordinary carelessness or mismanagement, it is clear that the danger to property must be very considerable. Of the advantages of Mr. Perkins's "recent" improvement we know nothing excepting what he tells us in his "Answer;" but, how ill soever he may think of us, we do most sincerely assure him, that if it really renders the apparatus secure, we shall hail its application with much pleasure; not altogether with a feeling of satisfaction, resulting from the consciousness that we have hastened, if not occasioned it, by having proved that it was necessary. From his own showing, therefore, Mr. Perkins ought, in this case, to be grateful, rather than angry. We have given to the apparatus a popularity which it did not previously possess, while we have pointed out its defects; these defects Mr. Perkins affirms that he has "recently" completely removed; and, therefore, the very detection of his former errors has tended to diffuse more widely a knowledge of his present state of perfection. Had an "opportunity" been "afforded" to Mr. Perkins "of assisting" us in our "experiments," it is far from probable that he would ever have obtained these advantages, of the source of which he so unreasonably complains.

It seems to be almost impossible to satisfy Mr. Perkins. At first he condemns us because we attended to "appearances;" and he afterwards inveighs against us because we resorted to "experiments:" it is, therefore, difficult to conceive how we should have proceeded to form our Report, unless by an implicit reliance upon his assertions, which certainly do not, in some cases, rest upon either appearances or experiments.

The great gist of the charges against us is, that we employed in our experiments an apparatus improperly constructed; for he says, "the patentee *utterly disclaims the apparatus experimented upon* by Messrs. Davies and Ryder as his, any further than that the pipes were closed in all parts."—This charge assumes a very imposing aspect; and if we had done designedly that which he here imputes to us, we should indeed have been highly culpable. From a few facts the reader may judge of the truth of the allegation. Mr. Perkins sold some time ago to Mr. Walker the patent right to the apparatus for Manchester and the vicinity. When we were professionally engaged by the Directors of the Assurance Company, we first inspected the premises which had been recently injured; and then, previously to the performance of any experiments, applied to Mr. Walker to see what information or assistance he was able and willing to afford. Mr. Walker acceded, in the most obliging manner, to our application; accompanied us to some establishments where the apparatus was in operation; and promised to get erected on his own premises, and under his own superintendence, a suitable apparatus, on Mr. Perkins's system, for the express purpose of our experiments. Some little delay occurred; and, as it happened, Mr. Walker had in the interval several interviews on the subject with Mr. Perkins, to whom our investigation was no secret! The apparatus was at length put up; the form and the proportion of the parts were precisely those which Mr. Perkins had taught Mr. Walker, and on the same principle which had guided Mr. Walker in others which he had erected, and might be called upon to erect; and was, therefore, in every respect as essentially on "Perkins's System" as any of those which have been yet introduced into any building in Manchester. In short, Mr. Walker made the apparatus; we the experiments. In all the operations we had the assistance of Mr. Walker's intelligent Foreman, and that of other persons belonging to his establishment.

Mr. Perkins does not find fault with 26 feet of coil in the furnace, though he forgets that only 21 feet, as stated, were exposed to the fire, a fact which, being in his favour, he conveniently suppresses; but he seizes with avidity upon a presumed deficiency in the expansion pipe, insisting that from the proportions in the diagram annexed to the Report, it must have been "six inches less than the apparatus required." Now, even in this plausible objection a slight inadvertency on our parts has rendered him unfortunate; for the diagram having been originally drawn from dimensions given by one of Mr. Walker's assistants was, as it happened, six inches less than it was found, on actual admeasurement, to be in the apparatus really employed in the experiments performed.

It is asserted in the "Answer" that "in the *absence of Mr. Walker* a stopcock was introduced, which, cutting off the greater part of the circulation, left only 40 feet of the tubing out of the furnace to carry off all the heat that could be communicated from 26 feet within it." This is a grave charge; but like the others, it rests entirely upon Mr. Perkins's vivid imagination. A reference, however, to our diagram, which, by singular ill luck is, whether correct or incorrect, a stumbling-block to Mr. Perkins, will clearly show that instead of 40 feet of tubing there were 140, with 21 feet only exposed to the action of the fire! As to the stopcock, it is sufficient to remark that it was contrived and attached by Mr. Walker himself!

Mr. Perkins, in his allusions to his safety valve, places himself in an awkward dilemma. Such an addition is either necessary or it is not: if unnecessary, then it renders the apparatus no better than it was previously; but if it is really necessary, what are we to think of the person who has been until "recently" endangering, by his own acknowledgment, in his "some hundreds of apparatus," life and property to an unlimited extent? What are we to think of him who could, knowingly, leave such places as Messrs. Crafts and Stell's unsupplied with an essential protection? Did he carefully and promptly impress Mr. Walker with its great importance?

We have reason to believe that this gentleman was not acquainted with it previously to the publication of our Report. It appears, then, that Mr. Perkins sold for Manchester and the vicinity an apparatus which he has, for some time, known to be dangerous, and against which danger he did not warn either Mr. Walker or his customers until he produced his "Answer" to our statements. The public have, therefore, derived some information from our Report, whatever may be the advantage which the "Answer" has conferred upon its author.

Mr. Perkins rallies us very much for having said that the experiments made at the Natural History Museum, and at Messrs. Vernon and Co.'s, were "unsatisfactory." Whatever may be his opinion, we regard it as unwarrantable to make experiments, even with his apparatus, where other people's property might be endangered. That was, we can assure him, the reason which induced us to afford him this opportunity for the display of his pleasantry.

When he taunts us, so humourously, in reference to the explosion, by saying, to our discomfiture, that "some grey calicoes spread round the furnace were alone wanting to complete the scene, and put the finishing touch to this exquisite specimen of 'Perkins's Hot Water Apparatus,'" he forgets that this experiment was so amply illustrated in the warehouse of Messrs. Crafts and Stell, that it could not, by possibility, be rendered more striking by repetition. This is a portion of his "Answer," in which he is peculiarly jocular; as if the destruction of "grey calicoes" by fire, and the consequent loss of a great amount of valuable property, were a most amusing exhibition. It can only be compared to the case in which Nero fiddled while Rome was burning. This sort of wit may induce an enemy to smile, but it must, certainly, make a real friend look very serious.

An attempted explanation of an unexpected phenomenon is pronounced to be a "manifest absurdity," because, as Mr. Perkins positively avers, "it is impossible that increase of heat can be produced by the condensation or cooling of steam!!" He must surely have intended this statement as a piece of irony to relieve a dull discussion; for, if he had really any doubts upon the subject, he might have easily and readily proved that the very reverse of his assertion is the fact; and if that failed to satisfy him, he might have demonstrative evidence whenever he may pay his contemplated visit to Manchester.

Mr. Perkins might on this point have consulted authority. An author who treats of his system, and with whose work he may be supposed to be acquainted, says, that "the specific heat of condensed steam, compared with [that of] water, is, for equal weights, as ·847 to 1: but the latent heat of steam being estimated at 1000°, we shall find the relative heat attainable from equal weights of condensed steam, and of water, reducing both from the temperature of 212° to 60°, to be as 7·425 to 1."

Mr. Perkins afterwards says, that "another observation from which erroneous conclusions are drawn," (of course from an error in the premises,) "is that the temperature of the pipes, is influenced by the variation of their internal diameter: this is not the case; the amount of heat conducted off depends on the surface exposed to the atmosphere, and not upon the internal diameter:" from which all that can be inferred is, that Mr. Perkins's pipes must be of a very peculiar kind, when, all other things being the same, the internal diameter affords no indication of their magnitude.

Mr. Perkins tries to evade another explanation by the assurance that "the expansive power of hydrogen gas is far less than that of water." Let us examine this singular statement. Professor Graham, of the London University, says, "Hydrogen gas, steam, and the vapour of sulphuric ether, expand in the same proportion as air."—"The expansion by heat of the different forms of matter is exceedingly various. By being heated from 32° to 212°,

1000	cubic inches of iron become	1004
1000	.... water......	1045
1000	.... air........	1375

Gases are, therefore," he adds, "more expansible by heat than matter in the other two conditions of liquid and solid." Thus Mr. Perkins rests his objection on the assumption that 1000 increased by 375 is "far less" than 1000 increased by 45! The reader can now judge for himself how much, in even this simple case, Mr. P. knows of the properties of the agents which his apparatus requires, and of those which it is liable to bring into action.

Mr. Hood, in treating of the hot water apparatus, says that "a most material difference of temperature occurs in the several parts of the apparatus;" a fact, which we have attempted to explain, but the very existence of which Mr. Perkins denies. It is thus accounted for in the work before us:—"The difference, amounting sometimes to as much as 200° or 300°, arises from the great resistance which the water meets with, in consequence of the extremely small size of the pipes, and also from the great number of bends, or angles, that of necessity occur, in order to accumulate a sufficient quantity of pipe."

"We shall find," says the author, "that a temperature of 450° produces a pressure of 420 lb. per square inch, while a temperature of 530° makes the pressure 900 lb.; and when it reaches 560°, the pressure is then 1150 lb. per square inch. Those who are acquainted with the working of steam engines are aware that a pressure of 45 to 48 lb. per square inch is considered as the maximum for high pressure boilers; but we see that in this apparatus the pressure varies from ten times to twenty-four times that amount. It will also be borne in mind that, in consequence of the extremely small quantity of water used in these pipes, the slightest increase in the heat of the furnace will cause an immediate increase in the pressure on the whole apparatus. For it appears that if the temperature of the pipes be increased 50° above the amount before stated, the pressure will be raised to 1800 lb. per square inch; and by increasing the temperature 40° more, the pressure will be immediately raised to 2500 lb. per square inch; so that *any accidental circumstance which, causes the furnace to burn more briskly than usual, may, at any moment, increase the pressure to an immense amount.*"

Mr. Perkins seems, in some allusions, to insinuate an impression on his part, that we entertain towards him something like a feeling of hostility. Any impression of the kind is, we can assure him, completely unfounded. He is entirely unknown to us, excepting in connexion with his system. We were required to investigate his apparatus *as we found it*; and, without any personal consideration, we conducted that investigation to the best of our knowledge and ability.

In conclusion, we beg to assure Mr. Perkins, that if he can really render his "system" safe, we shall, on being satisfied as to the fact, be quite as ready to recommend it, as we have been to warn the public of the danger which might arise from its use in the state in which it was when we were called upon to examine it.

Report of William Fairbairn, Esq.

Having directed my attention to the experiments recently conducted by Mr. Davies and Mr. Ryder on this apparatus, I have been induced further to extend my inquiries, and to visit several establishments where Mr. Perkins's system of heating has been introduced. Amongst others I may mention those of Messrs. Schunck, Mylius & Co., Messrs. Novelli & Albanelli, as instances where the apparatus has worked satisfactorily for a number of years, and apparently without risk or danger to the buildings. At both places the parties expressed themselves satisfied with the apparatus, and appeared to have no apprehension beyond the alarm and excitement caused by the late accident at Messrs. Crafts and Stell's.

It is true that reflecting persons, and indeed the whole community, have been seriously apprehensive of danger since that accident took place; and Mr. Davies's report, and the opinion of Mr. Ryder, seem conclusive on that point. In fact, it could not be otherwise, as the practical conclusions deducible from the experiments are clear, namely, the singeing of feathers, explosion of gunpowder, charring of wood, &c., are in themselves sufficient evidence of the risk to which the property of individuals is exposed. It is also apparent, that no system of heating is safe where the water, circulating through pipes of small bore, is raised to a high temperature, and subjected to the changes of increased and sometimes suddenly diminished pressure. On this question, therefore, I have no hesitation in giving it as my opinion, that Mr. Perkins's principle of heating is imperfect, and that more particularly from its liability to be overheated, either by improper treatment or a sudden change of temperature, to which the apparatus is at all times exposed.

Mr. Perkins, in describing his apparatus, replies to these objections by stating that, in order to maintain for any length of time an equal temperature, it is only necessary to proportion the furnace to the time the heat is required to be continued, and the damper will regulate the combustion of the fuel, and the heat of the pipes. By this Mr. Perkins means, that the attachment of his heat regulator or governor, as given in his description of the apparatus, will so regulate the admission of air to the furnace, by the expansion and contraction of the flow-pipe acting upon a series of levers, as to open or close the damper according to the temperature or intensity of heat contained in the flow-pipe. Now I have closely examined this part of the apparatus, and although exceedingly ingenious on the part of the projector, it is nevertheless inefficient in its operation upon the furnace, and cannot therefore be depended upon under all the changes to which the whole series is from time to time subjected. Whether this arises from excess of heat in the coils on the one hand, or from a diminution of temperature on the other, is immaterial, as it appears that the apparatus, as now constructed, is liable, either through neglect or otherwise, to almost all the changes of temperature indicated by the experiments of Mr. Davies and Mr. Ryder.

Mr. Perkins, in his description of the apparatus, gives (Mr. Babbage's experiments) the range of temperature in the flow-pipe and chimney as follows:

	Thermometer on Flow-pipe.	Thermometer in Chimney.
	185°	116°
	225	130
	244	132
	249	176
	249	182
	249	178
	249	180
	249	182
	246	184
	247	146
	235	135
	229	202
Giving a mean temperature during a period of 6 hours of.........................	238	162

Being an exceedingly low temperature, and such as under the regulations prescribed by Mr. Babbage, would be perfectly safe. But comparing the above with the experiments of Mr. Davies and Mr. Ryder, we have the temperature of the flow-pipe equal to that of melted lead, nearly 400 in excess of that which was considered safe by Mr. Babbage. It is clear that in a series of experiments such as those conducted by Mr. Davies and Mr. Ryder, the temperature of the water in the coils and in the flow-pipe, as it issues from the furnace, might be raised to nearly the melting point of iron; but in justice to Mr. Perkins, I am bound to observe, that it is only an experimental case, no doubt carefully and properly conducted, but certainly not indicative of the general working state of the apparatus.

In Mr. Perkins's system of heating there is, I believe, considerable economy, and convenience in its application; it is not, however, the best, nor yet the most wholesome or safe mode of heating. It appears to me to be liable to the following objections:—

1st. The increase of temperature to which the coils and pipes are exposed, and the consequent danger arising from the ignition of flocculent matter, which by accident or neglect might surround the pipes.

2nd. The impurity of the air, caused by its contact with metallic surfaces highly heated.

3rd. Deficient ventilation, where means are not provided for carrying off the impurities, and admitting fresh air at proper intervals.

The above appear to me to be some of the more prominent defects of this system; it is, however, a simple and ingenious apparatus, and provided certain improvements were introduced, I have every reason to believe it might be rendered an agreeable, if not a safe and efficacious mode of heating.

In this country it is obvious that large sums of money have been expended on the use and application of this apparatus; and as numerous buildings, shops, houses, &c., are already fitted with all the necessary furnaces, coils, &c., and as it is impossible to change the apparatus for a better all at once, it appears very desirable to adopt such measures as will prevent the possibility of accident, and afford greater security to property. For these objects I would suggest the attachment of a mercurial tube to the flow-pipes issuing from the furnace, with a metallic piston to rise and fall, and by its action on a throttle-valve damper to check the draught in the furnace, and thus reduce the heat whenever the flow-pipe indicates an excess above the maximum temperature.

Again, I would recommend the flow-pipes to be incased in a perforated iron tube, to a distance sufficient to render a reduction of the temperature certain, and to prevent the possibility of ignition, even when in contact with inflammable matter.

These precautions being adopted, and having encircled the furnace by brick work, I should, under such circumstances, consider the apparatus less objectionable, and freed, in a great measure, from the danger which now surrounds it.

WM. FAIRBAIRN.

Manchester, Apr. 17th, 1841.

ON VENTILATION OF THE COURTS IN THE OLD BAILEY, LONDON.

On the 6th ult. a Court of Aldermen was held for the purpose of receiving a report from the Gaol Committee on the important subject of the ventilation of the courts of the Old Bailey. Dr. Reid was present during the proceedings.

Sir M. Wood brought up the Report of the Committee to whom it had been referred to consider Dr. Reid's plan for improving the ventilations of the courts of the Old Bailey. The committee were of opinion that the plan ought to be adopted. The committee recommended this Court to direct a communication to the Committee for Letting the City Lands, requesting they will present a report to the Court of Common Council, for authority for the work to be preceeded with under their directions accordingly. Sir M. Wood, in conclusion, moved that the Court agree with the Committee in their Report.

The following is the plan, as described officially by Dr. Reid:—

"My Lord and Gentlemen,

"The defective state of the ventilation at the courts in the Old Bailey, which I have examined according to your instructions, arises principally from the following causes;—

"1. The inadequate supply of fresh air.

"2. The imperfect discharge of the vitiated air, a large proportion of which is returned indefinitely upon the person, instead of being removed with certainty and decision.

"The severity of the currents, arising from inadequate diffusion, and the necessary opening of doors and windows from time to time, when complaints are great from the deficiency in the supply of air.

"4. The imperfect nature of various parts of the apparatus in use, which presents different causes that render the air less wholesome and agreeable than it otherwise would be.

"5. The contamination of the small proportion of air supplied to a great extent with vitiated air, more particularly from the hall and other passages. In the kitchen there is a cesspool having no connexion with any drain, into which about 30 pails of water are introduced daily during the sitting of the Courts, all of which appears, so far as I have been able to ascertain, to mingle by evaporation with the atmosphere of the kitchen, and to find its way to the passages.

"It will be obvious that defects such as these cannot be effectually remedied without introducing arrangements of proportionate magnitude, as in the original construction of the courts, it could not be expected, from the period at which they were built, that provision would be made for meeting the views now entertained as to the nature and importance of ventilation; while the chambers below and above both courts, excepting on the roofs of the New Court, are so much occupied that few facilities are presented for diffusive ventilation, by which alone any degree of comfort can be given in places so liable to a fluctuating attendance as these courts must be. Under the circumstances, and proceeding upon the assumption that 2000 persons are as many as it would be necessary to provide air for, according to the replies to the various inquiries upon which I entered in reference to this point, I have to propose the following arrangements. It may be proper for me to premise, however, that 2000 persons 12 hours a day in court require air for 28,800,000 respirations during that period, independent of what may be necessary for the surface of the body:—

"1. Let a chamber be provided for the reception of fresh air where it shall escape much of the contamination which it receives at present from eating-houses, chimnies, &c., in the immediate vicinity.

"2. Let the air be filtered from soot as it enters the chamber, washed, when necessary with lime-water to remove various impurities, and finally be propelled to the courts by a fanner worked by a steam engine. This arrangement appears to be the only economical plan that will insure the ventilation of the courts, considering the peculiarity of their position, and the manner in which they are hemmed in on all sides by different apartments.

"3. Let chambers be provided below each court, that the air may enter diffusively, and as imperceptibly as possible, the diffusion being regulated by perforated zinc or porous cloth at every place represented by the red dotted line in the plan of the courts.

"4. Let a mild hot water apparatus be procured, and let it be arranged in such a manner that by the mere opening or shutting of a valve, it may be made to afford any proportion of warmth, such as the circumstances of the moment may require. I must here remark, that though ventilation may be induced without warming the air before it enters the court, still the two questions are inseparably connected, more especially as in an apartment not ventilated, the vitiated air stagnated around the person produces part of that warmth which ought to be procured from other sources, and which is required to a greater and greater extent, the more freely the air is supplied. To some constitutions the absence of offensive currents, and the supply of air at a proper temperature, are as important as a supply of pure air.

"5. Let the entrance of the air to the court be regulated by a single valve, so that the amount may be proportioned to the state of the external atmosphere and the fluctuating attendance, so that the effect produced upon the person may in all cases be as nearly as possible the same, whatever changes may ensue, either on the attendance at the court or in the external atmosphere.

"6. Let the foul air also be discharged through a single aperture, a valve being provided there also, to be used under particular circumstances.

"7. One external discharge from each court may be provided, but one alone for both would be preferable, but also more costly, from the cuttings required in the roof.

"8. The external discharge should be protected from the action of currents of air by a cowl, or any equivalent modification of the cowl.

"9. The galleries should be supplied with pure air from the fresh air chamber.

"10. A communication should be established between the cesspool in the kitchen and the adjoining drains.

"All the above points are essentially connected with the ventilation of the courts alone, and would cost, as nearly as I can estimate, about 1,925*l.* In stating this sum, it may be proper for me to mention, that a precise estimate cannot be formed, as the precise facilities or difficulties that may be met with in following out the underground cuttings must necessarily modify the result. But I do not consider that there would be a difference of 100*l.*, which might be either less or more than the sum mentioned, according to details that could only be ascertained as the works proceeded. I ought also to observe, that my estimate is founded principally upon the cost of similar works executed in the Queen's Bench and Bail Courts, Westminster, in the Insolvent Debtors' Court, and in various other buildings in London.

"I should not consider the report complete did I not submit for your consideration, that it would be advisable that some minor arrangements should be made for the ventilation of the hall, staircases, and some of the principal apartments in connexion with the courts. In places where the principal room has been ventilated without some attention being paid to lobbies and contiguous apartments, the contrast between the air where ventilation has been introduced and where it has not often leads to complaints that would not otherwise be made, and to the introduction of ventilation in these minor apartments at a future period at a considerable increase of cost. An additional sum of 150*l.* or 200*l.* would enable the ventilation to be greatly improved in all the places now referred to.

"Again, in all buildings constructed in the usual manner there is a defect observed in the movement of air near windows in cold weather, which can be remedied entirely only by double windows; this not being essentially connected with the general arrangements for ventilation, though most important in preventing local discomfort in the seats next the windows, is brought before your notice as a separate question, that can be considered either at present or at a future period.

"Lastly, in making the above report I have to mention, that I have had the advantage of communicating with Mr. Mountague, who has assisted me in obtaining the information required as to the present state of the buildings; and I have the satisfaction to state, that he is of opinion that the several works may be executed without interfering with the character or stability of the building.

"I have the honour to remain, my Lord and Gentlemen.

"Your very obedient servant,

"D. B. Reid."

Sir P. Laurie seconded the motion. He trusted the Court would be unanimous in recommending the adoption of Dr. Reid's plans. It was universally admitted that he had successfully applied them in the ventilation of both Houses of Parliament, an object of paramount importance, which had often been attempted and as often failed. The best evidence that Dr. Reid had been completely successful in his operation on the Houses of Parliament was to be found in the fact that at the conclusion of his labours they had rewarded his talent and perseverance with a complimentary gratuity of 1,000*l.* over and above the stipulated compensation.

The report was confirmed *nem. con.*, so that this complaint will soon be effectually removed.

THE MIASMA OF AFRICA.—NIGER EXPEDITION.

Mr. J. F. Daniell lately read a paper at the Royal Institution, "*On the spontaneous evolution of sulphuretted hydrogen in the waters on the western coast of Africa and elsewhere.*" He commenced by observing, that this subject was now interesting on two accounts—1, because it would recall to the members of that institution the experiments of Sir Humphrey Davy on the subject, and which led him to advise the adoption of ship protectors; and, 2, in consequence of the Niger expedition, fitted out to visit and endeavour to introduce civilization on the western coast of Africa. The effect produced on copper sheathing by the presence of sulphuretted hydrogen in the waters on that coast, was, he premised, well known to every one informed respecting vessels visiting it, and it was a fact that a cruise of nine months on the western coast of Africa injured the copper sheathing of a vessel as much as four years' wear in any other part of the world. The lecturer showed a piece of sheathing taken from the bottom of a Government frigate that had not been many months on the African station, and also a piece from the Royal George, sunk at Spithead, and which had been under water 60 years: the former was eaten through in very many places, and so thin all over that he might push his thumb through it, while the latter was tough and in excellent condition. His attention had been directed to the subject by the Lords of the Admiralty sending him 10 bottles of water, from as many different places on that coast, extending from 8 deg. north of the Equator to 8 deg. south, to analyse, and to report on the component parts thereof, and the accompanying table was the result:—

	Sulphuretted Hydrogen.	Saline Matter.
	Cubic Inches.	Grains.
Sierra Leone, per gallon	6·18	1,696,0
Volta	6·99	2,480,0
Bonny River	1·21	1,788,0
Mooney	..	2,104,0
Gaboon	..	2,169,0
Lobez-bay	11·69	2,576,0
Congo River (Mouth)	0·67	188,0
Congo River (35 miles inland)	..	8,0
Bango	4·35	2,736,0
Lagos	14·75	1,920,0

All the bottles were hermetically sealed, and he had no doubt the water was in every way as good as when taken from the rivers. On drawing the cork, he was immediately struck with the smell of sulphuretted hydrogen, and adopted the general idea that it arose from animal and vegetable decomposition, but it had since appeared to him that such was not entirely the case. The gas extended a distance of 15 or 16 deg., and in some places as far as 40 miles to sea, covering therefore a space of 40,000 square miles. Now what could the origin be? He thought that it arose from the action and reaction of vegetable and animal matter brought from the interior of the rivers upon the sulphates in the sea water. With this idea he gathered last autumn some leaves from a shrubbery and put them into three jars; into one of which he poured some plain New River water, into the second some of the same water in which three ounces of common salt had been dissolved, and into the third the like water, in which some crystallized sulphate of soda was dissolved. To the covers of the jars he fixed inside some litmus paper, and placed them in a cupboard, the temperature of which varied from 70 to 100 or 110 deg. The effect was, that in the first the litmus paper was perfectly white, and the smell by no means unpleasant; in the second the paper was quite white, and the smell similar to that of a preserve; but in the third jar, in which a sulphate was present, the paper was nearly black, and the stench was horrible and nauseous in the extreme, as every one knew the smell of sulphuretted hydrogen gas to be. Now sea-water contained sufficient sulphates to produce this effect, under peculiar circumstances. But a more interesting part of the subject was the miasma so injurious to life on the marshy shore of Western Africa. Some persons said that if science cannot point out a remedy, it is useless to investigate the causes, but he did not so think; if science could not point out a remedy, still it could point to something as a palliation of the evil. The presence of the injurious gas was easily tested by the roughest hand, so that places in which it abounded could be avoided; and if imperative duty rendered it absolutely necessary to go to those places, then plentiful fumigations of chlorine gas would effectually destroy the sulphuretted hydrogen. The effect of this gas was not only visible on the Western coast of Africa, but in many places elsewhere, although not to so great an extent. Might not the jungle fever of India, the periodical fevers of New York and Charleston in America, and the minor diseases on the coast of Essex, be traced to the effects of this deleterious gas? It was a well known fact that the ships in the mouth of the Medway consumed more copper than other ships. Chlorine gas then destroyed the injurious gas, and it was easily made, and the materials very cheap; the Government had plentifully supplied the African Expedition with the materials necessary for the most perfect chlorine fumigations, and he had the pleasure of believing that his report founded on the analysis of the waters submitted to him, and the precautions taken, had imparted confidence not only to the gallant men who composed that expedition, but also to those who had interested themselves in its welfare.

SEVERN NAVIGATION IMPROVEMENT.

(Concluded from page 247.)

Abstract of the Evidence on behalf of the Worcester and Birmingham Canal Company against the Bill for improving the Severn, given before the Committee of the House of Commons on the Bill, May 17, 18, 21, 24, 25, 27, & 28, 1841.

Mr. P. Giles, engineer, examined by Mr. Austin.—I am a civil engineer, and have surveyed many rivers, harbours, canals, and railways. I am acquainted with the Thames, Mersey, Medway, Ayr, and Calder, and many other rivers; I have also planned the construction of works with reference to the Severn; I have surveyed the Severn with reference to the navigation; I then particularly directed my attention to the drainage and scour of the river, as far as they were compatible with the navigation; I surveyed the river in 1837 with Mr. Rhodes' plans; I have surveyed it partially in the present year. I am acquainted with the plan of Mr. Cubitt. Mr. Rhodes' plan was for a ship canal up to Worcester, and a barge canal up to Stourport. [Witness then described Mr. Rhodes' plan. That plan was not carried into execution. I have heard the whole of the evidence on the present plans. My objections to it beginning at Stourport are to the proposed solid dams; I object to the principle of damming a river permanently. With reference to this river, it will decidedly obstruct the drainage, and be a great bar to the navigation, when there is sufficient depth of water to pass; and I think a different kind of weir could be constructed that would afford the means of passage in low-water season. In the first place, a solid dam must necessarily raise the summer water level to the height of the dam; when the flood is above the summer water level, supposing it to commence as the summer water is now, not impounded (but you can pound it five, six, or seven feet) supposing the flood to commence rising above the artificial sum, if in the first place the flood rises five feet or more above the original summer water, it must rise it also five feet above the artificial sum of water, and so on every flood it must increase with the rise of the flood in the same degree that the summer water is to the flood.

By Mr. Barneby.—My answer does not refer to the river when bank full, but of course it would fill sooner.

By Mr. Austin.—This plan would affect some of the existing drains, particularly that which is made in the sewer at Worcester, and the drainage up the country from the Salwarp to Ombersley. The drainage is about eighteen inches above the low summer water, and of course the dam at Upton must raise the water permanently in proportion to its height, and thus in flood affect the drainage; and that is not all, for the drainage of the gross matter which comes from the sewers of large towns would be collected in pools, which I think would be a very important matter. The Bevere Island dam in like manner would affect the drainage of the Salwarp; for if the water was penned up below the Salwarp, it would be penned up in the Salwarp too. The Salwarp drains an important district, which would consequently be affected. In my opinion, if oblique weirs would pass more water than straight ones, which I do not think they will, it would not the less affect the drainage of the district. Whether oblique or at right angles the permanent height would be the same, and from that I apprehend the effect to the drainage. The deposit would silt upon the upper side of the weir; and I understand this to be the effect at the weirs on the Ayr and Calder, where they have flood-gates which would assist to remove the deposit. I would have the weirs so constructed as to have two, three, or more flood-gates, sixty feet wide, so as to be open whenever freshes come down; I believe this would have a good effect upon the drainage. With any weir there must be a lateral lock, but when the weir was open there would be no necessity for using the lock. I can form but one opinion of the mode in which it is proposed to construct the weirs—and that is, that they must wash away. I have never built one myself but with solid masonry, and with a puddle bank to back it; I believe a footing is absolutely necessary. I don't hesitate to say that it would be most advisable to dispense with weirs between Gloucester and Worcester; I certainly think the experiment should be tried. I would put a weir above Worcester, at the upper end of the pool, opposite the "Dog and Duck;" I would dredge up to this point, through the bridge at Worcester. I think also the dam at Bevere Island should be at the Salwarp. This would render it necessary to sink the soil at Diglis lock, nothing more. The channel-dredging in the river would necessarily lower the water at the wharfs at Worcester, and it would therefore be necessary to dredge up to the wharfs also; this would improve the drainage at Worcester. It would be necessary to have a dam at Worcester bridge, and to underpin the piers. I think the improvements below Worcester should be executed, according to the exigencies of the case, as they presented themselves during the undertaking. I would first proceed to narrow the river to a certain channel in the soft parts by groins, the points of which would form one grooved channel down the river. I should be able to ascertain the force of the scour as the works proceeded, and thus to regulate the extent to which I would apply the operation of dredging. I should dredge at once in the hard shoals with an inclination of four feet to one; I would propose to dredge six feet for the purpose of obtaining five. I should not let my groins run into the river to the full extent at first, but should add to them, if I found it necessary to do so, to maintain the depth. Deerhurst shoal being wholly composed of sand, it would be an interminable task to attempt dredging alone, but with the assistance of the jetties or groins, I think the scour of the river would maintain the depth required. I think Mr. Provis' mode of throwing in stones for the foundation of his side walls a very bad one. I propose in forming my groins to use stakes of larch, lined in the usual way with faggots. My groins will generally be about 120 yards apart. The quantity to be dredged I estimate at 500,000 cubic yards, which, at 1s. per yard, would come to £25,000; the groins I estimate at £28,500; and I have put down £6,000 to be spent upon Worcester Bridge, but I think that is much more than will be required, for I believe £1,000 for each pier will be quite sufficient. Then I have set down £10,000 for contingencies (which is more than 10 per cent.) so we will take the total cost, in round numbers, at £70,000. I was employed by the Worcester and Birmingham Canal Company to form a plan of my own for improving the Severn; this was after Mr. Rhodes' plan had been given up. My plan went before Parliament, but it did not pass.

Cross-examined by Mr. Serjeant Merewether.—I cannot tell you the height of the weir in my plan for improving the Severn, but it was up to high water mark. I have this morning had a model brought here, at the request of an hon. member made to me yesterday, but I should like to speak with Mr. Austin before I produce it. [Here a question arose whether the model should or should not be produced. Previous to the termination of the conversation, it was understood that the Committee would re-examine Mr. Cubitt towards the close of the investigation, to hear his answer to the objections which had been made against his plan.] This plan was suggested by me to the Worcester and Birmingham Canal Company, who paid for the surveys and application to Parliament, and who intended to have carried out the improvement by a commission. The toll was to be 2*d*. per ton from Diglis to Gloucester. I have proposed another plan for the improvement, where the toll to be paid was 1*s*. per ton, but that was for a Company, and not in connexion with the Birmingham Canal Company. It was brought forward in opposition to Mr. Rhodes' plan, and when that plan dropped my plan also dropped. I agree with Mr. Walker's regret—as expressed in his report—that so little has been done towards the improvement of the Severn. I do not think that Mr. Cubitt has sufficiently considered the drainage in his plan. I know the situation of Lord Sandys' drain. I went down last Friday night to open it and examine its level, and I knew the drain before. This drain is about 100 yards above Holt Fleet Bridge. The sewer at Worcester, which I mentioned yesterday, has been lately constructed, and I particularly mentioned it because it is the principal one in the city. I was told the fall of that sewer by the person who built it. I am only acquainted with the outfall of that drain. I do not believe the fall is 25 feet. The bottom of the outfall of this drain is 18 in. or 2 ft. above the present low summer level of the Severn, and the sewer is perhaps 5 ft. in height.

By Mr. Godson.—The basin in Lowesmoor is at least 20 feet above the low summer level of the Severn.

Cross-examination continued: I have no doubt but that there is a great fall in that drain. I should think the entrance of the drain may be 20 feet above its outfall. I have not heard of any public meeting of the people of Worcester, in alarm at the effect of the improvement on this sewer, but I have seen a gentleman on the subject. It was Mr. Williams, of the Distillery. He resides on the opposite side of the river to where this sewer enters. Where the water, in consequence of these artificial ponds, stops up the mouths of drains, it must impede the drainage. I do not know the particular effect it may have upon this sewer, because I do not know the fall, but the silt will have a tendency to collect at the mouth, and will certainly be deposited at the foot of the weir. The banks are about 16 or 17 feet above the sewer at Worcester. There is not a considerable fall on the Salwarp a short distance from its mouth; there is only a fall of a few inches about a quarter of a mile up the river. The height of the banks of the Severn near the mouth of the Salwarp is about 15 or 16 feet. I do not know the fall a quarter of a mile further up where the mill is situate. I still say that the valley of the Salwarp would be flooded sooner in consequence of the weir at Bevere Island than it otherwise would be. I have never seen weirs constructed as Mr. Cubitt proposes to construct his, but I still think that his weirs would not stand. Though I know Mr. Cubitt well, and know him to be a man of great experience in these matters, I have no hesitation in saying that I believe him to be wrong in the construction of his weirs, both in the mode of forming them and the material to be employed (red sandstone from Holt and its neighbourhood). I never heard of such a weir giving way, because I never heard of such a weir being constructed. I do not believe that Mr. Cubitt's weir will be water-tight, for I do not think the sheet-piling will be water-tight; and I do think that the water leaping over the sheet piling will blow up the stone-work. I think a single row of sheet piles will not be water-tight. I have never seen a weir on the Tail, and I do not know that there is one there constructed by Mr. Cubitt.

By Mr. Hastie.—I have seen the weir at Hampton Court, but it is not applicable to those proposed to be constructed on the Severn, as it is formed of strong piles, having sluice-boards, and I will undertake to say that it has a solid foundation, either of timber or masonry.

Cross-examination continued.—The placing of rubble stone as an apron in front of the sheet-piling will strengthen the weir, if the piling be water-tight. I shall construct my groins with a slight inclination downwards. My groins will be formed of willow stakes wattled; they will be triangular, the base being against the back of the river, and the apex running into the stream. It is a very old mode of forming groins, and groins constructed in this manner were formerly in the Severn at Upton and near the Ketch. They were removed as a nuisance, because they canted the stream to one side. I mean to construct my groins so as to preserve a continuous channel as much as possible. I have certainly no doubt but that longitudinal walls would get a more perfectly continuous channel than the use of groins, if they could be perfectly formed, which I think could not be the case by dropping in the stones, as proposed by Mr. Cubitt. No doubt it would be a great evil for a boat to strike the point of one of my groins. I do not approve of Mr. Cubitt's proposal to take advantage of the deepest parts of the channel, but prefer dredging a straight channel along the centre of the river. There are five arches at Worcester Bridge, and the centre one is 42 feet wide. The total ascent I have by my plan from Gloucester to Worcester race-course is 6 ft. 4 in. The deepest water is under the centre arch and the one to the left. When the water is low, I do not think there is more than 3 feet under the centre arch. I shall first dredge three arches, then a channel 60 feet wide, through the shoal up the race-course, and subsequently dredge up to the wharfs. When I have dredged through the arches and shoal, I should think all the water will be drawn from the wharfs, as it generally is at present. I have been employed for years by the Worcester and Birmingham Canal Company. I do not know that, in consequence of the boats not being able to unload at the Worcester quays, from want of water, they go into the Birmingham canal to unload. I have not calculated the amount nor the cost of the dredging along the quays. [illegible] allowed enough in the £10.000 for contingencies, and in the £6.000 for the bridge. I should think the quays would require under-pinning in consequence of the dredging, but I think the parties connected with them will find it their interest to do it themselves, as the quays are very different to interfering with the bridge, which of course it would be my duty to protect from injury. The surface of the water at the quays will be lowered 5 feet. There will be 19 or 20 feet from the surface of the water, after the bottom has been dredged, to the top of the quays. Below the bridge, there is the wall of the Bishop's Palace, and the Cathedral is not far from the edge of the river; dredging would have the effect of undermining these structures if it were carried close up to them.

Re-examined by Mr. Spooner.—The model I have exhibited does not apply to any part of my plan below Worcester. The groins will be about 50 feet long, by 10 feet wide at the head, and 25 feet at the base or abutment, and packed inside the faggots with hard clay. The channel will not be dredged up to the wall of the Bishop's Palace, but merely in the middle of the river. I am still of opinion, notwithstanding the five hours' cross-examination, that I could successfully dredge up to the Dog and Duck.

By Mr. Barneby.—I do not think the weirs on the Thames are at all applicable to those proposed to be put on the Severn.

Mr Giles examined by Mr. Lowndes.—There is a lower drain on Lord Sandys' property which is not stated in the section. I have had it opened at various points, and it applies to the under springs. I should say that the outfall of this under drain will be 18 inches below the crown of the pen of water formed by Mr. Cubitt's weir at Bevere Island. The fall of this drain in the first 200 yards is 4 feet If the present outfall were raised, it would lose the full force which at present exists there. I think the dam at Bevere Island will affect the drainage; about 100 acres of good land are drained by this under drain. The dam at Holt Fleet will affect the drainage of the surrounding land there, which is also very good land. My plan would only raise the level at Salwarp and at Holt one foot, instead of upwards of 4 feet, which it would be raised by Mr. Cubitt's scheme. I see no difficulty in the way of dredging quite up to Holt, and thus have no weir below that point. I think the weirs below Worcester will not only have the effect of affecting the drainage, but also prevent the foul air escaping from the sewers, which would be a great nuisance to the city. The towing paths in the neighbourhood of Lord Sandys' property are very bad. I know of none in such bad condition. I think any plan which would place the river under the control of one body and the towing paths under another must be bad. This inconvenience could be avoided

Cross-examined by Mr. Serjeant Merewether.—I knew the under drain before, but I did not open it till Saturday. In stating that this drain will be 18 inches under Mr. Cubitt's level, I stated on the supposition that there would be 6 inches water on the crown of his weir above the drain. I think that a crust would form in the mouth of the drain, because the floods bring down clay and slime which soon harden.

Mr. W. C. Milne then gave evidence in favour of dredging, which closed the case of the Worcester and Birmingham Canal Company.

Evidence on behalf of the Gloucester Canal Company, and the Corporation of Gloucester.

Mr. Walker examined by Mr. Sergeant Wrangham.—I am a civil engineer of long standing. I was employed to build the Haw Bridge on the Severn 12 or 14 years ago. I also surveyed the river in 1836, and reported upon Mr. Rhodes' plan to the then Severn Navigation Company, by whose chairman, J. W. Lea. Esq., I was employed. I was requested in March last by the Berkeley and Gloucester Canal Company to give my opinion upon Mr. Cubitt's plan. I differ very little with respect to that plan from Mr. Cubitt, up to Upton Ham, except in the details. As we differ so much as to the mode of improving the river above Upton, I should state that Mr. Cubitt proceeds upon the same principle between Gloucester and Upton. I think the river might be made navigable up to Diglis without weirs; and I think it would be a pity to introduce them into so fine a river. My great objection to a lock below Diglis, is, that it would be unnecessary and expensive. I see no reason why the fall from Diglis to Upton could not be practically maintained, as well as the fall below. I do not know any objection to dredging above Upton on account of the hardness of the shoals. It is on account of their hardness they are there, and were they removed the scour of the river would keep the channel clear. If locks and weirs are placed in the Severn, and prove inefficient, I think the matter deposited would be so great in quantity (as in fact the bottom of the river would be then at the top of the weir) that it would be a work of more labour to remove it than to remove the weirs themselves. The shoals formed by the weirs would be greater than the present shoals, but I do not say they would proportionally obstruct the navigation, because the trade will pass through lateral cuts. I am supposing that the bed of the river is formed of gravel and similar substances, which would be washed down in a flood. This in the course of time would have to be removed from the mouth of the cuts by the dredging machine, or else the cuts must be carried further above the weirs. The river below is capable of taking more water than could pass over the oblique weirs, which would consequently be an obstruction. I heard the evidence given in reference to these weirs with great surprise. The only advantage of oblique weirs over others is when little water is coming down, when there would be a thinner sheet of water over the oblique weir than there would be over a cross one, but in a sharp fresh the water would flow over, parallel with the banks, and the oblique weir would not be more advantageous than another. In some instances the oblique weir has an advantage over the direct one, but it is not of more advantage in preventing floods, and I think they would not be so convenient for shooting boats over them in flood time. I think boats would have a greater tendency to capsize over an oblique weir than over a direct one. The expense of my plan up to Diglis would be, including contingencies, £66.000. The cost of maintenance would not be so much as in the plan of Mr. Cubitt; except the lock and weir at Upton, there is not much difference in the expense of our respective plans, so far as Diglis. I see no engineering difficulty in placing the lock at Diglis above the entrance to the Birmingham canal. There is no reason why there should not be steamers up to Worcester all the way from Bristol, so that Worcester may become a little Glasgow. On the Clyde steamers are employed not only to convey passengers, but also to tow up fleets of vessels carrying merchandize. I see no great difficulty in dredging through Worcester Bridge, the only question is the amount of work necessary to secure the foundations, but I think it would be advisable to place the weir a little below the bridge, that there might be an extensive pool opposite the city. On the whole I agree with Mr. Cubitt's plan so far as relates to that part of the river between Worcester and Gloucester, with the exception of the solid weirs. In point of fact, if we had an opportunity of consulting together, I think that as repects the whole line there would be little difference between us.

Mr. Walker cross-examined by Mr. Sergeant Merewether.—Were I the friend of Worcester, I should endeavour to prevent six feet being the maximum depth of the improvement of the river. I have taken a great many soundings, but no borings. I think Worcester bridge cannot be built upon a shoal; there is deep water under the arches, and the shoal is below the bridge I did not say wherever there is dredging there should be walling, but wherever the material is soft it should be walled; but this is not the case above Upton. If the slope of the rubble stone facing is 1½ to 1, it requires packing; but a slope of 3 to 1 would not require packing. I do not know that the Deerhurst shoal has increased: I do not know whether the gravel which is marked in the first section is natural to the place, or has been brought there. The support of each side of the gateway of my weirs would be brace piling. The rest of the river would be occupied by standards about 16 feet apart, and level at least with the top of the proposed weirs, which weirs again would be level with the top of the penned water. There is no reason why the gates should not be raised by machinery, but they are not so in the Thames. If the parties waited till a flood came they could not be moved, and in such case there would be no advantage over the solid weirs. I have seen the Teddington gates partly opened. I think the weeds floating down the stream might have a tendency to fill up the gates. I have made no estimate of the expense of this sort of weir, nor of the expense of attending to or repairing it. I think all the frame-work might be taken out at the beginning of the winter, and put in again about April. While I entertain the opinions that I do at present respecting the improvement of the Severn, I shall always prefer open weirs. No human art can altogether prevent the necessity of dredging in the river. I think a basin at Worcester would be a very desirable thing.

Re-examined by Mr. Sergeant Wrangham.—Since I was examined on Thursday I have carefully re-perused Mr. Cubitt's evidence; and the opinions I then expressed respecting it are strengthened by my having done so. It would be very easy to pick out the weeds from the gates and timbers, much more so than to dredge the deposit at a solid weir. According to my doctrine, if none of the shutters of my weirs could be removed before the flood came, the obstructions would not be greater than by the solid weirs. My weir would cost more *per se* than Mr. Cubitt's; but if you include the dredging that would be required at Mr. Cubitt's weir, mine would be much the cheapest. I think a lock below Worcester would be a great disadvantage to the future navigation to that city; but if it were constructed on my principle I think that inconvenience would be proportionally diminished.

By Sir W. Rae.—The additional expense of dredging by my plan from Upton to Diglis would be £10.640; the expense of walling 4½ miles would be £10,000. I take the whole expense at £25.000 up to Diglis; and there would be £4,600 additional for dredging up to Worcester; £1,600 for walling, and £2.000 for dredging opposite the quays.

By Mr. Barneby.—There would be as much dredging above Worcester bridge if my plan was put in execution.

By Viscount Ingestrie.—The gates of the weir would be ordinarily raised by hand by a person in a boat; I dare say it would take three hours from beginning to end to raise them.

By Mr. Bailey.—The obstruction by a solid weir is 7 times 16, or 112; the obstruction by the open weir would be about one-third of this. There would be no danger in short water of not being able to keep sufficient water for the navigation in consequence of the leakings. I give my plan simply as a general idea; I did not expect to be examined so closely respecting it.

By the Hon. R. Clive.—My honest opinion is that dredging should be first tried for the improvement of the river; if that should fail, a weir of some kind should be tried; but I think they would be the worst friends of the navigation of the river who would recommend the construction of the weirs in the first instance. I think, as I said in my report, it would be very important to try of what the river is capable without locks and weirs.

By an Hon. Member.—There is more tide in the Clyde than in the Severn. The shoals in the Severn would be more difficult to remove than the soft stuff now in the Clyde; but there were originally hard shoals in that river.

By Mr. Godson.—The sum about to be expended upon the Clyde is about half a million. I can't tell what has been expended. Whether the improvement I propose would be worth a shilling a ton to the trade is out of my department to answer; but I think all the trade would be benefitted by it. The Severn will never become so large a navigable river as the Clyde, because the tide does not so much assist it; but I have no doubt it will become a fine river one day. The resistance on any given amount of an oblique weir would be less than on a direct one, but on the whole sum it would be the same. I have seen Mr. Giles's model of a weir. I think there is a complexity about it that should be avoided; it would also be expensive. I don't think walls would be required on both sides the river; two might be injurious. At the time Mr. Smeaton made his survey of the Clyde the shoals were much worse than they are in the Severn.

By Mr. Pryme.—I do not know what the piers at Worcester Bridge are, but I should think the dredging under it could not affect the safety of the bridge.

By Mr. Barneby.—It may be necessary to remove the shoal in the Avon in consequence of the dredging below Upton. Every weir makes as it were a step in the river; and if you remove it, it would be necessary also to remove the deposit that would be accumulated.

Mr. John Timperley, formerly resident engineer of the Ayr and Calder Navigation, was then called to prove that in that Navigation the oblique weirs were of no advantage, and that dredging to a great extent was still necessary, and was now carried on at a considerable expense. The only portion of his evidence relating to the matter before the Committee was the following:—I do not agree with Mr. Cubitt that in floods the water will pass off just as freely as if his oblique weirs were not in the river at all—it is impossible. I do not think Mr. Cubitt's weirs will be nearly strong enough. I have seen a vessel washed over the top of the dam on the Ayr and Calder, and it was not a very unusual occurrence, as they could not always stop the boat; the rope might slip or break, and then the boat would go over the dam. I have not examined the Severn, but from what I have heard, I have no doubt the river might be improved up to Worcester without weirs. If weirs are used they should not be solid.

Cross-examined by Mr. Talbot.—I only know personally about the Severn, from having once driven over the Haw Bridge. There are many mills on the Ayr. The weirs were originally put in to keep up the water for the mills. There are dam boards in these weirs, and if there is a heavy fresh it is difficult to remove them. They require repairing sometimes. The Calder is a tortuous river.

Re-examined by Mr. Wortley.—The Calder is a tortuous river, but the Ayr is not.

By Mr Godson.—The water at the highest floods goes straight over the weir, but it goes at right angles when it is a moderate stream; at six or seven inches water it goes at right angles, but at six or seven feet it goes over straight. I agree with Mr. Walker that it is possible, after dredging up to Worcester to the depth of six feet, further to improve the river so that ships might come up. I do not know the exact depth of the Gloucester & Berkeley Canal.

By Captain Winnington.—I believe that the Ayr and Calder Navigation is not wider above the oblique weirs than at any other part.

Mr. Fulljames, examined by Mr. Wood. I am an architect and engineer, and am surveyor to the county of Gloucester. I have erected a bridge over the Isis, superintended the removal of the old Over Bridge, and have put up large flood-gates on the Severn six miles above Gloucester, &c. I have been employed by the landowners between Worcester and Gloucester to oppose this measure, and have made observations accordingly. There are about 20,000 acres between Worcester and Gloucester under flood water-mark, (or the level of the banks) and the parties employing me own about half that quantity. I have been used to the Severn all my life, and from observations made during the last ten or fifteen years, I find that, on an average, there is one summer flood in five years, three land floods per annum, and three winter floods in two years. Summer floods are wholly injurious, and so are back water or land floods, but the winter floods are sometimes useful, inasmuch as they deposit a sediment which is beneficial. In 1839 the whole crop of hay on this extent of land was either carried away or destroyed. The loss was about 3*l.* per acre, and nearly the whole tract is grass land. I believe that the weir at Upton would cause a flood to overflow these low lands for miles, which would not rise above the banks if there were no weir there. [Here the witness stated, in answer to various questions, that he entirely agreed with Mr. Walker's evidence, and on Mr. Pryme informing Mr. Wood that the weir at Upton was abandoned, he turned his attention to the improvement as effected by dredging up to Diglis.] I do not approve of Mr. Cubitt's mode of dredging, because he does not take the centre of the stream, as proposed by Mr. Walker; by dredging near the banks they would be liable to slip in. I do not approve of the mode of forming the side walls, because there would not be enough stuff to fill up the space between the walls and the banks. I should not recommend the landowners to assent to Mr. Cubitt's plan of dredging up to Diglis, supposing that the weir was not put in at Upton. Mr. Fulljames was further examined, but his evidence mainly coincided with that of Mr. Walker.

Cross-examined by Mr. Craig.—The 10,000 acres I spoke of are subject to floods. I think about 200 of them belong to Mr. Hyett. They are about ten miles from the proposed weir at Upton Ham. Part of them are 1½ mile from the Severn. About 600 acres belong to Mr. Fulljames, a near relation of mine. About 158 acres belong to Mr. Yorke. They are all below flood mark, and are 5 miles below the proposed weir. The witness was examined at considerable length, but his evidence was merely a repetition of what has been already published in that of other witnesses. In answer to questions by Sir W. Rae he said:—By doing away with the weir at Upton, steam tugs could come up to Diglis. Vessels tugged by a steamer would require three men for general purposes. Steam boats have been tried on the river, but were discontinued for want of water.

Mr. Cubitt was recalled by the Committee, and confirmed his former evidence. In answer to questions by Mr. Bailey, he said—I am not aware of the length of the drains of Worcester nor of the fall.—(Mr Bailey then stated the dimension and fall.) I do not think, if such is the dimension and fall, our works will affect it. I think covering up the mouth of the drain would be beneficial rather than otherwise, as it would prevent the effluvia from reaching the city. It is possible to widen the river to so great a width and to put in a weir across it at so great a length that it shall be able to take the whole water of the river at summer time or flood time; therefore, assuming I make a weir of great length across the bed of the river, and widen out the river to admit free access to the weir, and make the weir so long that six inches of water along the weir should be of a sectional area equal to the whole of the river, of the same height above and below the weir; and it must be evident to those who think about it, that there is as much water way at the height of two feet six inches as in any cross section of the river above or below, at any dead level. It is, therefore, possible to make a weir which shall be an obstruction to a certain height, and after that height shall be no obstruction. The merit of the weir consists not in its obliquity but its length. (Mr. Cubitt then produced a model to show the amount of obstruction that would be occasioned by the weirs, the details of which he explained to the Committee.) He also said that he could [illegible] oblique [illegible] which would not affect the stream at all: others might say it could not be effected, but it was a fact which could not be affected by their statements. I could produce a model in which water could pass over a weir, but I have an objection to do so, since they never act well on any scale. I have heard dredging down the centre of the stream mentioned as preferable to my plan; my only objection to it would be its expense; I kept expense constantly in view in my arrangement. I said in my cross-examination that it was feasible to dredge up to Worcester. We could sooner build a lock and weir at Upton than we could dredge from Upton to Worcester: dredging would take one season more. It does not appear to me that there is any material objection to that plan being followed. It would be impracticable to dredge from Worcester to Stourport: millions might do it, but hundreds of thousands would not: it would be quite out of question to dredge to the Dog and Duck on account of the fall. With six feet navigation over the lock sills, vessels from 80 to 120 tons could come up from the sea, through the Gloucester and Berkeley Canal, up to Worcester and Stourport; steam boats could pass through the locks without difficulty. If the bill passed I should be content to confine myself to one lock and weir this winter, and in the spring I would commence the others together. I think it would be best to commence below Worcester; I would engage to get the Diglis lock completed before Christmas. Suppose the bill passed, omitting the Upton weir, I would put all the lower Severn in a fit state for dredging by that time. I would finish the Diglis lock and weir at the same time; and I would be content that further operation should depend upon the effect of those works.

By Mr. Lowndes.—I admit the level near Lord Sandys's drain may be raised 18 inches.

Mr. Cubitt and Mr. Giles then entered into mutual discussion and explanation as to the effect of the works upon the drainage at Holtfleet and the Salwarp, when it appeared that in consequence of the section being very small, Mr. Giles had supposed the line representing the level formed by the Bevere Island weir to be horizontal, whereas in fact it sloped one inch per mile.

The Committee came to the following resolution.—

"That the preamble of the Bill is proved;" and then proceeded to consider the Bill clause by clause. The Bill was ultimately postponed until next Session, in consequence of the early conclusion of the Session.

REVIEWS.

The True Principles of Pointed or Christian Architecture: set forth in Two Lectures, delivered at St. Marie's, Oscott. By A. WELBY PUGIN, Architect and Professor of Ecclesiastical Antiquities in that College. Small 4to. London: J. Weale, 1841.

That this new work of Mr. Welby Pugin's will excite much interest, both among his professional brethren, and amateurs, may be confidently pronounced by us beforehand, since whatever comes from him must command attention; but that it will please every one is more than we dare assert; or rather we are certain that a good deal in it will prove unpalateable to a good many folks. By not a few, this volume—and a very handsome and tasteful volume it is—will be opened with anxious misgivings and apprehensions for themselves and their productions, since Mr. Pugin is known to be a tolerably plain-spoken man, and if anything rather overstrict than at all lax in his critical opinions. He is not one of those who keep beating about the bush, who fearful of giving offence, or of being thought too severe, rather hint at than utter what may be unpalateable truths. On the contrary, he gives free utterance to what he thinks, and he both thinks and speaks to the purpose; consequently what he does say must on that very account be all the more provoking to those who would be exceedingly glad to be able to gainsay not a little that his book contains.

Among the malcontents will be those who have been taught, or who teach others to look upon *classical* architecture, as the very perfection of the art—as its culminating point both in taste and genius, and who even consider it to be the highest merit of us moderns to be able to transplant a portico from a Grecian or Roman temple. The following extract will at once convince our readers, that Mr. Pugin will scandalize those whose orthodoxy is of the above kind.

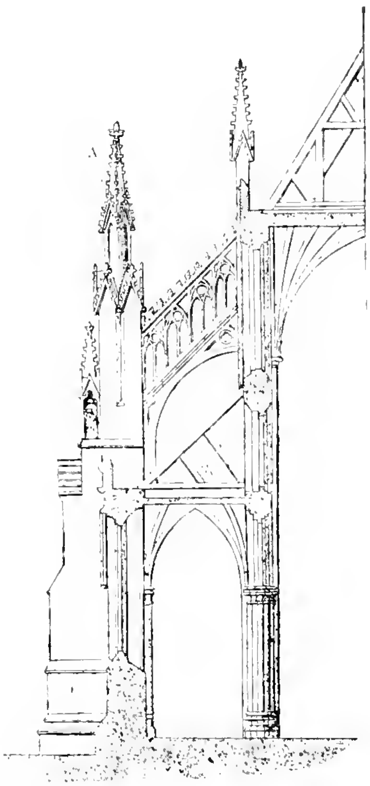
Grecian architecture is essentially *wooden* in its construction; it originated in wooden buildings, and never did its professors possess either sufficient imagination or skill to conceive any departure from the original type. Vitruvius shows that their buildings were formerly composed of trunks of trees, with lintels or brestsummers laid across the top, and rafters again resting on them. This is at once the most ancient and barbarous mode of building that can be imagined; it is heavy, and, as I before said, essentially wooden; but is it not extraordinary that when the Greeks commenced building in stone, the *properties of this material did not suggest to them some different and improved mode of construction?* Such, however, was not the case; they set up stone pillars as they had set up trunks of wood; they laid stone lintels as they had laid wood ones, *flat across;* they even made the construction appear still more similar to wood, by carving triglyphs, which are merely a representation of the beam ends. The finest temple of the Greeks is constructed on the *same principle* as a large wooden cabin. As illustrations of history they are extremely valuable; but as for their being held up as the standard of architectural excellence, and the types from which our present buildings are to be formed, it is a monstrous absurdity, which has originated in the blind admiration of modern times for every thing Pagan, to the prejudice and overthrow of Christian art and propriety.

The Greeks erected their columns, like the uprights of Stonehenge, just so far apart that the blocks *they laid on them would not break by their own weight.* The Christian architects, on the contrary, during the *dark ages*, with stone scarcely larger than ordinary bricks, threw their lofty vaults from slender pillars across a vast intermediate space, and that at an amazing height, where they had every difficulty of lateral pressure to contend with. This leads me to speak of buttresses, a distinguishing feature of Pointed Architecture, and the first we shall consider in detail.

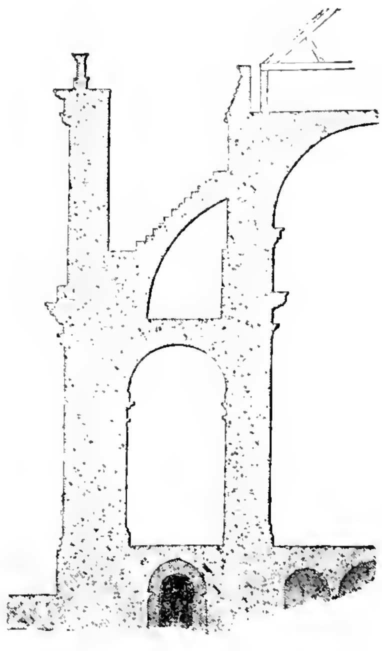
It need hardly be remarked that buttresses are necessary supports to a lofty wall. A wall of three feet in thickness, with buttresses projecting three feet more at intervals, is much stronger than a wall of six feet thick without buttresses. A long unbroken mass of building without light and shade is monotonous and unsightly; it is evident, therefore, that both for strength and beauty, breaks or projections are necessary in architecture. We will now examine in which style, Christian or Pagan, these have been most successfully carried out. Pointed architecture does *not conceal her construction, but beautifies it:* classic architecture seeks to conceal instead of decorating it, and therefore has resorted to the use of engaged columns as breaks for strength and effect;—nothing can be worse. A column is an architectural member which should only be employed when a superincumbent weight is required to be sustained *without the obstruction of a solid wall;* but the moment a wall is built, the *necessity and propriety of columns cease*, and engaged columns always produce the effect of having once been detached, and the intermediate spaces blocked up afterwards.

A buttress in pointed architecture at once shows its purpose, and diminishes naturally as it rises and has less to resist. An engaged column, on the contrary, is overhung by a cornice. A buttress, by means of water tables, can be made to project such a distance as to produce a fine effect of light and shade. An engaged column can never project far on account of the cornice, and all the other members, necessarily according with the diameter of the column, would be increased beyond all proportion. I will now leave you to judge in which style the real intention of a buttress is best carried out.

I have yet to speak of flying buttresses, those bold arches, as their name implies, by which the lateral thrust of the nave groining is thrown over the aisles and transferred to the massive lower buttresses. Here again we see the true principles of Christian architecture, by the conversion of an essential support of the building into a light and elegant decoration. Who can stand among the airy arches of Amiens, Cologne, Chartres, Beauvais, or Westminster, and not be filled with admiration at the mechanical skill and beautiful combination of form which are united in their construction? But, say the modern critics, they are only props, and a bungling contrivance. Let us examine this. Are the revived pagan buildings constructed with such superior skill as to dispense with these supports? By no means; the clumsy vaults of St. Paul's, London, mere coffered semi-arches, without ribs or intersections, *have their flying buttresses; but as this style of architecture does not admit of the great principle of decorating utility*, these buttresses, instead of being made *ornamental, are concealed by an enormous screen*, going entirely round *the building. So that in fact one half of the edifice is built to conceal the other.*



Section of a Pointed Church, with the Flying Buttresses decorated.



Section of St. Paul's, London, a Church built in the revived Pagan style, with the Flying Buttresses concealed by a Screen.

Although we will not go so far as to say it is inconsistent with correct principles of taste to introduce columns merely for the sake of decoration,—a doctrine which if consistently and strictly followed up, would put us out of conceit with the ornamental parts of many Gothic structures also;—we certainly do agree with Mr. Pugin in the main. Beautiful as we consider Grecian architecture to be as regards its mere forms, we have always felt it to be exceedingly *borné* and limited in expression. The whole of it lies in a very narrow compass; it admits of scarcely any combinations; it may, in fact be said to be stereotype. Like a barrel-organ it can play only a single set of tunes, which however agreeable they may be at first, become tiresome by repetition. Antiquarian travellers visit Lycia and other parts of Asia Minor, and merely return with *mare's-nest* discoveries of what we may find just as well, in our own libraries and portfolios; or if they do chance to meet with something like a new idea for a column or capital, scarcely ever is it turned to account, but we go on with our hackneyed Ilissus Ionic, &c., *usque ad nauseam.*—But we are now *improving* upon Mr. Pugin, so let us cut short our own remarks, and return to him and his book.

As it will, doubtless, be ere long in the hands of most of our readers, who will then have the advantage of the numerous illustrations as well as the whole of the text, we shall not attempt to follow its author step by step; therefore, passing over many clever original remarks in regard to 'mouldings,' and the 'use of the splayed form,' &c., we shall notice his free animadversions on the preposterous absurdities passed off by fashionable upholsterers, cabinet-makers, and paper-hangers as

Gothic furniture and Gothic patterns, in the true Brummagem gusto; illustrating some of these mongrel monsters by specimens in his engravings and cuts,—among the rest, of a "New Sheffield pattern for a modern *Castellated Grate!*"

"Modern grates," he observes, "are not unfrequently made to represent diminutive fronts of castellated or ecclesiastical buildings with turrets, loopholes, windows, and doorways, all in a space of forty inches.

"The fender is a sort of embattled parapet, with a lodge-gate at each end; the end of the poker is a sharp pointed finial; and at the summit of the tongs is a saint. It is impossible to enumerate half the absurdities of modern metal-workers; but all these proceed from the false notion of *disguising* instead of *beautifying* articles of utility. How many objects of ordinary use are rendered monstrous and ridiculous simply because the artist, instead of seeking the *most convenient form*, and *then decorating it*, has embodied some extravagance *to conceal the real purpose for which the article has been made!* If a clock is required, it is not unusual to cast a Roman warrior in a flying chariot, round one of the wheels of which, on close inspection, the hours may be descried; or the whole front of a cathedral church reduced to a few inches in height, with the clock-face occupying the position of a magnificent rose window. Surely the inventor of this patent clock-case could never have reflected that according to the scale on which the edifice was reduced, his clock would be about two hundred feet in circumference, and that such a monster of a dial would crush the proportions of almost any building that could be raised. But this is nothing when compared to what we see continually produced from those inexhaustible mines of bad taste, Birmingham and Sheffield: staircase turrets for inkstands, monumental crosses for light-shades, gable ends hung on handles for door-porters,(?) and four doorways and a cluster of pillars to support a French lamp; while a pair of *pinnacles* supporting an arch is called a Gothic-pattern scraper, and a wiry compound of quatrefoils and fan tracery an abbey garden seat. Neither relative scale, form, purpose, nor unity of style, is ever considered by those who design these abominations; if they only introduce a quatrefoil or an acute arch, be the outline and style of the article ever so modern and debased, it is at once denominated and sold as Gothic.

"While I am on this topic it may not be amiss to mention some other absurdities which may not be out of place, although they do not belong to metal-work. I will commence with what are termed Gothic-pattern papers, for hanging walls, where a wretched caricature of a pointed building is repeated from the skirting to the cornice in glorious confusion,—door over pinnacle, and pinnacle over door. This is a great favourite with hotel and tavern keepers. Again, those papers which are shaded are defective in principle; for, as a paper is hung round a room, the ornament must frequently be shadowed on the light side.

"The variety of these miserable patterns is quite surprising; and as the expense of cutting a block for a bad figure is equal if not greater than for a good one, there is not the shadow of an excuse for their continual reproduction. A moment's reflection must show the extreme absurdity of *repeating a perspective* over a large surface with some hundred different points of sight: a panel or wall may be enriched and decorated at pleasure, but it should always be treated in a consistent manner."

These cavalier censures will hardly obtain for Mr. Pugin the good-word of the honourable company of Paper-Stainers and Paper-Daubers. It may reduce the value of their stock on hand, and also of that of the Sheffield and Brummagem artists, at least 75 per cent.; but let them and Messieurs the upholsterers plaister up their pique with the comfortable reflection that, as many people will now be ashamed of their trumpery *Gothicizings*, and proceed to get rid of them as fast as they can, they must have their rooms refurnished,—which will, of course, be all for the benefit of trade.

In his second lecture he again touches upon the subject of furniture, and has another slap at the Upholsterers; who

"Seem to think that nothing can be Gothic unless it is found in some church. Hence your modern man designs a sofa or occasional table from details culled out of Britton's Cathedrals, and all the ordinary articles of furniture, which require to be simple and convenient, are made not only very expensive but very uneasy. We find diminutive flying buttresses about an arm chair; every thing is crocketed with angular projections, innumerable mitres, sharp ornaments, and turreted extremities. A man who remains any length of time in a modern Gothic room, and escapes without being wounded by some of its minutiæ, may consider himself extremely fortunate. There are often as many pinnacles and gablets about a pier-glass frame as are to be found in an ordinary church, and not unfrequently the whole canopy of a tomb has been transferred for the purpose, as at Strawberry Hill. I have perpetrated many of these enormities in the furniture I designed some years ago for Windsor Castle. At that time I had not the least idea of the principles I am now explaining; all my knowledge of Pointed Architecture was confined to a tolerably good notion of details in the abstract; but these I employed with so little judgment or propriety, that, although the parts were correct and exceedingly well executed, collectively they appeared a complete burlesque of pointed design."

This last confession is highly creditable to Mr. Pugin. Such a frank avowal of his own artistical delinquencies, speaks much in his favour, and shows that if he is severe towards others, he cannot be reproached with being over-indulgent towards himself. At the same time we must say that if the censures he levels against architects and their employers be for the most part well merited, they are occasionally too sweeping and overstrained. His objections, for instance, against the application of the Italian style, to domestic architecture in this country, amount to little more than a sophistical tirade. "What," he asks, "does an Italian house do in England?" Which question put forth by him as an unanswerable one, might be turned against the cause he himself advocates; for just as well might it be asked, on the other hand, why should a house erected in the reign of Queen Victoria, be made to resemble one built in the time of Edward IV., or, Henry VII. or VIII? Why should a Protestant church of the 19th century be in any respect modelled like a Roman Catholic one of the 14th or 15th? Is not the Italian style to the full as applicable to our actual wants and purposes in the majority of cases, as any mode *borrowed*—for borrowed after all it must be—from examples to be found, indeed, in our own country, but belonging to periods more dissimilar from, than in aught resembling the present one? Nominally Italian as to design, are not Barry's two Club-houses in Pall Mall, perfectly English in their accommodation? We could easily extend this list of questions; but until they are answered they will answer for the present occasion. Even our ancestors themselves were addicted to change: they endeavoured to make their buildings keep pace with the progress of social improvement and the spirit of the times. Nay, *mutatis mutandis*, what Mr. Pugin himself urges against the castellated style might in some degree be objected to some other styles of much later date.

"What can be more absurd than houses built in what is termed the castellated style? Castellated architecture originated in the wants consequent on a certain state of society: of course the necessity of great strength, and the means of defence suited to the military tactics of the day, dictated to the builders of ancient castles the most appropriate style for their construction. Viewed as historical monuments, they are of surprising interest, but as models for our imitation they are worse than useless. What absurdities, what anomalies, what utter contradictions do not the builders of modern castles perpetrate! How many portcullises which will not lower down, and drawbridges which will not draw up!—how many loop-holes in turrets so small that the most diminutive sweep could not ascend them!—On one side of the house machicolated parapets, embrasures, bastions, and all the show of strong defence, and round the corner of the building a conservatory leading to the principal rooms, through which a whole company of horsemen might penetrate at one smash into the very heart of the mansion!—for who would hammer against nailed portals when he could kick his way through the green-house? In buildings of this sort, so far from the turrets being erected for any particular purpose, it is difficult to assign any destination to them after they are erected, and those which are not made into *chimneys* seldom get other occupants than the rooks. But the exterior is not the least inconsistent portion of the edifices, for we find guard-rooms without either weapons or guards; sally-ports, out of which nobody passes but the servants, and where a military man never did go out; donjon keeps, which are nothing but drawing-rooms, boudoirs, and elegant apartments; watch-towers, where the housemaids sleep, and a bastion in which the butler cleans his plate: all is a mere mask, and the whole building an ill-conceived lie."

We would give a trifle to know what is Mr. Pugin's opinion of Windsor Castle;—in fact we should very much like to see a volume of comments from his pen relative to some of the principal modern Gothic structures he has examined in various parts of the country. We do not imagine that he is perfectly satisfied with any one of them —not even with Windsor itself; still, they cannot all be equally bad: some must possess more or less merit in particular parts, or else be conspicuous for egregious sins and defects; and at any rate, we should then obtain something in the shape of specific criticism from Mr. Pugin, instead of those generalized observations to which he has hitherto chiefly confined himself. In the meanwhile, we thank him for the present work, from which much profitable instruction is to be obtained. Considerable praise is also due to the publisher, for the truly elegant manner in which the volume is got up, so as to render it one well fitted not only for the library, but the drawing-room and boudoir; nor is it deficient in the popular recommendation of being unusually cheap.

History of Belvoir Castle, from the Norman Conquest to the Nineteenth Century; with a Description of the Present Castle, and Critical Notices, and the Paintings, &c. &c. By the Rev. Irvin Eller, of Queen's College, Cambridge. 8vo. London, 1841.

We shall confine ourselves to the latter half of this volume, namely, the description of the Castle itself and its apartments, as being that which more properly comes under our cognizance, and which is most to our individual taste. From the first or historical part we content ourselves with gathering the following notices in respect to the building. After being wantonly laid in ruins by Lord Hastings, on whom it had been bestowed by Edward IV., the Castle was begun to be rebuilt in the reign of Henry VIII, by Thomas, first Earl of Rutland, and was completed by Henry, the second Earl, about 1555. It was afterwards dismantled by the Parliamentary forces under Cromwell, and again rebuilt in 1668. Excepting some slight alterations, such as the addition of a picture gallery, made by George, the third Duke of Rutland, about 1750, the structure underwent little change until the beginning of the present century, when the new works were commenced in 1801, and carried on under the direction of Wyatt till 1816, at which time the south-west and south-east fronts were completed, and the grand staircase and picture gallery in the north-west one nearly finished. On October 26th of that year a most calamitous fire broke out,* which consumed the whole of the north-west and north-east sides, and would probably have extended its ravages further, had it not been arrested by bricking up the doorway opening from the grand staircase into the Regent's gallery, which, with the chapel, form the south-west front of this extensive pile. Of the pictures destroyed we have here a complete catalogue, with the sums at which each was valued—varying from 5*l.* to 3000 guineas—and those for which each was insured. Among them were a great many family portraits by Sir Joshua Reynolds, and his large picture of the Nativity, painted for the centre compartment of the stained glass window in New College, Oxford.

After this event the north-east and north-west fronts were rebuilt under the direction of the Rev. Sir John Thoroton,† an amateur architect, who appears to have greatly improved upon the ideas of his professional predecessor, notwithstanding that the latter was no other than the "celebrated" Wyatt. One very material improvement on the original plan, both as regards external appearance, convenience, and internal effect, adopted by Sir John—is the grand entrance in the north-west front, consisting of a spacious advanced carriage porch, connected with the building by a short corridor forming an approach to the vestibule or "guard-room;" whereas, previously to the fire, there was nothing, whatever of the kind—no sheltered intermediate space, but visitors entered immediately from the open air into the vestibule.

"It would be tame language," says Mr. E., "to speak of the present entrance (merely) as an improvement. Nothing can be in better taste than the porch with its lofty doors, its pointed arches, its ogee-shaped canopies with finials, and the cloister-like entrance." "The porch, entrance-passage, guard-room and gallery, were all designed by Sir John Thoroton from portions of Lincoln cathedral. The entrance-passage is lighted by eight windows (four on each side), between which shafts rising from flowered corbels, form the support of moulded ribs on the vaulted roof."

Judging from the plans, we should imagine there must be a striking degree of effect in the view through the arch facing the entrance, into what is called the Guard-room Gallery, formed by a screen of arches on a higher level, it being in fact the first landing, off from which lies the grand staircase. For want, however, of more exact explanation, and of either view or section, it is difficult to comprehend so clearly as we could wish to do, what, owing to the difference of levels, is rather a complex and intricate part of the interior. We may, therefore, express our regret that none of our graphic "Illustrators" and view-makers, should have thought proper to satisfy our curiosity relative to Belvoir. The most that any of them, we believe, have done, is to give us one or two general views of the Castle, but from such points as rather to exhibit its locality, the general character of the structure, and the various masses of building composing it—as seen rising above the lofty trees embosoming it—than to show what its architectural design really is. This is the case with the view (the north-east front), which serves as the frontispiece to the present volume. Greatly do we desiderate a distinct architectural view of the entrance and corridor connecting it with the building; as likewise of another representing that portion of the south-west front which forms the exterior of the chapel, and which is spoken of as being of "purely perpendicular character."

"It has some good features about it," continues the writer, "especially in the parapet above the arcade in the basement story, which formed no part of the original design by Wyatt, but was added by Sir John Thoroton, in imitation of a portion of the parapet in Lincoln Cathedral. The windows are of elegant proportions, and harmonize well with the general character and intention of the building. We might, perhaps, have wished that the embattled parapet of the two towers had been of a rather less gossamer character, and that more substantiality had been imparted to the pinnacles. But, upon the whole, the architecture of the chapel forms an exquisite break upon the general plainness of this part of the Castle. It comes upon the view so unexpectedly, and contrasts as effectually with the remainder of this front, as the little cultivated spots which we meet with in the surrounding scenery, when, after passing through the dense foliage of gigantic trees, we suddenly arrive at an open area, where the tasteful skill of the floriculturist has been at work."

We return again to the interior; but, referring to the work itself for descriptions of the several apartments, and of the paintings and other works of art they contain, shall merely enumerate some of the principal rooms, adding their respective dimensions. From the upper landing of the grand staircase, any of the following rooms may be immediately entered. The Picture Gallery (over the Guard-room gallery, and the ascent to it), the Regent's rooms (over the Guard-room or Vestibule), the Regent's gallery, an Ante or Waiting-room, beyond which is the principal library.

Picture Gallery 61.10′×25.8′ and 31.5′ high, lighted from above by a series of windows fitted with ground glass.
Regent's Rooms.—Sitting-room 24.6′×20.9′.
Bed-room 24.6′×18.
Dressing-room 21×17.9′.
Regent's Gallery, 131×17.8′, or, including the semi-circular bay, (35.9′ in diameter, and containing five windows) 35.8′. Height 18.2′. The folding doors at the S. W. end open into the tribune of the chapel.
Ante-room, 30.4′×21.6′ with a single window towards the inner court, but lighted principally by a lantern in the ceiling.
Library, 47×23.9′ and 18 high; with four windows on the side towards the inner court.
Grand Corridor, extreme length including the staircase on that side of the building, 120×24. Though called a corridor, the proportions and dimensions of this thoroughfare room entitle it just as well to the name of Gallery; and it is in fact occasionally used as a ball-room.
Green or Assembling Room, 27×24, and 17.6′ high.
Chinese Rooms: Setting Room 29×22.
Bed Room 26×17.
Dressing-room 26×17.
Elizabeth Saloon, 55×36, and 20.10′ high.
Grand Dining-room, 55×31, and 19 high. Five recesses, viz. one at each end, and three on the side opposite the windows, with two fire-places between them.
Hunters' Dining Room, 21×17.
Family Dining Room, 34×21.

This last is one of the suite of private apartments in the S. E. front; above which is another suite, occupied by the late Duchess: the principal one, a boudoir, 22.4′×19.6′, exclusive of the oriel window, which adds 6·3′ more to the length of the room, and which commands a most delightful prospect, where "the eye, passing over the foliage on the terraces immediately below the Castle, is refreshed by a beautiful expanse of water, immediately beyond which is rising ground covered with plantations. The village of Woodthorp, in the valley, a little to the left, with the spire of its simple church, is sufficiently distinct to form a sweet feature in this scene of rural repose. At a more remote distance, the magnificent mansion of Mr. Gregory (at Harlaxton), forms a terminal point for the eye to rest upon near the horizon of the landscape."

Here we must take leave of Belvoir—not because little more remains to be spoken of, for we have not even mentioned one principal

* How the fire originated, could, it seems, never be discovered—probably because those who could have cleared up the mystery chose to keep their own counsel. For some piquant remarks on the subject of such "accidents," we may refer our readers to an article in the last No. of the Polytechnic Journal, entitled the British Museum and its Library," where the writer indulges in some pleasantry on the *pyrophobia*—the excessive horror of fires and candles exhibited by the managers of that national institution—which is such that it induces them to close the reading rooms very long before sunset, during several months in the year.

If not as a preventive against fire, at least as a means of checking its progress, we would suggest that in all very extensive residences, particularly where the entire pile consists of distinct masses and parts, there should be exceedingl thick internal party walls between the different ranges of rooms, so that the fire could not spread beyond that portion of the plan where it might happen to break out. Were this done, not only would there be comparatively little danger, but also less alarm and confusion in case of fire, as the inmates would feel themselves in safety in other parts of the building.

† This gentleman, who was rector of Bottesford, adjoining Belvoir, from 1782 to 1820, (in which year he died at Belvoir Castle, Dec. 18th, in his 62nd year,) and who was knighted by George IV. when Regent, deserves to rank high among those who have cultivated the study of architecture. "One half of the present Castle," says Mr Eller, "and certainly *the most beautiful portion* in an architectural point of view, was erected chiefly from his designs and under his superintendence."

object of attraction to visitors, namely the Mausoleum, of which, and also of Bottesford Church and its monuments, long descriptions are here given: but we do so because we have already bestowed as much notice on Mr. Eller's book as our limits will permit. It has afforded us considerable gratification, and we would suggest, for his consideration, whether it would not be desirable to republish the description of the castle, &c., separately in a duodecimo volume, omitting altogether the biographical notices of artists in the account of the pictures: which being done, there would be opportunity for entering into some particulars that are now either passed over or but slightly touched upon. It would be a further improvement were the terraces to be shown in the ground floor plan of the building

---

Graphic Illustrations with Historical and Descriptive Accounts of Toddington, Gloucestershire, the seat of Lord Sudeley. By John Britton, F.S.A. Publisher, the Author, 1840.

By this work, containing twenty-three external and internal views, and nine lithographed plates of details, Mr. Britton has sought to make known to the public one of those modern adaptations of the pointed style to private dwelling houses, the excellence of which he has by his earlier works so mainly assisted to bring about. The energy with which Mr. Britton for more than five and forty years, has continued to superintend the illustration of our ancient buildings, and to direct public attention to their beauties, affords an example well worthy of imitation, and must entitle him to the warm applause of the right minded.

Lord Sudeley, the owner and the designer of the new mansion at Toddington, formed one of the Committee (as Mr. Hanbury Tracy,*) appointed to select from the numerous designs sent in competition for the new Houses of Parliament, and devoted much time and zeal to the investigation. The building under consideration which has occupied his Lordship's attention more than twenty years, proves fully that he was well qualified for the task, having an intimate knowledge of architecture as a fine art. The construction of a modern mansion in the style of buildings of the middle ages is not an undertaking of trifling difficulty. "By a judicious attention to appropriate models," says Mr. Willson in his preface to Pugin's specimens, "a modern residence of whatever size, may be constructed in the Gothic style without departing from sound principles of taste. Some modifications of ancient precedents must be allowed, for an absolute fidelity will frequently prove incompatible with convenience; but as few deviations as possible should be gone into; and above all, nothing should be attempted which is inconsistent with the character and situation of the place, or which cannot be executed on a proper scale of dimensions." This feeling is evident throughout Toddington, and has led to a very successful result, redounding to the credit of its designer the more highly because of the difficulty. Attached to the account of the house is a short essay on the comparative merits and eligibility of the Grecian, Roman, and Monastic or Gothic architecture for the purposes of the modern English mansion, wherein the author traces lightly the progress of architecture in England, and refers to those men who have chiefly aided this progress. In this essay Mr. Britton observes, "of the manner in which architects were employed soon after the Reformation, the household accounts of Henry VIII. furnish some curious but deplorable information. From these it appears that painters, sculptors, carvers, and *architects*, were retained at stipulated periodical wages. Holbein, John of Padua, Lawrence Bradshaw, Richard Lea, and some others were thus engaged; and they designed several of the mansions which were then erected, and which are now more admired in the picturesque drawings and engravings of the artist, than as comfortable residences for the noble or wealthy families of this age. So the châteaux of the old noblesse of France, and the castles of the Edwardian dynasties of England, are picturesque and imposing objects in the landscape, but have few charms or attractions to render them endurable as permanent homes for persons who wish to enjoy domestic quietude and comfort."

For Walpole's advocacy of Gothic architecture, although ill exemplified by him at Strawberry Hill, Mr. Britton gives his tribute of praise, and then describes some few of the better sort of dwellings more recently erected in England in this style.

Want of space however prevents us at this moment saying anything more of the work in question, than that it is a very valuable and acceptable addition to the scanty stock of books which we at present possess on domestic architecture.

* Mr. Tracy was raised to the peerage July 12, 1838.

Illustrations of Windsor Castle. By the late Sir Jeffry Wyatville, R.A. London: Weale, 1841.

This is a folio work in two volumes, on a scale of magnificence but rarely seen, the size of the plates corresponding to the beauty of their execution. These plates are six and twenty in number, besides wood engravings, some of them too containing more than one view, and embracing nearly every part of the external architecture of the Castle and Stables, besides plans of the Castle in its former state. These engravings are executed in a manner so costly as only the devotion of an architect to his favourite subject could authorize, being quite beyond the usual limits of publishing enterprize. The letterpress being printed on paper of the same dimensions, makes the volume rather unwieldly as a readable book, which is to be regretted as the valuable matter contained in its pages is such as to excite great interest. The general superintendence has been confided to Mr. Henry Ashton, and the literary portion by him again transferred to Mr. Poynter, than whom few could be found better qualified. The editors having determined upon excluding a description of the interior of the edifice on account of so much of its decoration being not merely of a passing interest, but adopted against the will of the architect, necessarily restricted themselves to a mere antiquarian description of the Castle. To this task Mr. Poynter has brought a depth of research, which has added much that is new to our previous knowledge of the subject, and given a degree of certainty to many points which before were involved in obscurity. The result of these labours may not be great, but the extent of research required is easily to be appreciated. To transfer to our pages any thing like a complete history of the Castle would be of course impossible, but we cannot allow this volume to pass us without gleaning in some way from its pages.

In the reign of Edward the Third, called the Confessor, we find the earliest authentic notice of Windsor, when it was granted by that last reigning sovereign of the Saxon kingly race to the Abbey of Westminster, under the name of Wyndleshore, a grant which by William the Norman was resumed by an exchange for some lands in Essex. This prince erected a castle at Windsor, which is registered in Domesday Book. At Old Windsor, however, the Saxon kings are believed to have had a palace at an early period. In the reign of Henry III., the castle was rebuilt, and from this period begins to date its historical renown, being in the next reign considered second in importance only to the Tower of London. A few architectural fragments brought to light during the progress of the improvements, are supposed to be the only relics of this edifice. Henry III. made great improvements in the lower ward, and the traces of his work are to be recognized in the present day, during the whole of his reign indeed extensive buildings were in progress. Of the chapel built by this prince, Mr. Poynter is of opinion that a doorway may be recognized behind the altar of St. Georges. In two years the large sum of 873*l.* was allotted to the works. The Belltower the editor attributes to the 25th year of Henry's reign, and to the Garter Tower he is inclined to assign the same date. It is to be observed that during this reign we find frequent provision for chimneys and glass windows; it seems also that the erection of temporary wooden dwellings within the Castle was not uncommon. In searching out the particulars of the works of Henry III., Mr. Poynter has made a very diligent investigation of the Pope and Close Rolls and other records, which have enabled him to employ a minuteness of description equally interesting to the antiquarian and to the architect. Of how much value researches of this nature may become we see when we come to consider how they bear upon any restoration of the western extremity of the Castle.

The next great epoch in the history of the Castle is the reign of Edward III., a period respecting which we have ample information. The foundation of the College and restoration of St. George's Chapel was the first step taken by this monarch, which was succeeded by the inauguration of the Order of the Garter. In 1356, the celebrated William of Wykeham was appointed surveyor, and the works proceeded with great vigour, and in 1359 three hundred and sixty masons were pressed for the service of the castle, and in 1362 on account of a pestilence three hundred and two more. In the first half of 1363 as much as 3802*l.* 17*s.* 8*d.* was paid for the works including 932*l.* for lead, and thirty-six glaziers were impressed, twenty-four to serve in London, and twelve at Windsor. More masons were also impressed. In 1364 the whole expenditure was 3031*l.* 9*s.* 9*d.* In 1365 a payment occurs of 13*l.* 6*s.* 8*d.* to John, a canon of St. Catharine's, the king's picture painter, for a picture with images for the chapel, and another of 50*l.* to John de Lyndesay, for a table with figures also for the chapel. It is to be remarked that then as during the reign of Henry III., the artists appear to have been generally ecclesiastics, dignitaries of the church combining the practice of the arts with their clerical functions. In 1366, 600*l.* was paid for lead, and the whole expenditure was 4976*l.*

9s. 9d. To William de Burdon, the king's painter, was paid 13l. 7s. for a great tablet for the altar. In each of the years 1367 and 1368, the expenditure was about 2000l. To William de Burdon was paid 20l. more for his picture for the chapel, 10l. was paid for buying marble, 60l. for German copper for bells, and the very large sum of 200l. for a great alabaster table for the high altar of St. George's. This according to the largest estimate would be 6000l. of the present money. After 1369 no more workmen were impressed, and in a few years the expenditure was gradually diminished; the last payment being in 1374. In this reign from a payment of 50l. for a new bell for it, a clock seems to have been placed in the bell-tower, as has been the practice down to the present day. Of the early works of Edward III. a portion is the Dean's cloister, of other works the outlines are scarcely to be traced, although he added to the castle the upper ward. Here however is yet to be seen the principal gate adjoining the keep. In the interior of the castle the work of Edward III. is still visible in the vaulted basement of the Devil Tower. The arches of this vaulting are four centered, and present an early specimen of the systematic use of that form. By Edward III. most of the buildings of Henry I. were pulled down, and the Keep is supposed to have been rebuilt.

Under Richard II. in 1390, the appointment of Clerk of the Works was for a short time held by Geffrey Chaucer, the Father of Modern English Poetry, his salary being 2s. a day, with the power of appointing a deputy. Under Henry VI. the revenues of Windsor amounted to 207l. 17s. 5¼d., a sum far from sufficient to meet the expenses; the manors of Cookham, Bray, Binfield and Sunninghill were farther charged with 100 marks per annum for the repairs.

By Edward IV. the existing Collegiate Chapel of St. George was built, the direction of the works being confided to Richard Beauchamp, Bishop of Salisbury, a most distinguished prelate and architect. In 1480 the expenditure was 1408l. 16s. 9¼d. The principal part of the stone came from Tainton in Oxfordshire, where Henry Jennings the master mason purchased 9755 feet at 2d. per foot; the carriage by land through Burford and Culham to Henley cost 151l. 12s., and it was thence conveyed by water to Windsor bridge. Some portion of Caen stone was also used, and Heath stone from Cranbourne Chase. The timber came principally from Upton, Ashridge, Farnham, Wyke and Sunninghill, and the carriage of these materials and of sand and lime amounted to 29l. 10s. 3½d. The cost of scaffolding and other plant, tools, smith's bellows, tiles and tilepins for workmen's sheds, withes to tie scaffolding, straw, candles, seacoal, charcoal, steel, iron for the windows, iron bolts for the carts, sheet iron, tin, tin pans, nails, &c. amounted to 141l. 8s. 1d., and the workmen's wages to 555l. 6s. 1½d. For these works masons were impressed, and the best workmen were so monopolized by the king for St. George's, that other works were sadly impeded, as was the case with the Divinity School at Oxford. Carving seems now to have become a secular employment, and a large sum was appropriated for this class of work, being in this year 75l. 4s. 6d. With the Chapel the Chapter House was also rebuilt. In 1481 stone was obtained from Caen, Tainton, Sherborne, Ryegate, Milton and Little Daryngton, and the expenditure for the year 1249l. 18s. 5d., being for stone 137l. 5s., for carriage 349l. 18s. 0½d., for other materials and stores 144l. 11s. 11½d., and for wages 457l. 10s. 6½d., including 62l. 12s. 6d. for carving. The next year the expenditure was 1145l. 7s. 2¾d., of which for carving 100l. 10s. 4d.; and in 1483 960l. 12s. 10d., of which 186l. 10s. 4d. for carving. Thus in four years out of a total expenditure of 4674l. 15s. 3d., 425l. 7s. 8d. was paid for wood carving. In 1483 Edward IV. was buried here, behind a curious screen of iron work, an elaborate piece of workmanship, generally thought to be of foreign manufacture, but by the editor assigned to John Tresilian, the master smith. Among the benefactions of Bishop Beauchamp to the Chapel, was the following exertion of the influence in its favour. John Shorne or Schorne was a pious rector of Northmarston in Bucks, about the year 1290, and held in great veneration for the virtues which his benediction had imparted to a holy well in his parish, and for his miracles, one of which, the feat of conjuring the devil into a boot, was considered so remarkable, that it was represented in the east window of his church. Bishop Beauchamp obtained a license from the Pope to remove the shrine of John Shorne from Northmarston wherever he pleased, and he accordingly removed it to the Lincoln Chapel at Windsor. At the Reformation, the College of St. George's lost 500l. per annum from the offerings at this shrine. In 1481 Bishop Beauchamp was succeeded by Sir Reginald Bray. Richard III., the last of the Plantagenets, during the first year of his reign appropriated 733l. 10s. 9¾d. for the building of the College and Chapel. In 1484 the body of Henry VI. was removed from Chertsey and buried in the Chapel.

Henry VII. left his personal property and the profits of his lands for the completion of the new works in the body of the Chapel. During his reign the works were directed by Sir Reginald Bray, who built the Bray Chapel, now the South Transept. In 1508 the roof of the Choir was constructed in stone, the expense being supplied by a subscription of the Knights of the Garter. The main vaulting is by the editor cited as without exception the most beautiful specimen of the Gothic stone roof in existence. Henry VII. took down the original chapel of Henry III., for the purpose of building a royal mausoleum in its room, but the work was not completed. The shell of the building is supposed to be of his reign. In 1500 the Deanery was rebuilt by Doctor Christopher Urswick; the houses of the Minor Canons are also attributed to this reign. A lofty oriel in the upper ward and the inclosure of the stairs to the Keep may be assigned to the same date. By a typographical error in the work before us, the death of Henry VII. is assigned to 1503 instead of 1509. The principal work of Henry VIII. was the great gateway of the lower ward of the Castle. In 1528 the exquisite fan groining of the roof at the interstices of the Cross of the Chapel was executed by subscription of the Order of the Garter. Wolsey began a stately tomb at Windsor in the chapel erected by Henry VII. hence named Wolsey's Tomb House. On this work he employed Benedetto, a Florentine artist, who began it in 1524, and to him were paid 4250 ducats, and 380l. 13s. for gilding. These works were destroyed by some of the Parliamentary troops in 1646 for the sake of the metal, except a sarcophagus of black marble of Italian design, which in 1805 was placed over the tomb of Nelson in the crypt of St. Paul's. In 1519 James Denton, one of the canons, founded the building called the New Commons, now incorporated with the Prebendal Houses, but of which a doorway is preserved, richly ornamented. Under Edward VI. in 1537, the fan vaultings of the side aisles to the choir were executed, and works begun for bringing a supply of water to the Castle from Blackmore Park near Winkfield, a distance of five miles. To supply the pipes, Wallingford Castle and other ancient buildings were stripped of their lead, 370 cwt. from Maidstone. Under Queen Mary in 1555 the pipe was brought up into the middle of the Upper Court of the Castle, "and there the water plenteously did rise 13 foot high." In this place was formed a reservoir from which every part of the Castle was supplied. In this reign the houses of the military knights were completed, having been begun in the third year of Philip and Mary, and finished in three years at an expense of 2747l. 7s. 6d. The Square Tower and some portion of the structure to the east were previously standing, and the additions and alterations were made with materials taken from other buildings. The stone was brought from Reading Abbey, and eighteen fothers of lead, and "twenty old apparails for chimneys," from Suffolk Place in Southwark. To Elizabeth Windsor Castle is indebted for its terrace, although some parts of it appear to have been in existence previously, every ten feet of the terrace wall, twenty feet in height, and six feet at the base gradually sloping to six feet at the top, costing 125l. 16s. 8d. In 1570 1900l. was expended on a thorough repair of the Chapel, supposed to be the private Chapel adjoining St. George's Hall. A general repair of the Castle was made by this Queen, which in the six years ending 1575 had amounted to 6600l. In 1576 Queen Elizabeth's Gallery was built, it now forms a portion of the Library. In the seven years ending 1577 the works had cost 7800l. In the report on the works in 1580, a clause, relating to the apartments of the Maids of Honour, recites that these ladies "desire to have their chamber ceiled, and the partition, that is of boards there, to be made higher, for that the servants look over." In this reign for the first time we have a connected description of the Castle by Paul Hentzner, a German traveller who visited England in 1598. He says that in the Castle he was shown among other things the horn of a unicorn, eight spans and a half in length, and valued at 10,000l.

Under James I. was executed the survey of the Parks and Forest by John Norden, which contains the first view of the Castle. By an entry in the Issue Roll for 1607, it appears that this survey was presented to the King by its author, who was rewarded with a gift of two hundred pounds. Nothing it is said was done at Windsor under Charles I. until 1635, when several alterations were made. It was the intention of Charles I. to convert the Tomb-house into a place of sepulture for his family, but this plan was not carried out. On the deposition of Charles I., Captain Fogg, an officer of the Parliament, and subsequently, Colonel Venn, under orders from the Commonwealth, carried off the plate and decorations of the Chapel and ruined the painted windows. In the reign of Oliver Cromwell many repairs were made, and the revenues of the Castle greatly improved. This prince also attached to the Chapel the foundation of the Military Knights, for whom Sir Francis Crane's building was erected. Under Charles II. a complete alteration of the Castle was made by Sir John Denham and Sir Christopher Wren, and the best artists were employed upon the paintings and carvings of the interior, in which a profusion of the exquisite works of Grinling Gibbon still exist. Charles's principal addition to the Castle was the Star Building, now called the Stuart Building, about one hundred and seventy feet long. Verrio was employed on the allegorical paintings, for which he was to receive a sum of above seven thousand pounds in five years; in 1701, however, 20 years after, 1800*l*. was still due to him. In 1674 St. George's Hall was fitted up as a theatre, and French plays performed in it. In 1675 the North Terrace was enlarged to its present extent. Wren's alterations of the exterior of the Castle were far from improvements, for he left it with a most unpicturesque appearance which it retained for above a century. In 1680 the equestrian statue of Charles II. was erected by Tobias Rustat, Yeoman of the Robes. It is the work of Josias Ibach Strada of Bremen, but the sculptures on the pedestal are attributed to Grinling Gibbons. In this reign was commenced the Long Walk. James II. fitted up the Tomb House as a Catholic Chapel, which Verrio was employed in decorating. William III. contemplated great improvements, and employed Wren to draw a plan in the Italian style, which is inserted in the work under our consideration; nothing however was done. Under Queen Anne Sir James Thornhill was employed in painting the Great Staircase, and in the first eight years 40,000*l*. were laid out in repairs. The extraordinary works were principally confined to the Parks.

The two first Hanoverian kings merely kept the Castle in repair, George the 2nd however employed William Kent at an expense of 400*l*. in restoring some of the paintings. George III. erected the detached edifice opposite the South Terrace, called the Queen's Lodge, which was completed in 1782 at an expense of nearly 44,000*l*., and is said by the editor to have been executed from the plans of His Majesty, "whose taste for practical architecture is well known." It was removed in 1823 by George IV. In 1787 Mr. Emlyn was employed to restore the interior of St. George's Chapel, at the private expense of George III In 1796 the painted glass window in the Chapel was completed by Jarvis and Forest, from the designs of West. In 1796 James Wyatt was appointed Surveyor General, who effected many improvements. In 1810 the design of establishing a royal sepulchre was carried into effect, and a vault constructed under the Tomb House. George IV. having decided upon extending the Castle as an imperial residence, obtained a preliminary grant of 300,000*l*. from parliament, and appointed Mr. Jeffry Wyatt to the superintendence of the works, who in 1828 received from the monarch the honour of knighthood, by the title of Sir Jeffry Wyatville. The cost of the whole of Sir Jeffry's works was 771,000*l*., and they included the following works, new, rebuilt, or thoroughly repaired, New St. George's Gate; New Octagon Turret to Devil Tower; York, Lancaster, Chester, Prince of Wales's, Brunswick, George III., and Round Towers; George IV. Gateway; a great length of walling; a new Turret to the Stuart Buildings; Grand Entrance Tower; Front of St. George's Hall; Kitchen Gateway; and two octagon Turrets; Gallery from the Devil Tower to St. George's Hall, 550 feet long, new terrace 1060 feet long, some part of the walls of which is 30 feet high, lowering the court-yard from three to six feet, removed 13,000 cubic yards. Internally :—His Majesty's apartments with a corridor 500 feet long, kitchen and servants apartments, state apartments, St. George's Hall: ball-room; Waterloo Gallery; grand staircase. In the Waterloo Gallery George IV. placed the series of portraits painted by Sir Thomas Lawrence. In the reconstruction of the Keep Sir Jeffry managed with great skill to sustain the increased weight of this enormous pile on an artificial rock of concrete. During the reign of William IV. and Queen Victoria, the works left unfinished by George IV. were successfully prosecuted by Sir Jeffry, until his death in 1840, when the task devolved upon Mr. Henry Ashton, by whom the new stables are being constructed at an expense of 70,000*l*.

As Windsor Castle has employed the talents of some of the most celebrated of our architects and artists, we thought that the following chronological account of officers and persons employed, drawn up by us from Mr. Poynter's materials would prove of interest to our readers.

1173. Master Geoffry, master of the works.

1179. Master Osbert, ditto.

1223. John le Draper and William, the clerk of Windsor, ditto, (Master Thomas, the king's carpenter).

1225. (Master Nicholas, the king's carpenter, allowance for a gown 15*s*., Master Jordan, ditto).

1228. William de Millars, constable of the castle.

1237. William de Burgh, director of the works.

1240-52. (Friar William of Westminter, a painter, and John Sot his assistant).

1241. (Master Simon, king's carpenter).

1260. (Master John of Gloster, king's mason).

1261. Richard de Fremantle, Custos of the manor of Cookham and Bray.

1350. (John de Spaulee, master of the stonehewers).

1351. James de Dorchester, deputy constable of the Castle.

1356. William de Wykeham, surveyor, (Bishop of Winchester), salary a shilling a day, a shilling extra while travelling, and three shillings per week for his clerk. He succeeded Robert de Bernham and Richard de Rochell who had the same salary. In 1357 Wykeham obtained an increase of a shilling a day.

1363. William de Mulso, canon of Windsor, surveyor.

1366. (John, canon of St. Katharine's, king's painter; John or William de Lyndesay, of London, wood carver).

1387. Adam de Hertyngdon, canon of Windsor, surveyor or clerk of the works; (William de Burdon, king's painter).

1390. Geffrey Chaucer, clerk of the works, salary two shillings a day, with privilege of appointing deputy.

1391. Unknown.

1474. Richard Beauchamp, Bishop of Salisbury, surveyor of the works. (Henry Jennings, master mason: Thomas Canceler, clerk of the works, salary 10*l*.; John Tresilian, master smith, 1*s*. 4*d*. per day. The clerk of the works, master mason and master carpenter had gowns allowed them. Robert Ellis, John Filles, Derrick Van Grove and Giles Van Castel, carvers.)

1481. Sir Reginald Bray, surveyor of the works.

1505. (John Hylmer and William Vertue, contractors for the stone work of the roof of St. George's Chapel).

1524. (Benedetto, artist, employed on Wolsey's tomb).

1575. Humphrey Muhill, clerk of the works; ditto, comptroller, 2*s*. per day; Henry Hawthorne, clerk of the works, 2*s*. per day.

1603. Sir John Norris, comptroller; Sir John Trevor, surveyor of the works.

1637. Sir Robert Bennet, surveyor of the works; (David Ramsay, Esq., king's clockmaker).

1639. (Christopher Van Vianen of Nuremburg, makes the plate for the Chapel).

1660. Sir John Denham, surveyor-general; Sir Christopher Wren, deputy.

16—. Sir Christopher Wren, surveyor-general; Baptist May, clerk of the works.

1676. (Antonio Verrio, painter; Grinling Gibbons, carver).

1679. (Josias Ibach Strada, casts statue of Charles II).

1707. (Henry Wise, landscape gardener).

1710. (Sir James Thornhill, painter).

1746. (William Kent, painter).

1778. George III. builds Queen's Lodge after his own designs.

1787. Mr. Emlyn restores part of St. George's Chapel.

1795. (Benjamin West, painter; Jarvis and Forest, painters on glass).

1796. James Wyatt, surveyor-general.

1815. (Sir Thomas Lawrence, painter).

1824. Sir Jeffry Wyatville, surveyor-general; (Sir Richard Westmacott, sculptor).

1840. Henry Ashton, architect.

The description of the plates is far from being so copious as we could wish, being confined principally to an account of the alterations made by Sir Jeffry Wyatville; but it is but fair that we should mention that Mr. Poynter is not responsible for this portion of the work. It is mentioned in describing the Round Tower, that Sir Jeffry being unwilling to disturb the associations of the spot, has provided holes in the stonework of the Castle for the jackdaws and starlings who build here in numbers, to form their nests in. They are for the most part invisible from below, except between the corbels of the battlements of the Keep. From the level of the road on the west side, to the top of the flags left of the Keep, is a total height of 203 feet, of which the Flag Tower is 25 feet, and the flag staff 50 feet; the diameter of the Keep is 102 feet.

On the Nature, Properties, and Applications of Steam, and on Steam Navigation. From the seventh edition of the Encyclopædia Britannica. By John Scott Russell, M.A., F.R.S.E. Edinburgh: Adam and Charles Black.

The volume before us comprises, in addition to the articles on the above subjects which are printed in the Encyclopædia, an historical account of the origin and progress of the art of steam navigation down to the year 1839, by the same author; besides the account of the locomotive steam-engine, from the Treatise on Railways by Lieutenant Lecount.

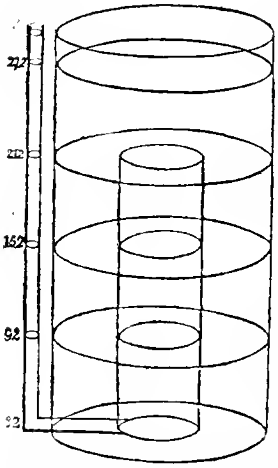
The present articles, STEAM and STEAM-ENGINE, in the Encyclopædia Britannica, are intended to contain all that was interesting and valuable in the original articles (written by Dr. Robison,) with Mr. Watt's notes, enriched by the results of subsequent labour and research; and it has been the author's aim, as he states in the preface to the present volume, "to add to all that Robison had originally said of

Watt's invention, what he would have required to add if he had lived to witness its present extended use, its multifarious applications, its varied forms, its modifications in material and construction* He has endeavoured to place before the reader, in a simple form, all the most important information which many years of research and of practical experience in a favourite subject have placed in his possession: and "the reader who is familiar with the subject will," he says, "readily discover that he has read and thought for himself, and that his errors, if many, are at least his own. In one point he trusts he has facilitated the progress of the student. While giving the general reasoning of complex calculations, he has endeavoured to disembarrass them as much as possible of that parade of calculus which exhibits the author at the expense of the reader; and rather to present their results in that simple form in which alone great truths present themselves to those who thoroughly understand them."

The plan of the work here laid down is in accordance with the nature of an Encyclopædia, which, being a work of a popular character, and a book of reference rather than instruction, many, if not the majority of its readers, moreover, being uninitiated in the arcana of abstruse mathematical science, and therefore willing to take for granted the truth of propositions, the demonstration of which they are unable to comprehend, should not be unnecessarily encumbered with complex and difficult calculations. It should, however, at the same time be borne in mind that some, and we trust we may say many, of the readers of the Encyclopædia are possessed of sufficient scientific knowledge to enable them to think and judge for themselves. Therefore, although the facts advanced should in general be such as are recognized by the best acknowledged authorities, and in support of which it suffices in most cases to cite the authority, yet, when any *new* proposition is enunciated, or any new doctrine propounded, it should be accompanied by a rigorous demonstration, or it must incur the risk of being rejected as unfounded. There are two instances in the work under review, in which we do not find the reasoning adequate to justify the conclusion; we allude to the determination of the *best vacuum* in the condenser of a steam engine, page 276, and of the best proportion of power to tonnage in sea-going vessels, page 288. We must, however, remark, in justice to the author, that we have seldom, if ever, met with a work so full of typographical errors, by which so much unnecessary labour is imposed on the reader, that many are deterred from attempting to make themselves masters of the author's meaning, and which are in some cases so serious as perhaps even to render the accomplishment of the task impossible. Some of the errors are of such a nature that it is difficult to decide whether they are to be ascribed to the author or to the printer.

The article STEAM, which occupies nearly the first half of the volume is on the whole a valuable contribution, particularly the second section, in which are collected together all the most recent experimental researches concerning the elastic force of steam at different temperatures, as well as the most esteemed of the earlier experiments, accompanied by figures of the apparatus employed.

In the first section, where the properties, phenomena, and application of steam are considered in a general manner, there is the following simple illustration of the doctrine of latent heat by Dr. Dalton, from which those who are not familiar with the operations of heat may form a tolerably correct notion of the phenomenon in question:



The liquid and its vapour may be considered as two reservoirs of caloric, capable of holding different quantities of that fluid. Let figure 1 represent to us such an arrangement; the internal cylinder of smaller capacity, the external one of enlarged capacity surrounding and extending far above it, and a small open tube of glass, communicating freely at the bottom with the internal cylinder. Let us now conceive water to be poured into the internal cylinder, the water will manifestly flow into the slender tube till it stand on the same level in the tube as in the cylinder. If any additional quantity be now poured into the internal cylinder, the rise of water in the slender glass tube will serve as an index of the quantity of added fluid; and when it is filled to the top, the fluid will stand at the height marked 212°, and will still be a correct index of the addition of fluid. But if more water be now added to it, it will not make its appearance in the slender tube, but will simply overflow from the internal cylinder over into that of enlarged capacity, so that, while a large quantity is passing into the vessel and gradually filling it up to 212°, no additional rise takes place until the whole of the outer cylinder becomes filled to that point, after which any further addition will again become sensible, by a corresponding rise in the tube. This process is in precise analogy to the succession of circumstances in heating a liquid, and converting it into steam. The internal cylinder represents the liquid, the external one the vapour of greater capacity, and the slender glass tube at the side the thermometer placed in communication with them. When heat flows into the liquid, it passes equally into the thermometer; and each increment of the one produces an equal increment in the other, until the liquid reaches the limit of its capacity, when it suddenly begins to enlarge its bulk and take the form of steam; but the quantity of heat required to fill up this enlarged capacity is so great, as to require about $5\frac{1}{2}$ times as much to fill it as was contained in the whole liquid before, so that all this time the thermometer is standing still, and it is not until the whole of the steam is thus supplied with 212° of caloric, that the thermometer will begin to show any further elevation; after which, any increment of heat thrown into the steam will make its appearance on the thermometer, and proceed as formerly, by simultaneous increments.

* The article on the Steam-engine is, we believe, published in a separate volume; but, as we have not yet seen it, we are unable to notice it in this month's Journal.—ED. C. E. & A. JOURNAL.

As a practical application of the influence of pressure on the boiling point of water, the following rule is given for finding the heights of mountains by boiling water:

Boil pure water in an open vessel at the bottom of the elevation, and observe on the thermometer the point at which it boils. Boil it again at the top of the mountain, and observe with the thermometer the point at which it now boils: the difference of temperature, multiplied by 530 feet, will give a close approximation to the height of the upper above the lower station.

This will give an approximation; but, if greater accuracy be required, it will further be necessary to correct for the difference of the temperature of the air at the two stations, in the following manner. Add the temperatures of the air at the stations, and subtract 64 from their sum, multiply the remainder by one thousandth part of the height found; and this will be the correction to be added to the height formerly found. The result thus found will still require a slight correction for the figure of the earth and latitude of the place; but this does not amount to more in our latitude than an addition of about two feet in a thousand, which forms a second correction.

To illustrate the mode of deducing heights from the boiling point, as we have given it, we take the following example.

Water boils on the top of Ben Nevis at 203·8°, while at the side of the Caledonian Canal it boils at 212°, the temperature being 30° on the summit of the mountain, and 35° below. In order to determine the height,

From 212°	
Take 203·8°	To 30°
	Add 35°
There remains 8·2°	
Multiply by 530	Sum 65°
	Subt. 64°
246·0	
410	Remain 1° mult. by 4·346
4346 first approx.	Latitude 56° nearly
4 first correct.	Mult. 4·350
	by 2·
4350 second approx.	
8·7 second correct.	8·700

Calc. height, 4358·7 third approximation.

4358· true measured height—the difference being less than 1 foot.

This method, however, is seldom susceptible of so high a degree of accuracy, even with the most carefully conducted experiments.

There is also a description with explanatory figures, of the elegant and compact apparatus contrived by the Rev. F. J. H. Wollaston for facilitating the procedure of taking the observations with the requisite precision.

Among the contents of the second section we may mention, as particularly worthy of notice, the abridged account of the experiments undertaken by the French Academy of Sciences, and conducted principally by the M. M. Arago and Dulong, having for its object the discovery of the relation existing between the temperature and elastic force of steam; and those conducted, with the same object, by the committee of the Franklin Institute of Pennsylvania, appointed to examine into the causes of the explosions of the boilers used on board of steam-boats, and to devise the most effectual means of preventing the accidents, or of diminishing the extent of their injurious effects. The former were completed in 1829, and are in every respect entitled to a larger share of confidence than the latter, as well on account of the greater perfection of the apparatus employed and the extraordinary care bestowed upon the manipulations, as the names of two philosophers so well versed in experiments of a similar nature.

In the 3rd section, *on the mathematical law which connects the elastic force of vapour with its temperature*, Mr. Russel has certainly laid before his readers a considerable collection of formulæ (15 in number) previously proposed by divers authors to represent that law, none of which are applicable but in a limited extent of the scale; but we are surprised to find that he has made no mention of that proposed by Mr. A. A. Mornay in the second volume of our Journal, page 200, which represents Dalton's experiments below 212°, and those of the French Academy up to 24 atmospheres, (beyond which they did not extend) within 2·45 degrees Fahr. at the latter limit, where a new formula, proposed by the author of the present work, gives a difference of 10·26 degrees.

In the reasoning through which he arrives at this formula, we rather suspect that Mr. Russell has fallen into the error he deprecates so much in his preface—that of *exhibiting the author at the expense of the reader*, though we think his *parade of calculus* only calculated to dazzle the *very* ignorant, without being intelligible to the mathematician. What, for instance, do the series α, β, γ, and the equations δ, ϵ, (page 113) signify? We confess they are above our comprehension, but perhaps some more profound mathematician might be able to explain their meaning, and to point out their connexion with the laws of temperature and pressure, mentioned in the previous part of the paragraph, and with each other. By some means, however, we are led to the equation, (page 116)

$$\frac{t+121}{333} = (1{\cdot}11401)^{\frac{\log F}{\log 2}}, \qquad \text{T}$$

which appears in an entirely different form from any other that has been published, but which differs in fact from Tredgold's only in the values of the constants; it is, indeed, when freed from logarithms, nothing more or less than the following:

$$F = \left(\frac{t+121}{333}\right)^{6{\cdot}42}.$$

Mr. Mornay's formula alluded to above, possesses this great advantage over the others, that it furnishes a very simple equation for finding the elastic force of steam in terms of its density alone, which is necessary in calculating the effect of steam used expansively in steam engines. Regarding the density of steam Mr. Russell has given no calculations at all, although, besides the formula just alluded to, one has been proposed by Mr. Navier, and a modification of it employed by the Count de Pambour in his *Theory of the Steam Engine*, published in 1839; but there is in the 4th section a very comprehensive table of the density of steam at different temperatures, by Gay-Lussac, as well as an engraving and description of the simple and elegant apparatus used by that philosopher, with his method of operating.

The 5th section, *on the application of our knowledge of the properties, phenomena, and laws of steam to practical and economical purposes*, is interesting as far as it goes; but, as we stated at the beginning of this notice, the most important application, the Steam Engine, is published in a separate volume.

The article STEAM NAVIGATION might, with greater propriety, be entitled "the Steam Navigation of Scotland and the United States," the share of that part of Great Britain called England being represented by the following paragraph:

"To the talent of Mr. Maudslay of London, the present marine engine owes the introduction of that high degree of precision in its construction and details, which gives it so much durability and efficacy as a machine."

From the tenor of this article it would appear that the author was utterly ignorant of the numerous steam boats with which the river Thames is studded at all hours of the day, and some of which vie in speed with the vaunted American steam boats, and that he knew of no steam vessels which navigate the ocean with other than Scotch engines. He does not say (is he ignorant of the fact?) that the Great Western, with Maudslay's engines, makes better passages to New York than the British Queen, with Napier's. The history of the progress and present condition of the art, as here traced, thus bears reference only to the two countries named above—Scotland and the United States; it is, however, as such, interesting enough, but would be rendered much more so, if combined with the history of the art in England.

The following paragraph in page 268, taken in conjunction with the omission of all mention of Maudslay's four cylinder engine, and with the description of Humphreys' trunk-engine, accompanied by a wood cut, in the preceding page, would corroborate the opinion that the author had but a very limited knowledge of the state of Steam Navigation in England.

For a like purpose, oscillating cylinders have been used with some measure of success. Rotatory engines have been unsuccessfully tried. The reader may now examine the vertical engines in the plates.

We believe the only trunk-engine yet made is that of the Dartford, which turned out a failure, while many steam boats now running on the Thames are fitted with oscillating engines, among which are some of the swiftest boats on the river.

We copy the following proof of the doctrine that *the vacuum in a condenser may be too good*, or rather that any improvement in the vacuum beyond a certain limit must be obtained at the expense of more fuel than it is worth; because it is not altogether without foundation, but, by reason of false notation, seems a tissue of absurdity and contradiction.

Let t = the caloric of water of 1°.
c = the constituent caloric of water in the state of steam.
e = the total force of steam in the boiler in inches of mercury;
and x = the elastic force of steam at the temperature of best condensation which we seek to discover.

Then from the law which connects the elastic force of steam with temperature, as already determined in our treatise on Steam, it follows, that in the case of maximum effect, or the temperature of best condensation,

$$\frac{t}{c} = \frac{x}{e} \text{ that is } x = \frac{e\,t}{c}$$

now $c = 1000$, and if the steam in the boiler be at 5 lb. above the atmosphere, or if $e = 40$ inches of mercury, and $t = 1$.

$$x = \frac{40}{1000} = 0{\cdot}04$$

Again, if the steam be at $7\frac{1}{2}$ lb. = 45 inches,

$$x = \frac{45}{1000} = 0{\cdot}045$$

Again, if the steam be at 10 lb. = 50 inches,

$$x = \frac{50}{1000} = 0{\cdot}05$$

Hence, we find that the best elasticity or temperature in the condenser depends on the elastic force of the steam in the boiler.

With steam of 5 lb. in the boiler, the elasticity of maximum effect in the condenser is at 93° of Fahrenheit, and the best vacuum in the barometer is 28. With steam of $7\frac{1}{2}$ lb. in the boiler, the elasticity of maximum effect in the condenser is 95° of Fahrenheit, and the best vacuum in the barometer is 27·8. With steam of 10 lb. in the boiler, the elasticity of maximum effect in the condenser is 97°, and the best vacuum in the barometer is 27·5. In like manner it would be found that with steam of 50 lb. in the boiler, worked expansively, as in Cornwall, the best vacuum in the condenser would be about 26° on the barometer.

Our first impression on reading this proof was that it was altogether fallacious, and, as the calculation was not supported by reasoning, it was not likely to convince us of the contrary; but, on consideration, it seeming probable that the general proposition was true, although Mr. Russell's equation was not the interpretation of a truth, we investigated the subject more closely, and found that this equation did not represent the author's own opinion, but that x ought to stand for the increment of elastic force due to the increment t of heat at the temperature of most advantageous condensation, that c ought to represent the total quantity of caloric required to evaporate water from that temperature, and not merely the amount of latent heat at 212°, and that e should express, not the total pressure in the boiler, but the mean effective pressure on the piston before the allowance for friction has been deducted. The equation should therefore stand thus, retaining x with the signification first assigned to it by Mr. Russell, and expressing by *dif.* x a very small difference of elastic force, and by *dif.* t the corresponding very small difference of temperature,

$$\frac{dif.\ x}{e} = \frac{dif.\ t}{c};$$

the explanation of which is as follows:

The first member expresses the ratio of an assumed small gain of power to the total power exerted by the steam, and the second member the ratio of the quantity of heat thereby abstracted from the feed water (which must be restored in the boiler at the expense of a proportionate quantity of fuel) to the total amount of heat requisite to convert it into steam, or, which is the same thing, the ratio of the extra fuel to the total quantity used. Now it is obvious that, if these two ratios are equal, that is, if the increase of power is in proportion to the increase in the consumption of fuel, there is no gain of duty, and, of course, if the second member were greater than the first, the result would be a diminution of duty.

If we make the small difference of temperature = 1°, as Mr. Russell has done, *dif.* x will express the increment of force due to an increment of 1° of temperature; and, if we suppose the best temperature of condensation to be 100°, we shall have $c = 112 + 1000 = 1112$, and the above equation may be put in the form,

$$dif.\ x = \frac{e}{1112}.$$

If the pressure in the boiler be about 5 lb. above the atmosphere, we shall not have a greater mean pressure than about 30 inches in the cylinder, in which case

$$dif.\ x = \frac{30}{1112} = 0{\cdot}027.$$

This is about the difference between the elastic force of steam at 72 and 73 degrees, according to Dr. Dalton's latest experiments, and the force at 73° is 0·95 inch; so that, when the mean pressure in the cylinder is 30 inches, and the barometer without stands at 29½ inches, the condenser barometer should mark 28·55 inches.

The calculation of the best proportion of power to tonnage (page 288) is so confused by errors (of the press?), that we have no leisure at present to wade through it.

The article on *the immediate Mechanism of Propulsion* is defective in as much as the Archimedean Screw Propeller is not so much as mentioned, and the author seems to have formed an erroneous idea of the principle of Morgan's Paddle Wheel, in consequence of a trifling resemblance which it bears to Oldham's Wheel. See the article *On Paddle Wheels* in the Appendix to the new edition of "Tredgold on the Steam Engine."

The Historical Sketch of Steam Locomotion, by Lieut. Lecount, forms an interesting appendix to the work, which on the whole contains much useful information on the subject of steam, perhaps more than is to be found combined in any other volume of its size, although we do not think it does full justice to its title, particularly in what regards Steam Navigation, as we have already observed.

ON WIERS OR DAMS ON RIVERS.

Observations on the Effect produced by erecting Weirs or Dams on Rivers, and on their efficacy for Navigation Purposes.

By William Bull, Civil Engineer.

Weirs are generally erected either for the purpose of raising a head of water for the use of mills, or for the purpose of navigating the channel of a river, and they cause in the first instance a permanent elevation of the ordinary surface of the water.

If a weir has the same length of top surface as the section of the river at the place where it is erected, it will cause such flood waters as would have been retained within the natural banks of the river, before it was erected, to rise above them in proportion to its height, and overflow the adjoining lands if artificial embankments of proportional height are not erected to prevent it.

When more water comes down the river than its banks could have previously held, then, although the weir causes an increase of height, the evil is less in proportion than in the former case.

In extreme floods, when the water would rise far above the surface of the valley, the small increase of height caused by the weir is of little or no consequence, as other causes generally exist, such as embanked roads leading to bridges, and the contraction of the stream by the bridges which obviates the effect of the weirs; unless the latter be situate at or close to the bridge.

Weirs cause the beds of rivers to rise by retaining the sand and gravel brought down by the stream, with much more rapidity than the adjoining lands rise from the deposit of lighter silt first in the upper portions of the rivers where they are erected, and ultimately throughout their course as far as the weirs extend, by which the sectional area of the rivers is diminished and of course the land adjoining rendered more subject to floods.

This is an evil that may be partially remedied by dredging and embanking. I say partially, because, from the manner in which the former is usually done, (*i.e.* only with a view to keep open a narrow channel in the river for the use of boats,) it has very little tendency to produce it, and if done to the whole extent of the river, would become a very expensive operation, and the latter, even when well executed at first, being constantly liable to delapidation, is for ever subjecting the lands to inundation. This is particularly illustrated in Holland, where the rivers, having been dammed up and embanked, have been permanently elevated above the adjoining lands, and where destructive inundations are by no means of rare occurrence.

Where no weirs exist, rivers have generally a tendency to deepen their beds (particularly if the water is confined to a channel of moderate width) from their source to their confluence with the sea, or until they arrive at an estuary or low flat track of land, when the sand and gravel or other material driven or borne down by the water, is either deposited in such estuaries or on bars at the river mouths, or is dispersed along the shores of the sea by the tidal wave.

I have observed many instances of the gradual lowering of the beds of rivers, but more particularly one which has recently come under my observation, where the out-fall of a mill-goit has been lowered two feet in about four years. This phenomenon is, of course, most obvious where the fall in the river is greatest, all other circumstances being equal.

By making a weir of greater length than the general section of the river, and by widening the river above and below the same, a part of the injury to adjoining lands by raising the surface of the water may certainly be avoided, so long as the river is continued of the increased width, and by extending the length of the weir and the widening of the river to a great or almost indefinite extent, both in line of the current as well as in width, the injury to adjoining lands may be nearly if not entirely obviated for a limited time, but it can only be for a limited time without constant care and attention, and a considerable periodical outlay, (much more of each than is usual or likely to be devoted to such purpose,) because, from the surface of the water being extended, the stream will become proportionally sluggish, particularly towards one or both sides, where, as well as in the natural bed of the river, the matter brought down by the stream will be deposited, and the river will again assume its original width or nearly so, and render the increased length of the weir of little or no avail. The time which will expire before the river assumes its original width will depend materially on the quantity of matter held in suspension by the water, or driven forward by the impetus of the stream, and on the velocity of the stream above and at the point where the weir is erected.

In such instances as where, for some distance before arriving at the weir, the fall and consequent velocity of the stream is of a moderate degree, and where the upper surface of the river has been enlarged, and thereby the velocity of the current diminished, there being only a light alluvial matter and sand held in suspension, or driven forward by the stream, such matter will be rapidly deposited on the sides of the river, until the sectional area is again so contracted as to increase the rapidity of the current to its original rate.

If, instead of the fall and velocity being of that moderate degree which will only carry forward the lighter matter, it is of such a degree as to force down gravel and other heavy matter, the length of the pond first caused by the erection of the weir will be gradually diminished, until the whole of the original bed of the river is filled up to the weir, so as to form the inclination of the new bed at nearly the same angle as it was before the weir was erected; but in this case the contraction of the stream to its original width will go on much more slowly than in the former case, arising from the filling up of the bed, causing the velocity of the stream to be reduced in a less ratio than it would have been if the heavier matter had not been brought down into the original bed of the river.

If the bed of the river is constantly dredged, so as to keep it of its original depth to the upper end of the pond formed by the weir, then the top surface will contract much more rapidly than in the last case, until it arrives at or approximates to its former width, as in the first case by reason of the heavy material being prevented by the dredging from raising the body of the stream so much as it would have done had no dredging been used, and the consequent less velocity of the stream allowing the lighter matter to be deposited at the sides.

From the foregoing observations it will follow that the increased length of the weir, and accompanying width of the river beyond its former dimensions, renders but a partial and temporary advantage, in diminishing the damage to adjoining lands arising from the erection of such weir, and that such erection, whether of greater length than the section of the river or not, does not in itself provide a permanent means of navigation.

Many instances of the inadequacy of weirs for supplying a permanent means of navigating natural rivers may, I have no doubt, be adduced. In the instance of the Calder and Hebble navigation, where I have been practically acquainted with the subject for the last eight years, they are abundantly manifest, as well as in the adjoining navigation of the Aire and Calder, with which I am well acquainted, the proprietors of both of which have been for many years adopting means to avoid the natural stream by substituting cuts or canals.

When first the River Calder was made navigable, it was divided into pools by weirs of sufficient height to give the required depth of water and these weirs were passed by means of locks; but it was soon found that the matter brought down by the stream was rapidly filling up the pools, and consequently diminishing the depth of water, whereby the navigation was much impeded; this was first most apparent at the upper ends of the pools, where the heavy materials, such as gravel and boulders, were first deposited on coming in contact with the comparatively still water produced by the weirs, and as the stream advanced, by deposit of the sand and lighter materials further down. At first recourse was had to remedy the evil by raising the weirs by means of boards, which were frequently washed away by the floods, and had to be renewed as the water subsided, and partly by raking the gravel and sand to the sides of the river. But as soon as the power of the dredging engine became known, recourse was had to it; it was, however, still found that although they had procured and kept in constant work two of these engines, the deposit was gaining on them; they therefore had recourse to the adoption of canals, as before stated, commencing with those parts which were the most affected by the deposit, until they now use only a little more than four miles out of a distance of twenty-two miles of the river. The Aire and Calder Company now use about nineteen miles out of forty-three, by having recourse to dredging, and raising their weirs by means of boards, as before described. That they, are enabled at present to navigate a greater proportion of the rivers than their neighbours, no doubt arises principally from the circumstance of their being situated further down the stream, and their being numerous weirs above, which retain the sand and gravel from coming down to them.

I cannot conclude these remarks better than by giving the result of my observation and experience, which is that converting natural rivers into artificial navigations by erecting dams across them, is much to be deprecated. First, because the dams cause the adjoining lands to be more frequently overflowed than they otherwise would be. Secondly, because dams obstruct the ordinary drainage of the country. Thirdly, because the object sought is but imperfectly obtained, and lastly, because it is the means of materially retarding, if not of entirely preventing, the adoption of the more efficient means of providing for inland navigation by artificial canals, which, if made at all, are rarely or never made so complete as they would have been had no attempt been made to adapt the natural rivers.

PROCEEDINGS OF SCIENTIFIC SOCIETIES.

INSTITUTION OF CIVIL ENGINEERS.

March 9.—The PRESIDENT in the Chair.

"*Description of the Arched Timber Viaducts on the Newcastle and North Shields Railway, erected from the designs of Messrs. John and Benjamin Green; and on the application of the same system of construction to oblique and other Bridges, to the Roofs of Railway Stations, and to other large Buildings.*" By Benjamin Green.

The construction of viaducts and bridges forms so important an item in the cost of a railway, that the engineer is induced to devise new methods of completing his works with due regard to stability and durability, and at the same time with the least possible expense. Stone and brick have been the materials most generally used for bridges; cast iron has been introduced where the heights were too low for the spans, in large arches, or in trussed beams where a certain clear space beneath was required, with only a limited height to the level of the rail. Timber, from its lightness, strength, and cheapness, has been extensively used, but only in spans of limited extent, owing to the sole mode of its application being by framed trusses, upon the same principles as those usually employed for roofing.

These considerations induced Mr. John Green, as far back as the year 1827, to make a design and model for a bridge, with timber arches resting upon stone piers. In 1833 the plan was adopted, and in 1837 it was put into execution at the Ouse Burn Viaduct, where the construction was of great extent, and the cost was an important consideration.

The Viaduct is 918 feet in length, and 108 feet in height from the bed of the river. There are five arches, the versed sine 33 feet, and the radius 68 feet; three of them are 116 feet span each, and two are 114 feet each: two stone arches of 40 feet span each have been introduced at each end to give length to the abutments, and to prevent the embankments from being brought too near to the steep sides of the ravine. The piers are of stone: the springing stones for the three ribs, of which each arch is composed, are on offsets, within 40 feet of the top of the piers; cast-iron sockets are there bedded in the masonry, and secured so as to receive the feet of the ribs. Two of the piers are placed upon piles; the others are founded upon the rock: immediately beneath the centre of one of them an old coal-pit shaft was discovered, and close adjoining to it the remains of the working of a coal seam: both were rendered secure by being filled up with grouted rubble masonry.

The ribs for the arches are composed of planks of Dantzic deal (Kyanized): the lengths vary from 46 feet to 20 feet, by 11 inches wide and 3 inches thick: they are so disposed, as that the first course of the rib is two whole deals in width, the next is one whole and two half deals, crossing the joints longitudinally as well as in the depth. Each rib consists of fourteen deals in thickness, bent over a centre to the required form, and secured together by oak treenails 1½ inch diameter at intervals of 4 feet apart, each treenail traversing three of the deals. A layer of strong brown paper dipped in boiling tar is placed between the joints, to bed them and exclude the wet. Trussed framings and beams are secured upon the arched ribs; the platform composed of planks, each 11 inches wide by 3 inches thick, is spiked down and covered with a composition of boiling tar and lime mixed with gravel in laying on, forming a coating impervious to the wet; upon this platform the two lines of railway are laid, leaving a foot-path between them.

The centreing for turning the ribs was very light and simple, and as every convenience was afforded by having a railway with travelling cranes along the sides of the piers, a whole centre could be moved by twenty men from one arch, and fixed in another in one day.

The author then describes the construction of the Wellington Viaduct, and that which has been erected by him at Dalkeith for the Duke of Buccleuch; giving the relative costs of the three structures which have been mentioned, and stone buildings of the same dimensions: whence it appears that in the Ouse Burn Viaduct there was an economy of £9000, resulting from the adoption of this system.

He then shows the application of this system to the structure of oblique bridges, particularly where a certain clear space is required beneath, and the total height is limited: this is illustrated by a description of a bridge of 71 feet span, on the Newcastle and North Shields Railway, which crosses the turnpike road at Walker, and by one erected over the River Wear on the West Durham Railway.

He describes also the application of the same system to the extensive buildings and sheds of the Shields Railway Station; to churches and to private houses: in the latter the arched form is very advantageous in gaining space for the upper rooms, showing at the same time the economy resulting from the adoption.

The paper is illustrated by a series of nine elaborate detailed drawings, showing the application to every kind of construction.

Mr. Rendel remarked, that on those railways where first cost was a matter of importance, the introduction of a superior kind of Timber Bridge was a great desideratum. The communication proposed the application of tarred paper between the joints, from experience he could not recommend either paper or felt in such situations. He found that both substances prevented the intimate contact of the surfaces of the timber; in all framings exposed to the action of the weather the tar was absorbed by the wood; the paper and felt then became saturated with and retained the moisture, so that decay very speedily ensued. The mode he at present adopted was to have all the joints and mortices of the framings very closely fitted, leaving only sufficient space at the edges to be caulked with oakum, and the joint run with pitch, like the seams of the deck of a vessel. Wherever it was practicable, great advantage would result from covering the joints with sheet lead, to exclude the moisture and prevent the decay, which was the great bar to the more general use of timber in many engineering works.

Mr. Vignoles was inclined to think the curve of the arch was too steep; he should prefer its being flatter. He would not then enter into the subject, but he would present to the Institution a large model of a Timber Bridge, and with it a communication, explaining his views on this subject, which was one to which he had paid much attention.

Mr. Macneil had found constant trouble to result from the decay of wooden bridges. The Dalmarnoch Bridge, which had been erected about thirty years, now demanded continual repairs; the struts were nearly all decayed at the points of insertion into the cast-iron sockets. The original floor had been replaced by one of teak wood.

In answer to a question from the President as to the process of "Kyanizing" timber for the Hull and Selby Railway, Mr. Timperley described the method pursued there. In a close cylindrical wrought-iron vessel, 70 feet long and 6 feet diameter, filled with a solution of corrosive sublimate, the timber was piled, leaving a space along each piece; the air was then exhausted by air-pumps to a vacuum of about 25 inches by the mercury gauge, and by the application of a force-pump, under a pressure of 100 lb. per square inch, the solution was driven into the pores of the timber. From experiments he had made he believed that the timber was thus thoroughly saturated, and although sufficient time had not elapsed to give any correct result as to the comparative duration of the sleepers, he thought very favourably of the process.

The original cost of the timber, which was the best Riga Balk, squared, was 5*l.* 10*s.* per load (50 cubic feet). The expense of "Kyanizing" about 400,000 cubic feet, including the interest of the first cost of the apparatus, was between fourpence and fivepence per cubic foot. The process was carried on with greater rapidity, and much more effectually, than it could have been done in open tanks.

Mr. Lowe was of opinion, that although the mechanical part of this process appeared very effective, it was not really so. There were chemical difficulties: a certain length of time was required to dilute and extract the sap and aqueous matter from the pores. The greater or less duration of the process might in some measure account for the difference of the results practically obtained. Dry planks succeeded better than wet ones; with sound dry timber any solution of the metallic salts, such as the sulphates of iron or copper, was efficacious, but with wet timber he doubted whether any preparation would be effectual.

Mr. Cooper believed that in the process of "Kyanizing" the chlorine united with the albumen, and formed chloride of albumen; it was possible that in the exhausting process the air contained in the timber would expand and prevent the capillary tubes from becoming perfectly saturated with the solution of corrosive sublimate.

March 16.—The PRESIDENT in the Chair.

John Hambley Humfrey was elected an Associate.

"*Description of the Methods adopted for raising and sustaining the sunken Roof of St. George's Church, Dublin.*" By Robert Mallet, Assoc. Inst. C. E.

St. George's parish Church, one of the finest ecclesiastical edifices in the city of Dublin, was completed in the year 1802, from the designs of the late Francis Johnston, Architect to the Board of Works at that time, at a cost of about £90,000.

The church had not been built many years, before the roof, which was covered with ton slating and copper, gradually sunk in several places, by which the cornices at the flank wall were pushed several inches outward. The subsidence slowly but continually increased. The ceiling cracked in various places, the ornamental stucco work began to drop off, and in the year 1836 the state of the roof was such, that the church was deemed unsafe for use, and was shut up.

Messrs. John and Robert Mallet were consulted as to the practicability of restoring the roof. In November, 1836, they reported that they considered the ceiling might be preserved, and described the manner in which they proposed to accomplish it.

The mode proposed consisted in interweaving with and adapting to the timber framing of the roof, a system of metallic framing, so arranged, that all strain or stress should be removed from the former, and borne by the latter, as well as removing all lateral pressure from the walls of the building.

A careful survey of the roof showed that the ends of several of the principals were unsound. A small hole was then bored through the ceiling, close to each queen-post, and a deal rod, ½ an inch square, dropped through each. These rods were all of equal length, and their upper ends were secured level with the top surface of the tye-beam of each principal; then with a levelling instrument placed in the gallery, observations were taken, and the exact amount of the deflection of the framing ascertained. The variation was considerable, but the greatest amount of depression was found to be 5¾ inches. The whole roof was strained and distorted, and was so unsafe that the slightest effort caused vibration throughout.

The causes of this failure appeared to be threefold: a radical want of strength in the framing of the roof; secondly, the employment of unfit tye-beams, which having been constructed during the Continental war, when timber was scarce and dear, were formed almost wholly of short lengths, averaging not more than 20 feet, lapped and scarfed; thirdly, in the queen-posts having been badly constructed and ill placed.

The stone corbels, which supported the oak cantilevers, being originally cut almost through to receive the wall-plate, were nearly all broken in the middle. It was proposed, therefore, to remove the oak cantilevers and stone corbels, and to cut away the timber wall-plate beneath each principal, to level up the wall, placing a suitable cast-iron abutment piece at each end, and to spring from side to side a cast-iron arch, in "double flitches," connected through the spaces of the timber framing by hollow distance pieces, and also by a certain number of equidistant cross-heads, from which should drop down vertical suspending rods, capable of being adjusted in length, and connected with the tye-beam of the principal, so that being drawn up straight, and the respective parts secured, the weight of the whole roof would be transferred through the framing to the tye-beams; whilst they being hung from the system of suspension rods of the cast-iron arches, which would thus sustain the whole load, and their abutments being held together by the tye-bars in the chord line, the load would bear vertically upon the walls.

It was then determined to raise the roof and ceiling by forces applied from below; to cut away the rotten ends of the principals and to reconnect them with the walls by a modification of the cantilever bracket, invented by Mr. Alfred Ainger, and described in the Transactions of the Society of Arts (vol. 42). The whole of the oak cantilevers and stone corbels were to be removed as useless incumbrances.

The total weight of the roof being about 133 tons, each framed principal would sustain about 16½ tons, and each vertical suspending rod about 1½ ton.

Although the weight of material in this roof and ceiling may be considered uniformly distributed, it was impossible to foresee what change might be effected in the framing by forcing the ceiling and roof up to a level line, or what amount of force might bear upon particular points, from the elasticity of the materials being thus forcibly constrained. It hence became a matter of prudence to provide in all parts a large surplus of strength, bearing in mind that, in any complete system, "the strength of the whole is limited by that of the weakest part, and thus that partial strength becomes total weakness." The dimensions of the scantling were accordingly so calculated that the utmost strain upon it should not exceed 4·5 tons per square inch, considering 9 tons to be the practical limit to which wrought iron might be exposed.

After giving the formulæ for calculating the strains upon the different parts of the roof, with the reasons why the theoretical dimensions were in some instances departed from, the author apologises for entering so much into detail of the construction, quoting at the same time the writings of Smeaton and Telford, as abounding in the richest details of theoretic deduction, modified by practical judgment. He then proceeds to describe the means adopted.

Immediately beneath each of the fourteen queen-posts of the roof, an aperture of 30 inches square was cut through the floor of the church, and a piece of brick and cement built up from the arches of the vaults beneath to the level of the floor; on the top of each, a plate of cast iron was bedded, and upon each plate a block of oak timber about 4 inches thick.

Fourteen straight whole balks of Memel timber, each 3 feet shorter than the height of the church between the floor and the ceiling, with their extremities cut square and smooth, were placed vertically upon the blocks; upon this level a platform was laid; across the tops of the vertical balks, pieces of oak scantling were placed; fourteen powerful screw-jacks were then fixed, one beneath each queen-post, and the ceiling cut away for the points to bear directly upon the beams.

During the progress of these operations, the whole of the ceiling and roof framing had been carefully examined. The dust was removed from the joints and open mortices, &c., of the framing, and the cracks in the ceiling were cleared out by passing a fine whip saw through them, so as to permit their closing when the ceiling was raised to a plane surface.

The preparations being completed, the word was given to heave simultaneously upon the screw-jacks; the roof rose slowly and steadily, and as soon as any one of the small deal standard rods had reached the level plane, the motion of the screw-jack at that spot was stopped. In about two hours, the whole roof, together with the ceiling, was brought up level, without any accident or injury to any portion of the ceiling. The cracks in the latter as well as the joints and mortices of the framing were found to be nearly all closed. Some slates were broken, and the copper of the platform, which before was wrinkled and loose, was now found to be drawn tight over the timber sheathing.

The roof being thus supported from beneath, the masonry was cut out round the ends of the principals; the oak cantilevers and corbels of granite, and the rotten ends of the timbers, within a few inches of the inside face of the walls, were also removed.

The cantilever and abutment castings were now applied and bedded with lead and oil putty, on blocks of stone set at the level of the under side of the tye-beams, on footings of brick and cement. The chord bars were next placed, and temporarily adjusted by means of their screw nuts. The arch segments were put up in succession, their centre or key pieces bolted in, and the segments adjusted to them by means of wedges of African oak: the suspending rods were then hung on from the top shackles, and the junction made good with the tye-beams, by means of the lower cross-heads, stirrups, and shackles.

As soon as the whole system of the seven arched frames was complete, and the cantilevers adjusted to the ends of the decayed timbers, standing lengths of pine rods were placed in right lines from centre to centre of each pair of abutment cross bolts, and all the chord bars and suspending rods were brought up by means of their adjustment screws, until the united effort of the whole system had lifted and supported the entire roof and ceiling from the screw-jacks, on which they had previously rested, so that these latter all became loose.

The whole was now left quiet for some days, in order that every part might take its bearing, and that the sufficiency of the structure should be proved before the final removal of the screw-jacks, &c., which remained within about ⅛ of an inch of the blocks beneath the tye-beams, by which means, in case of accident, the amount of fall would have been limited to that small distance. The entire work, including the repairing the cracks in the ceiling, occupied little more than four months, and has never since required either alteration or repair.

The total amount of the contract for this work was 1362*l.* 6*s.* The repair of the injury done to the ceiling only amounted to 33*l.* 0*s.* 8*d.*, and the damage done to the slating, platform, flooring, &c., did not amount to more than an equal sum.

The total amount of cast and wrought iron in the structure was 21 tons 10 cwt. 2 qrs. 19 lb.

The communication is illustrated by five elaborate drawings on a large scale, showing the general arrangement and modes of proceeding, and also the details of the construction of the roof and of the cast and wrought-iron works used in the repairs.

ROYAL INSTITUTE OF BRITISH ARCHITECTS.

July 5.—EARL DE GREY, President, in the Chair.

A paper was read by Professor Willis, of Cambridge, Hon. Mem. F.R.S. &c., *On the construction of the Vaulting of the Middle Ages.*

The vaulting of the Gothic architects differs essentially from that both of ancient and modern times, inasmuch as it consists of a combination of ribs, each forming an independent arch, both laterally and diagonally, with the intermediate spaces filled in upon the extrados of the arches to form the spandrils, whereas, according to the ordinary system of vaulting, the whole is solid and keyed together. The principles of this latter mode of construction were first developed by Philibert de l'Orme, who, in his celebrated treatise, lays down the rules for drawing the vaults and setting out the voussoirs —but of the practice of the Gothic architects we have no account, and it remains to be inferred from an examination of their works. That they proceeded by geometrical methods there can be no doubt, though they were probably extremely simple, differing greatly in that respect from those expounded by Philibert de l'Orme. One thing to be especially observed in the plain vaultings of the middle ages is, that all the curves are segments of circles, the diagonals being struck from a centre below the springing of the lateral and cross ribs, and are contrasted in this respect with diagonals projected from the direct arches, according to the rule familiar to every carpenter, from which it results that all the points of a groined vault coincide, and will be touched by a straight line drawn from one end of such a range of vaulting to the other. To this mode of setting out the curves may be attributed the flagrant want of character which is apt to distinguish the modern imitations of Gothic vaulting, and it may even be observed in original examples, that the effect is less pleasing as this coincidence is more nearly approached. This is the case with vaultings executed after the four-centered arch came into fashion, in which, although the curves may not be projected, yet there is an approach to greater regularity from the springing of all the ribs being brought to one level. During the Norman period the drawing of the vaults is very rude, and we find it to have been frequently necessary to back up the extrados of the ribs in order to bring the spandrils into shape. In the succeeding period of our architecture more care was indispensable, on account of the greater complication of mouldings converging together at the springing, and the free and sketchy manner in which they are managed, and the superfluous mouldings got rid of before they overload the impost, is much to be admired, and is greatly superior to the method pursued in the 15th century, when the coverging ribs were all brought down to the impost, and died away into a mere bundle of reeds, of which the effect is exceedingly tame and uncharacteristic. Previously to the introduction of the last style of gothic vaulting, *fan groining*, various complicated figures were formed by the introduction of numerous cross ribs, but the mode of construction continued to be the same. The vaulting immediately preceding fan groining, which may, in fact, be considered as a transition style, Professor Willis designated as *stellar* groining, from the star shapes which usually enter into its composition, and it is remarkable, that in some cases this form is lost in execution, although laid down on the plan, the architect apparently not having calculated on the effect of perspective, whereas, in others, the artist has evidently depended upon it in order to bring out his design. At length, in fan groining, the compartments become so numerous that the system of separate ribs is abandoned, and the vaults are constructed according to the ancient and modern principle of cut stone. Professor Willis accompanied his lecture by an extensive display of drawings and models, illustrative of the geometrical system upon which he supposed the Gothic architects to have worked in producing these results.

After the lecture the noble President presented to Mr. Hall the medal of the Institute, which had been awarded for his essay on iron roofs.

July 19.—R. Wallace, Esq., in the Chair.

Henry Gally Knight, Esq., was elected an honorary member.

Mr. Hall's essay on iron roofs, to which the medal of the Institute had been awarded, was read.

This was the closing meeting of the session.

CALOTYPE.

The following account of some recent improvements in photography, by H. F. Talbot. Esq., was lately read before the Royal Society.

The author had originally intended, in giving an account of his recent experiments in photography, to have entered into numerous details with respect to the phenomena observed; but finding that to follow out this plan would occupy a considerable time, he has thought that it would be best to put the Society, in the first place, in possession of the principal facts, and by so doing perhaps invite new observers into the field during the present favourable season for making experiments. He has, therefore, confined himself at present to a description of the improved photographic method, to which he has given the name of *Calotype*, and reserves for another occasion all remarks on the theory of the process. The following is the method of obtaining the Calotype pictures.

Preparation of the Paper.—Take a sheet of the best writing paper, having a smooth surface and a close and even texture. The watermark, if any, should be cut off, lest it should injure the appearance of the picture. Dissolve 100 grains of crystallized nitrate of silver in six ounces of distilled water. Wash the paper with this solution, with a soft brush, on one side, and put a mark on that side whereby to know it again. Dry the paper cautiously at a distant fire, or else let it dry spontaneously in a dark room. When dry, or nearly so, dip it into a solution of iodide of potassium containing 500 grains of that salt dissolved in one pint of water, and let it stay two or three minutes in this solution. Then dip it into a vessel of water, dry it lightly with blotting-paper, and finish drying it at a fire, which will not injure it even if held pretty near; or else it may be left to dry spontaneously. All this is best done in the evening by candle-light. The paper so far prepared the author calls *iodized paper*, because it has a uniform pale yellow coating of iodide of silver. It is scarcely sensitive to light, but, nevertheless, it ought to be kept in a portfolio or a drawer, until wanted for use. It may be kept for any length of time without spoiling or undergoing any change, if protected from the light. This is the first part of the preparation of Calotype paper, and may be performed at any time. The remaining part is best deferred until shortly before the paper is wanted for use. When that time is arrived, take a sheet of the iodized paper and wash it with a liquid prepared in the following manner:—Dissolve 100 grains of crystallized nitrate of silver in two ounces of distilled water; add to this solution one-sixth of its volume of strong acetic acid. Let this mixture be called A. Make a saturated solution of crystallized gallic acid in cold distilled water. The quantity dissolved is very small. Call this solution B. When a sheet of paper is wanted for use, mix together the liquids A and B in equal volumes, but only mix a small quantity of them at a time, because the mixture does not keep long without spoiling. I shall call this mixture the *gallo-nitrate of silver*. Then take a sheet of iodized paper and wash it over with this gallo-nitrate of silver, with a soft brush, taking care to wash it on the side which has been previously marked. This operation should be performed by candle-light. Let the paper rest half a minute, and then dip it into water. Then dry it lightly with blotting-paper, and finally dry it cautiously at a fire, holding it at a considerable distance therefrom. When dry, the paper is fit for use. The author has named the paper thus prepared *calotype paper*, on account of its great utility in obtaining the pictures of objects with the camera obscura. If this paper be kept in a press it will often retain its qualities in perfection for three months or more, being ready for use at any moment; but this is not uniformly the case, and the author therefore recommends that it should be used in a few hours after it has been prepared. If it is used immediately, the last drying may be dispensed with, and the paper may be used moist. Instead of employing a solution of crystallized gallic acid for the liquid B, the tincture of galls diluted with water may be used, but he does not think the results are altogether so satisfactory.

Use of the Paper.—The Calotype paper is sensitive to light in an extraordinary degree, which transcends a hundred times or more that of any kind of photographic paper hitherto described. This may be made manifest by the following experiment:—Take a piece of this paper, and having covered half of it, expose the other half to daylight for the space of *one second* in dark cloudy weather in winter. This brief moment suffices to produce a strong impression upon the paper. But the impression is latent and invisible, and its existence would not be suspected by any one who was not forewarned of it by previous experiments. The method of causing the impression to become visible is extremely simple. It consists in washing the paper once more with the gallo-nitrate of silver prepared in the way above described, and then warming it gently before the fire. In a few seconds the part of the paper upon which the light has acted begins to darken, and finally grows entirely black, while the other part of the paper retains its whiteness. Even a weaker impression than this may be brought out by repeating the wash of gallo-nitrate of silver, and again warming the paper. On the other hand, a stronger impression does not require the warming of the paper, for a wash of the gallo-nitrate suffices to make it visible, without heat, in the course of a minute or two. A very remarkable proof of the sensitiveness of the calotype paper is afforded by the fact stated by the author, that it will take an impression from simple moonlight, not concentrated by a lens. If a leaf is laid upon a sheet of the paper, an image of it may be obtained in this way in from a quarter to half an hour. This paper being possessed of so high a degree of sensitiveness, is therefore well suited to receive images in the camera obscura. If the aperture of the object-lens is one inch, and the focal length fifteen inches, the author finds that *one minute* is amply sufficient in summer to impress a strong image upon the paper of any building upon which the sun is shining. When the aperture amounts to one-third of the focal length, and the object is very white, as a plaster bust, &c., it appears to him that *one second* is sufficient to obtain a pretty good image of it. The images thus received upon the Calotype paper are for the most part invisible impressions. They may be made visible by the process already related, namely, by washing them with the gallo-nitrate of silver, and then warming the paper. When the paper is quite blank, as is generally the case, it is a highly curious and beautiful phenomenon to see the spontaneous commencement of the picture, first tracing out the stronger outlines, and then gradually filling up all the numerous and complicated details. The artist should watch the picture as it developes itself, and when in his judgment it has attained the greatest degree of strength and clearness, he should stop further progress by washing it with the fixing liquid.

The fixing process.—To fix the picture, it should be first washed with water, then lightly dried with blotting paper, and then washed with a solution of bromide of potassium, containing 100 grains of that salt dissolved in eight or ten ounces of water. After a minute or two it should be again dipped in water and then finally dried. The picture is in this manner very strongly fixed, and with this great advantage, that it remains transparent, and that, therefore, there is no difficulty in obtaining a copy from it. The calotype picture is a negative one, in which the lights of nature are represented by shades; but the copies are positive, having the lights conformable to nature. They also represent the objects in their natural position with respect to right and left. The copies may be made upon Calotype paper in a very short time, the invisible impressions being brought out in the way already described. But the author prefers to make the copies upon photographic paper prepared in the way which he originally described in a memoir read to the Royal Society in February 1839, and which is made by washing the best writing paper, first with a weak solution of common salt, and next with a solution of nitrate of silver. Although it takes a much longer time to obtain a copy upon this paper, yet, when obtained, the tints appear more harmonious and pleasing to the eye; it requires in general from three minutes to thirty minutes of sunshine, according to circumstances, to obtain a good copy on this sort of photographic paper. The copy should be washed and dried, and the fixing process (which may be deferred to a subsequent day) is the same as that already mentioned. The copies are made by placing the picture upon the photographic paper, with a board below and a sheet of glass above, and pressing the papers into close contact by means of screws or otherwise. After a calotype picture has furnished several copies, it sometimes grows faint, and no more good copies can then be made from it. But these pictures possess the beautiful and extraordinary property of being susceptible of revival. In order to revive them and restore their original appearance, it is only necessary to wash them again by candle-light with gallo-nitrate of silver, and warm them; this causes all the shades of the picture to darken greatly, while the white parts remain unaffected. The shaded parts of the picture thus acquire an opacity which gives a renewed spirit and life to the copies, of which a second series may now be taken, extending often to a very considerable number. In reviving the picture it sometimes happens that various details make their appearance which had not before been seen, having been latent all the time, yet nevertheless not destroyed by their long exposure to sunshine. The author terminates these observations by stating a few experiments calculated to render the mode of action of the sensitive paper more familiar. 1. Wash a piece of the iodized paper with the gallo-nitrate; expose it to daylight for a second or two, and then withdraw it. The paper will soon begin to darken spontaneously, and will grow quite black. 2. The same as before, but let the paper be warmed. The blackening will be more rapid in consequence of the warmth. 3. Put a large drop of the gallo-nitrate on one part of the paper, and moisten another part of it more sparingly, then leave it exposed to a very faint daylight; it will be found that the lesser quantity produces the greater effect in darkening the paper; and in general, it will be seen that the most rapid darkening takes place at the moment when the paper becomes nearly dry; also, if only a portion of the paper is moistened, it will be observed that the edges or boundaries of the moistened part are more acted on by light than any other part of the surface. 4. If the paper, after being moistened with the gallo-nitrate, is washed with water and dried, a slight exposure to daylight no longer suffices to produce so much discoloration; indeed it often produces none at all. But by subsequently washing it again with the gallo-nitrate and warming it, the same degree of discoloration is developed as in the other case (experiments 1 and 2). The dry paper appears, therefore, to be equal, or superior in sensitiveness to the moist; only with this difference, that it receives a virtual instead of an actual impression from the light, which it requires a subsequent process to develope.

Plaster Ornaments.—The late Mr. Bernasconi was engaged, we believe, to a greater extent than any other ornamental plasterer of the present century, under all the leading architects of the day. We were lately induced to pay a visit to his former scene of business, in Alfred Street, Tottenham Court Road, now in possession of Mr. Brown, his son-in-law, who has lately arranged the numerous ornaments bequeathed him by the late possesor. They are well deserving of a visit by the architect; here he will find Grecian, Roman, Gothic, Elizabethan, the Renaissance, Arabesque, and almost every other style of ornaments that have been introduced at Windsor Castle, Buckingham Palace, Pavilion Brighton, Stafford House, Westminster Abbey, Fonthill, Woburn Abbey, York Minster, Ely Cathedral, and numerous other public buildings and mansions throughout the United Kingdom.

MISCELLANEA.

WESTMINSTER BRIDGE.

On Thursday, 15th ult., the water was admitted into the coffre-dam inclosing the 15th and 16th piers, and the next day a commencement was made in removing the clay preparatory to drawing the piles. It is intended to open two arches for navigation before any further steps are taken with the next dam, which is to enclose one pier only. A deep water channel is now in progress of being made on the north side of the river, in line with the two arches about to be opened, by a steam dredging engine, for the use of navigation. The present neglected state of the river not only interferes most injuriously with the interests of those who navigate it, but causes the velocity of the current at the latter part of the ebb to be greater than is consistent with safety to the number of small boats and inexperienced persons frequenting the river at this season of the year. It is, therefore, a consummation much to be desired, that a subject so important to the welfare of this great metropolis should receive the attention it deserves, and that the city authorities, aided by government, will yet be able to carry into effect either their former scheme of embanking the river to a more regular line, or some modification of this plan by which the present evils may be removed, so that this noble river may again be restored to its former usefulness.

OPENINGS OF RAILWAYS.

The thirtieth of June witnessed a great extension of the Great Western Railway, as on that day the main line was opened from Chippenham to Bath, 13 miles, the Cheltenham and Great Western to Cirencester, and the Bristol and Exeter from Bristol to Bridgewater, 33 miles. Thus the Great Western Railway is opened throughout 118¼ miles, and there is a continuous line of railway communication from London to Bridgewater of 152 miles in length.

On the 5th of July 28½ miles of the Brighton line were opened, being from the Croydon Junction to Hayward's Heath, and 5 miles from Clayton Tunnel to Brighton, a measure which augurs well for the successful opening of the remainder.

The extension of the Blackwall railway to Fenchurch Street was to take place about the period of our publication, so that all the metropolitan railways would thus be complete at their London termini.

The unfortunate accident to the Fareham tunnel on the Gosport branch of the South Western Railway, has unfortunately delayed the opening of that line, just when it was on the point of being examined by the Government inspector.

GREENWICH RAILWAY.

Amounts of the tenders delivered on the 6th ult. for the fourth contract for widening the Greenwich Railway from the Croydon Junction.

Messrs. Lee	15.825
Mr. Munday	15.990
Messrs. Little	16.189
Mr. Grimsdell	16.536
Messrs. Ward	16.698
Mr. Bennett	16.920
Messrs. Piper	16.920
„ Grissell & Peto	17.280
„ Baker	17.440

THE "PRINCESS ROYAL" STEAMER.

This splendid vessel, which appears to surpass the speed of any other in the north, is now running between Liverpool and Glasgow, and has made several successful trips; she performed a trip from Dublin to Liverpool in 9 hours, and another trip on the 9th ult. from Greenock to Liverpool in 15½ hours, the quickest passage on record, the distance is 227½ miles; she carried at the time 100 tons actual weight. Both the vessel and engines were built by Messrs. Tod & Macgregor of the Clyde Foundry, Glasgow the former is of the following dimensions, viz., 185 feet keel and 208 feet on deck, 28 feet beam, and 17 feet hold above the flooring, draws when light 8 feet, and when full 10 feet of water; her register is 750 tons (N.M.). She is entirely built of iron, (there is not a single beam of wood,) very strong, and has a fine appearance in the water, her cabins are very richly and tastefully fitted up. The vessel is propelled by two steeple or upright engines of 190 horse power *each*, or 380 together; the power is applied direct to the crank. Diameter of cylinders is 73 inches, length of stroke 6 ft 3 in., performs 18 strokes per minute when in good trim, and 17 strokes with from 100 to 120 tons of cargo, diameter of paddle-wheel over floats 29 feet length of float 7 ft. 9 in., and breadth 28 inches, speed in still water 15 miles per hour.

Launch of the Devastation War Steam-vessel—The launch of this first-class war steam-vessel took place at Woolwich, on Saturday, 3rd ult. Mr. Lang, master shipwright, superintended the launch; she was immediately after hauled into the dock, opposite the blacksmith's workshop, where she will be coppered, and will be afterwards taken into the basin to have her engines fitted and made ready for sea. The Devastation is about 189 feet long, and about 1,050 tons burden, old measurement, or about 1,000 tons burden according to the new mode of calculation.

The Cadogan Chain Pier, Chelsea.—Earl Cadogan, the lord of the manor, has erected a handsome and convenient pier for steam-boat passengers on a novel construction, at an expense of between £3,000 and £4,000. This erection was constructed by Mr. Cubitt, from the design and under the direction of Mr. Handford, the surveyor and architect of the manor. The pier is situated in the mall of Cheyné-walk, the most beautiful part of Chelsea, and forms one of the most interesting objects of the place. Shortly the pier will be open to the public.

Professor Wagner's Electro-Magnetic Engine.—The German journals publish the following extract from a protocol drawn up by the Germanic Diet.—"The Germanic confederation desiring to acquire, for the purpose of publishing for the public good, the secret by means of which citizen Philip Wagner, of Frankfort, makes use of electro-magnetism as a moving force, will secure to the said Wagner for the exclusive possession of his secret the sum of 100,000 florins (£8,000 British), on condition that he cause an electro-magnetic machine to be constructed at his own expense, and upon a sufficiently large scale, to serve as a locomotive; that a trial be made of this machine, in order that the diet be assured of its efficacy; and that M. Wagner consented to abide by the decision of the Diet on that trial. The Diet will wait for one month for M. Wagner to accept those conditions.

Land-slip at Sidmouth.—A land-slip of considerable extent took place at Sidmouth on the 11th ult., about seven in the evening. It commenced about half-past six by a rumbling noise, resembling a distant peal of thunder, and at seven o'clock part of the Peak Hill was observed to glide towards the ocean, carrying everything before it, and forming a rock or pillar out of the sea (70 feet high and 175 feet in circumference), opposite to the town, and a quarter of a mile from the shore. It is covered with fossils, and is of a hard iron-like substance. So singular an occurrence has attracted the attention of every one in the town, and hundreds are flocking from the immediate neighbourhood to gain a sight of its results.—*Dorset Chronicle.*

The Dissolving Views at the Royal Polytechnic Institution.—The directors of this scientific institution, ever seeking to combine amusement with instruction, have recently added to their numerous attractions an entirely new series of displayed [illegible] by Messrs. Wrench & Smith, which, for selection of subjects and the [illegible] feeling with which they are treated, may be considered unquestionably the best of the kind hitherto exhibited; there are sixteen in number, and if we may judge from the gratification evinced by the numerous company who attend upon each occasion that these beautiful views are shown, the spirited proprietors cannot but congratulate themselves upon having secured such to an exhibition, which is [illegible] must doubtless become an increasing attraction to this institution.

LIST OF NEW PATENTS.

GRANTED IN ENGLAND FROM 28TH JUNE, TO 28TH JULY, 1841.

Six Months allowed for Enrolment.

John Chater, of the Town of Nottingham, machine-maker, and Richard Gray, of the same place, lace manufacturer, for "*improvements in machinery for the purpose of making lace and other fabrics, traversed, looped, or woven.*"—Sealed June 26.

Willoughby Methley and Thomas Charles Methley, of Frith-street, Soho, ironmongers, for "*improvements in machinery for raising, lowering, and moving bodies or weights.*" (A communication.)—June 26.

Moses Poole, of Lincoln's-inn, gentleman, for "*improvements in producing and applying heat.*" (A communication.)—June 26.

William Losh, of Little Benton, Northumberland, Esq., for "*improvements in the manufacture of railway wheels.*"—June 26.

Nathaniel Benjamin, of Camberwell, gentleman, for "*improvements in the manufacture of type.*" (A communication.)—June 28.

William Knight, of Durham-street, Strand, gentleman, for "*an indicator for registering the number of passengers using an omnibus or other passenger vehicles.*"—June 28.

Christopher Nickels, of York-road, Lambeth, gentleman, for "*improvements in the manufacture of mattresses, cushions, paddings or stuffings; and in carpets, rugs, or other napped fabrics.*"—June 28.

William Thomas Berger, of Upper Homerton, gentleman, for "*improvements in the manufacture of starch.*"—June 28.

Thomas Marchell, of Soho-square, surgeon, for "*improvements in raising and conveying water and other fluids.*"—June 28.

George Henry Phipps, of Deptford, engineer, for "*improvements in the construction of wheels for railway and other carriages.*"—July 2.

Thomas Hagen, of Kensington, brewer, for "*an improved bagatelle board.*"—July 7.

George Onions, of High-street, Shoreditch, engineer, for "*improved wheels and rails for railroad purposes.*"—July 7.

Robert Mallet, of Dublin, engineer, for "*certain improvements in protecting cast and wrought iron and steel, and other metals, from corrosion and oxidation; and in preventing the fouling of iron ships, or ships sheathed with iron, or other ships or iron buoys, in fresh or sea water.*"—July 7.

William Edward Newton, of Chancery-lane, civil engineer, for "*certain improvements in the manufacture of fuel.*" (A communication.)—July 7.

Thomas Fuller, of Bath, coachmaker, for "*certain improvements in retarding the progress of carriages under certain circumstances.*"—July 7.

Andrew M'Nab, of Paisley, North Britain, engineer, for "*an improvement or improvements in the making or construction of meters or apparatus for measuring water or other fluids.*"—July 7.

Charles Wheatstone, of Conduit-street, gentleman, for "*improvements in producing, regulating, and applying electric currents.*"—July 7.

John Steward, of Wolverhampton, Esq., for "*certain improvements in the construction of piano fortes.*"—July 7.

Thomas Young, of Queen-street, London, merchant, for "*improvements in lamps.*"—July 9.

Charles Payne, of South Lambeth, chemist, for "*improvements in preserving vegetable matters where metallic and earthy solutions are employed.*" July 9.

William Henry Phillips, of Manchester-street, Manchester-square, civil engineer; and David Hichinbotham, of the same place, gentleman, for "*certain improvements in the construction of the chimneys, flues, and air tubes, with the stoves, and other apparatus connected therewith, for the purpose of preventing the escape of smoke into apartments, and for warming and ventilating buildings.*"—July 13.

Benjamin Beale, of East Greenwich, engineer, for "*certain improvements in engines, to be worked by steam, water, gas, or vapours.*"—July 13.

Moses Poole, of Lincoln's-inn, gentleman, for "*improvements of steam baths, and other baths.*" (A communication.)—July 13.

Miles Berry, of Chancery-lane, civil engineer, for "*improvements in the construction of locks, latches, or such kind of fastenings for doors and gates, and other purposes to which they may be applicable.*" (A communication.)—July 14.

Thomas Peckston, of Arundel-street, Strand, Bachelor of Arts, and Philip Le Capelain, of the same place, coppersmith, for "*certain improvements in meters for measuring gas, and other aeriform fluids.*"—July 15.

Andrew Smith, of Belper, Derby, engineer, for "*certain improvements in the arrangement and construction of engines, to be worked by the force of steam, or other fluids; which improved engines are also applicable to the raising of water and other liquids.*"—July 21.

John M'Bride, manager of the Nursery Spinning Mills, Hutchisontown, Glasgow, for "*certain improvements in the machinery and apparatus for dressing and weaving cotton, silk, flax, wool, and other fibrous substances.*"—July 21; four months.

John White Welch, of Austin-Friars, merchant, for "*an improved reverberatory furnace to be used in the smelting of copper ore, or other ores which are or may be smelted in reverberatory furnaces.*"—July 21.

Frederick Theodore Philippi, of Belfield-hall, calico-printer, for "*certain improvements in the production of sal ammoniac, and in the purification of gas for illuminations.*" (A communication.)—July 21.

William Ward Andrews, of Wolverhampton, ironmonger, for "*an improved coffee pot.*"—July 21.

William Newton, of Chancery-lane, civil engineer, for "*certain improvements in machinery for making pins and pin nails.*" (A communication.)—July 28.

Anthony Bernhard Von Rathen, of Kingston-upon-Hull, engineer, for "*improvements in high-pressure and other steam-boilers, combined with a new mode or principle of supplying them with water.*"—July 28.

Anthony Bernhard Von Rathen, of Kingston-upon-Hull, engineer, for "*a new method or methods* (called by the inventor, 'The United Stationary and Locomotive System') *of propelling locomotive carriages on railroads and common roads, and vessels on rivers and canals, by the application of a power produced or obtained by means of machinery and apparatus unconnected with the carriages and vessels to be propelled.*"—July 28.

ERRATA.

Sir—In my communication on "*Slopes in Sidelong Ground,*" in this month's (July) Journal, page 220, you will find the following misprints, which you will perhaps have the kindness to notice in your next publication.

For $(w \tan \beta - F L) = C F$, read $(w \tan \beta + h) = C F$.

For $C D = (w \tan \beta + h) \frac{\sin C F D}{\sin C E F}$, read $C D = (w \tan \beta + h) \frac{\sin C F D}{\sin C D F}$.

For $C E = (w \tan \beta + h) \frac{\sin C F D}{\sin C D F}$, read $C E = (w \tan \beta + h) \frac{\sin C F D}{\sin C E F}$.

For "therefore the angle $C D F$ will be constant," read "therefore the angle $C F D$ will be constant."

W. R.

In the review of Windsor Castle the following errors of the reviewer were passed unobserved until after the article had gone to press.

Page 278, col. 2, for Edward *the Third* called the Confessor, read Edward *the Confessor*.

In the 2nd paragraph, for Henry *III* read Henry *I*.

Page 279, col. 1, 3 lines from the bottom, for Henry 7 read Sir Reginald Bray. And in the last line, for *his* read *Henry VII*.

TO CORRESPONDENTS.

Mr Barrett's *and* Mr. Brooks' *communications must stand over until next month; also the communications from* S. L. *and* D. C. *We must beg of our correspondents to excuse us in postponing any articles of controversy.*

"A clear fire." *In our opinion his scheme is not practicable.*

"On the forms and proportions of steam vessels," *was received as we were going to press; it will appear next month.*

Two communications on long and short connecting rods are in type, but must stand over until next month for want of space.

Communications are requested to be addressed to "The Editor of the Civil Engineer and Architect's Journal," *No. 11, Parliament Street, Westminster.*

Books for Review must be sent early in the month, communications on or before the 20th (if with drawings, earlier), and advertisements on or before the 25th instant.

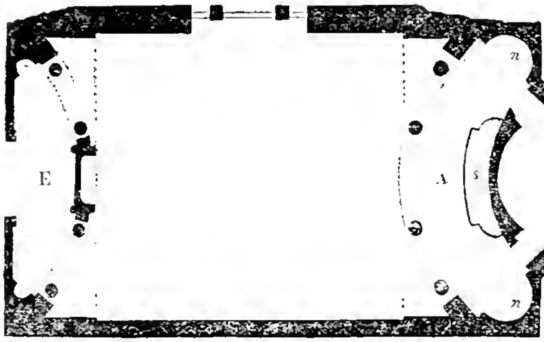
Vols. I, II, and III, may be had, bound in cloth, price £1 each Volume.

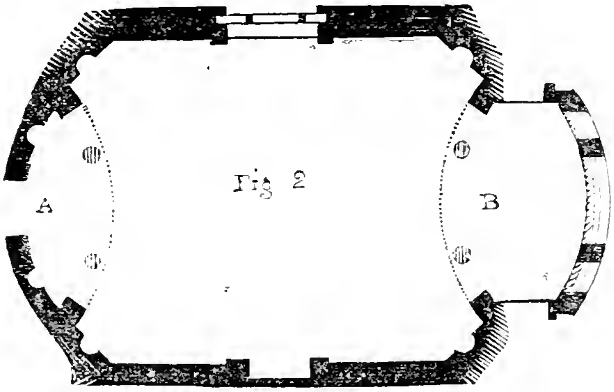
EPISODES OF PLAN.

(Continued from page 143.)

We should be less embarrassed by the extent and complexity of our subject, could we command an unlimited number of cuts to illustrate it; but being under the necessity of observing economy in that respect, and to confine ourselves to *floor-plans* alone, without attempting to show anything further, we experience no little difficulty in determining what sketches to give in preference, out of the ample stock of our materials. Under such circumstances it will perhaps be expected that we should select such as bear the least resemblance to each other; yet, by so doing, we could not show how the same leading idea may, by some slight modification of it, be so altered as to produce a room of quite different character. Which last consideration induces us to give a second plan for a dining-room, bearing a strong resemblance to the preceding one in its general shape and arrangement, yet greatly varied from it with respect to many other circumstances. Therefore, in order that the two may be more conveniently compared together, we will here again introduce the first one, which was but indifferently printed when originally given.

Fig. 1.



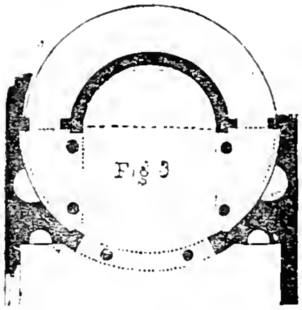


Owing to the peculiarity or singularity of both these ideas, the resemblance between them will probably be thought far more striking than the difference, since the second one also shows a room whose ends are convex in plan, and which is otherwise very similarly arranged. The situation here given to the fire-place would be in itself too trifling a variation to call for notice, were it not that it materially alters the character of the whole, by leaving the entrance recess entirely open to the room; and in consequence, the elevation of that end becomes precisely similar to the opposite one, each of them presenting three open intercolumns, formed in this instance merely by a distyle in antis, consequently with two columns less than in the other plan. A more important distinction is that in this second plan the corners of the room are cut off, whereby not only is the somewhat objectionable sharpness of the angles, occasioned in the other instance by the curved ends being brought up to the side walls, avoided, but the proportion which the end elevation bears to the entire breadth of the apartment is also altered. Besides which, four niches, placed diagonally on the plan, are thus obtained, where they would seem to come in with great propriety—conspicuously, but not obtrusively; on the contrary, where they are in some measure required in order to fill up, and give importance to those spaces. For the last assigned reason, niches are likewise introduced into the entrance recess A.

Should it be made an objection that in consequence of its forming two intersecting curves in its plan, the part A would either occasion much space to be lost, or render it difficult to connect this apartment with an adjoining one, it may be got over by converting the curved wall in which the door is placed into a flat one. Such alteration would still leave the rest of the design just the same as before; nevertheless its character would in some degree be affected by it, and that for the worse, if only because the uniformity now kept up, by the smaller recess A being curved both ways similarly to the larger one B, would then be destroyed. How far the circumstance here noticed would create difficulty by interfering too much with the general plan of the house, must depend upon what would be altogether foreign from our present purpose to take into consideration; our object here being merely to suggest new ideas, and bring forward episodical portions of a plan, not to adapt them to plans in general. We leave the particular application of them to others, leaving also those who may care to adopt any of our hints to adapt and modify them accordingly as circumstances may require; for what would be found eligible and convenient enough in one case, would prove exactly the contrary in another A remark to the same effect has, we find, already been made by us, nevertheless it is one that will very well bear to be repeated, as it is likely to be forgotten by others, though it is highly important that it should be constantly borne in mind by our readers.

The sideboard alcove B does not call for much explanation or comment, we shall therefore confine ourselves to saying that the same accommodation is here afforded as in the first plan, namely an entrance into it for servants. Though two doors are shown, one of them would be sufficient for the purpose, and the other might either be a sham one, or should the plan allow of its being done, might be made to lead to a strong closet for containing the more valuable articles of plate, and also a small retiring closet, &c. The window in this alcove is supposed to be at a considerable height from the floor—eight or nine feet—as the sideboard would be placed beneath it; and it is intended merely to obtain some light from a back court or area, for which reason it should have coloured or ground glass, but merely of such hue as would be sufficient to correct rawness of effect, and throw a sunshiny glow into that end of the room. Though it is differently represented in the cut (fig. 2), it would perhaps be better to confine this window to what now forms its centre compartment (corresponding in breadth with the centre intercolumn of the alcove), treating it as an oblong transparent panel, slightly sunk in the upper part of the wall.

We will now submit another idea professing to be no more than a variation of the alcove capable of being adapted to either of the preceding plans; for which reason it is unnecessary to show the whole of the room in the cut.



In this instance the alcove is greatly extended as to depth, more especially as compared with that in fig. 1, from which, indeed, it is altogether dissimilar, because there not only is the recess considerably shallower, but its back wall is curved convexly, and concentrically with the elevation towards the room. At the same time it resembles fig. 1, in so far as it occupies the entire width of the room; but then again, such resemblance is attended with a very material difference, inasmuch as in fig. 3, the alcove is more enclosed, so that it seems to expand itself within, as viewed through the external columns. The same may be said of it, if it be compared with fig. 2, that being a simple recess merely divided off from the room by columns, and no wider within than its opening towards the room.

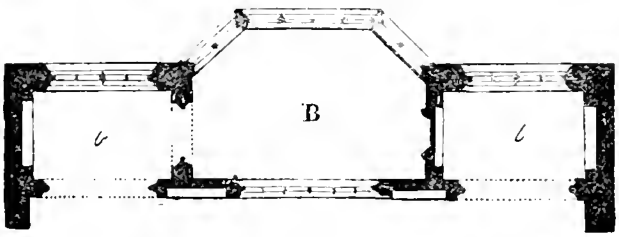
Fig. 3, on the contrary, affords an example of what may very well be distinguished by the name of a *compound* recess,—and also of what many will, no doubt, be apt to consider a strangely fanciful—not to say fantastical, arrangement. We certainly cannot produce authority for any thing of the kind, because we do not recollect, and therefore may safely affirm that we have never met with any similar instance. If others choose to say, it ought on that very account, to be received with a good deal of suspicion, they are certainly at liberty to do so—or for that matter, to reject our ideas and opinions altogether.

Capricious as it may at first sight be considered, this alcove (fig. 3), will, we think be found, on examination, to be well motived and commodious in plan. While the inner columns would produce great richness of effect—would render the whole a striking architectural picture; they serve also to define the central space, to keep that part more distinct from the rest, thereby giving more importance to that, and by screening off the spaces behind them, to convey the idea of the alcove's being greatly extended by the addition of these last. Nor is it in such respect alone that the plan belongs to the class we would distinguish as compound, since such character is still further increased by the addition it receives from the part *s*, which is here made to form a second or inner recess where the sideboard would be placed, and which therefore should be allowed to show itself distinctly as such by being treated as a large niche, or else covered with a semidome carried up above the ceiling of the alcove and room. In the last mentioned case, that recess might be lighted from above through its dome, nor would other light be then required; should that however, not be practicable, and should an arched niche-like recess also be objected to for the design, it would then be better to contract the space *s*, reducing it from a semicircle to a more shallow recess whose curvature would be *anti-concentric* to, and therefore correspond with, that on which the columns facing it are placed,—as is done in the recess B, fig. 2.

Almost any one of these three plans above will be found, if studied for that purpose, to contain within itself the germs of many others; and notwithstanding that they possess something in common—taking them altogether they furnish more variety, as far as plan is concerned, than is now to be met with in as many thousand examples,—which however they may differ as to matters of decoration and detail are nearly alike in regard to arrangement and plan.*

Instead of proceeding, as we could easily do, with other plans of the same class, and for similar purposes, we will, by way of change, now exhibit one for the window side of a library, occupied entirely by three bays. In order both to obtain novelty of character, and increase picturesque

Fig. 4.



effect, the larger bay B, in the middle, is converted into a sort of case separated from the rest of the rooms, by an open screen with tracery, and carried down to about three feet from the floor. This screen, which might either be glazed or not, as should seem most expedient, would not only be characteristic and ornamental in itself, but be rather serviceable than otherwise, by moderating the light within the body of the room, and thereby rendering the two open bays, *b b*, more piquant and brilliant by contrast. In fact the plan would admit of the lower part of the screen being closed up to the height of about six feet from the floor, by which means additional space for book-shelves, on one if not both sides of it, might be obtained. And although this would materially diminish the light in that part of the room, little if any inconvenience would result from that circumstance, because it is here supposed that the room itself is chiefly intended to contain books, and that the cabinet B, and the two bays *b b*, would be for sitting in. Accordingly the fire-place is put within B, as the most convenient situation; and as that one would be sufficient, the space that must otherwise be occupied by a chimney-piece and chimney pier would be left free for book-cases or shelfing.

With the same plan, a room of very different appearance as to design, if not exactly as to character, might be produced by merely transposing the situation of the enclosed and open portions,—that is by removing the screen between B and the room, and in lieu of it, screening off the two lesser bays *b b*, which might either immediately communicate with, and be open towards the larger bay, or entirely shut up from it, as one of them is shown in the cut. In the former case a vista would be obtained through the three bays, by a compartment at each end filled with a mirror, so as to give the effect of an open arch; or else instead of being filled with a single mirror, each of those compartments might be divided into panels by mullions, &c., like those of the screens, whereby the effect of an additional open screen in each of the smaller bays, might be obtained.

As our chief object is rather to afford suggestive hints, than to give plans definitively fixed, and intended for some one individual case, we do not pretend to enter into more exact description. The cut itself too, must likewise be received as a mere explanatory sketch, it being on too small a scale to admit of nicety as to detail, or do more than indicate the arrangement and principal forms.

(To be continued.)

* Should this be disputed, we should feel obliged to any one who would inform us what remarkable instances of the kind there are which would tend to support an opinion contrary to that here expressed.—Ed.

ON THE CONSTRUCTION OF OBLIQUE ARCHES.

Sir—I am sorry to trespass again on your pages in reference to Mr. Peter Nicholson's work on Railway Masonry, but having a few days since been made aware that a second edition of his book was published, in which a reference was made to some remarks I had previously written in your Journal, I procured a copy of it, and the reference in question being nothing more or less than a gross misrepresentation of facts, I trust you will allow me space to set the matter in its proper light.

The point in dispute is relative to Mr. Nicholson's trihedral system. In his first edition he says at page xxiii, "If a trihedral be cut by a plane perpendicular to one of its oblique edges, the section shall be a right angled triangle." Relative to this I made the remark that there were three sorts of trihedrals, and that this assumption only holds good with one of them, namely, a right trihedral.

In his second edition, page xxix. A, after stating that the trihedral there treated is a right trihedral, he says, "if *such* a trihedral be cut by a plane perpendicular to one of its oblique edges, the section shall be a right angled triangle." To the end of which he appends the following complimentary observation. "I have called this kind of trihedral a right trihedral; but a narrow-minded hireling, who signs himself W. H. B., in the Civil Engineer and Architect's Journal, page 152, has erroneously transcribed from a paragraph following, Def. 6, page xxiii., Railway Masonry, first edition, 'If a trihedral be cut by a plane perpendicular to one of its oblique edges, the section shall be a right angled triangle,' leaving out the part that would make sense. His remarks, founded on this mistranscription, resemble rather the puerilities of childhood, than the reasoning of mature age."

Setting aside his personal abuse which will neither benefit his position nor injure mine, the reply I have to make to the rest of his observation is, firstly, that in saying I have mis-quoted his work, he deliberately states that which he knows to be untrue; and there stands the paragraph at page xxiii., of the first edition to prove it.

Secondly. In saying I omitted the part that made sense of the passage, he accuses me of the very blunder he himself committed, of which the fact of his having corrected himself at page xxix. A, of the present edition, is abundant evidence.

The fact is, the page (xxix. A) is a fresh page which he has added to his book, for the express purpose of inserting the corrected paragraph; and has attached my remark to the corrected paragraph, declaring it to be a misquotation. It is really very lamentable to see a man of the standing Peter Nicholson once had, obliged to have recourse to so mean and unworthy a subterfuge; and it is still more lamentable to see him forget himself so much in the language he makes use of. I consider it to be the duty of every one who is in a position to do so, to expose the errors of a work addressed to the public; particularly when it comes from the pen of one who has enjoyed a considerable portion of their confidence and support, and is addressed to those classes who being unable to investigate the subjects contained in it for themselves, are compelled to rely implicitly on what is given to them by the author. With this view I made my remarks on Mr. Nicholson's first edition, and with this view I now proceed to show that a great deal yet requires alteration in the second.

Taking for example page 7, he says, "in order to prevent two joints from meeting each other, it is necessary that the number of arch stones in each face should be an odd number." Now every body at all ac-

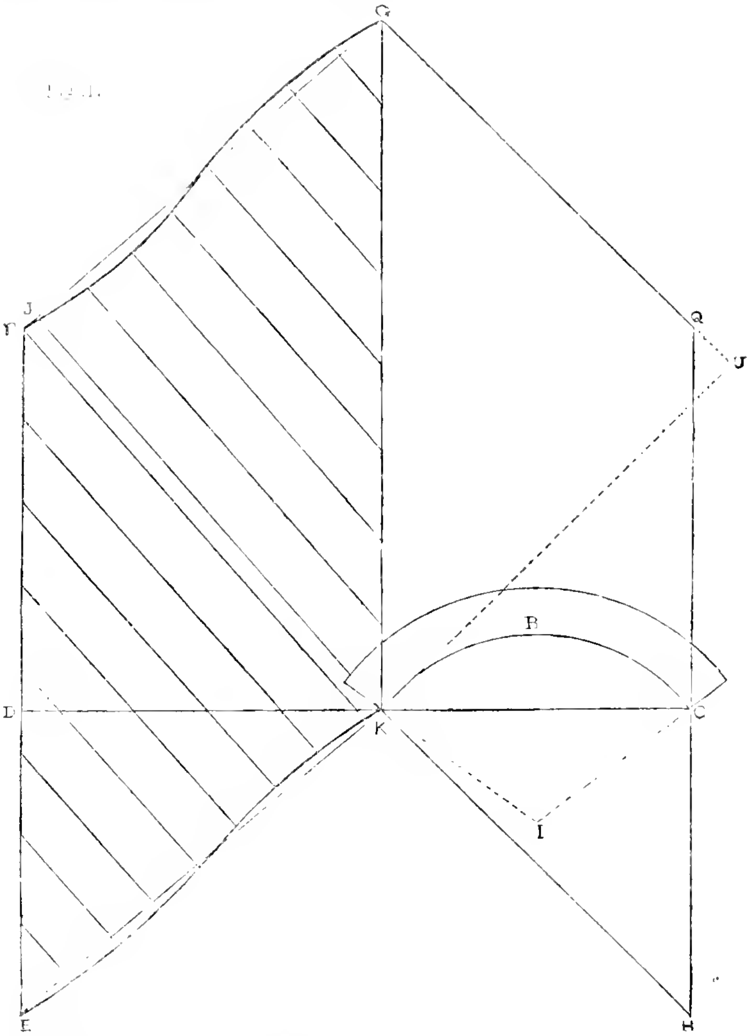


Fig. 3.

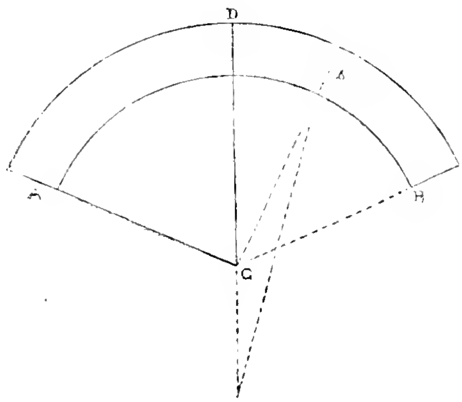

Fig. 4.

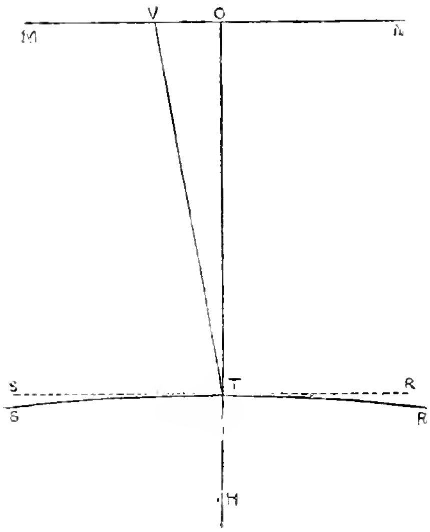

Fig. 2.

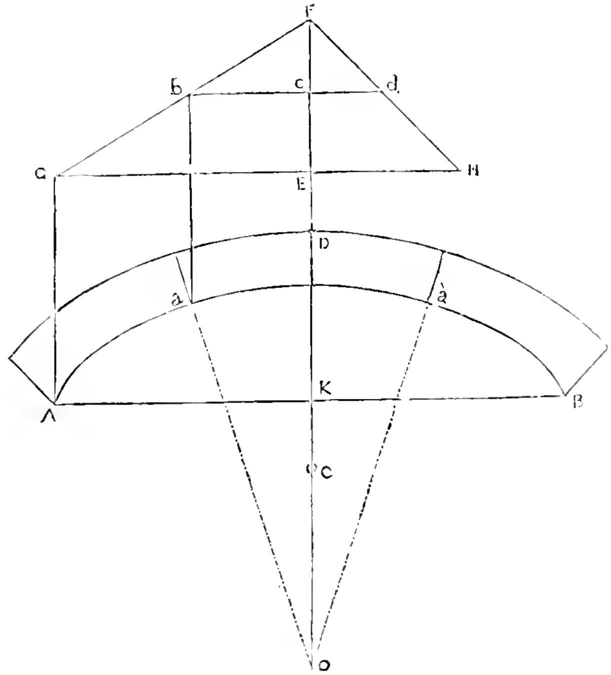


quainted with the subject knows that the number of courses being odd or even has nothing at all to do with the meeting of the joints.

Next, (referring to the same page), about dividing the line E A, fig. 1, we will here take a figure with his own letters as example, Suppose it was required to construct an oblique arch of the following dimensions, viz.:

Span 10 feet = A C.
Rise 2·5 feet.
Angle of obliquity 45° = A H C.
Width of bridge 16 feet = A u.

And take the case he does at page 7, in supposing the number of courses to be nine; following out the directions given by him, namely, to draw F K to meet the straight line A E perpendicularly in K, E K will be divided into eight courses, and A K will be the ninth; *which would require eight courses to be 1 foot 10·17 inches thick, and the remaining one to be 6·36 inches thick.* Now I would ask, does Mr. Nicholson really come forward with such a rule as this, and call his book a *Guide to Railway Masonry?* Is he ignorant of the fact that Mr. Buck has surmounted this difficulty by the simple expedient of adjusting the angle of intrado—or is it that, rather than acknowledge his inferiority, he persists in what he knows to be wrong, and addresses his book to the working classes in the hope of escaping detection?

Again, with reference to obtaining the angles between the joint lines in the face and in the soffit of the arch. It is perfectly distressing to see a problem which admits of easy solution so miserably mutilated as it is in his hands. The construction given by him, that is to say the only one that deserves the name of an approximation, occupies two and a half closely printed pages of his book, while these angles may be obtained with much greater accuracy, and with about a quarter of the labour as follows. Let A D B fig. 2 be the elliptical face of the arch, and O the point to which the joints in the face converge (see Buck on Oblique Bridges); produce O D to F any convenient distance, and make F E = half the obliquity of the arch. Draw G H parallel to A B, set off G E = A K, join G F, and draw the line F H, making the angle E F H equal the angle of extrado.

Then to find the curved bevel for any joint a, join $a\ o$, and draw $a\ b$ and $b\ d$ respectively parallel to O F and G H. Take two lines $m\ n$, $o\ h$, at right angles to each other, as at fig. 3, set off $o\ v = d\ c$, fig. 2, and from v, with a distance equal to $a\ o$, fig. 2, describe an arc intersecting $o\ h$ at t. Then applying the mould of curvature of the spiral line of the intrado $s\ t\ r$, so that the line $s'\ t\ r'$ drawn at right angles to $o\ h$, is a tangent to the curve at the point t; the angles $s\ t\ v$ and $r\ t\ v$, are the bevels adapted for the joint a, fig. 2, and the corresponding joint a' on the other side of the arch. With this construction the angles for all the joints may be obtained from fig. 2, without any confusion in the figure.

These angles may also be obtained by computation, for let A D B, fig. 4, be the elevation of the arch on a plane at right angles to the axis of the cylinder, and C be its centre, and let a the position of any joint be given. The angle D C a being then known,

If the angle D C $a = \lambda$,
Angle of obliquity of arch $= \theta$,
Angle of extrado $= \varphi$,
And the radius of the cylinder $= r$.
Let r (cot. θ, sec. φ) $= a$,
And r (cot. θ, tan. φ) $= b$,

*Then $\dfrac{a\ (\text{sin. } \lambda)}{(b\ \text{cos. } \lambda) + r}$ = tangent of the angle $v\ t\ o$ fig. 3.

An oblique bridge however is not necessarily built of stone, nor has it always stone faces. Yet Mr. Nicholson would have the same interminable process gone through in every case, while if the arch be entirely of brick, and the span, the angle of obliquity, and the radius are given, all that is required for the workmen is the angle of skew-back, and the length of the check on the impost, which are at once obtained as follows:

Let θ = angle of obliquity,
s = square span,
a = length of arc,

$\dfrac{(\text{cot. } \theta)}{a}\ s = \text{tan. } \beta$, the angle of skew-back, and (cosec. β) 3 = length of the check in inches, 3 inches being the assumed thickness of a course of bricks. The length of the check thus obtained may be either adjusted so that each extremity of the impost coincides with the extremity of a check, or retaining the computed length of check, they may be so placed on the impost that the springing shall take place at the same elevation on both sides of the arch. After which if the courses are properly gauged on the centre, and the course lines drawn down to their respective checks, no mistake can arise in laying the bricks.

Mr. Nicholson's rules however are not only very unnecessarily tedious, but it would appear by his own showing, that they are not over certain in their results. In a note at the bottom of page 22, in reference to a model made by the joint assistance of two masons, a joiner, and Nicholson's Guide to Railway Masonry, he says, "N.B. the model here alluded to has only 16 spiral courses, although 17 were intended. However, the calculations in all the principal parts will remain the same." One course too many in sixteen is not much certainly, but in these economising times it is just as well, considering that it is just as easy to know before hand how many courses there are to be in a bridge. In whatever way however the alteration of the number of courses was produced, one thing is clearly showed by it, namely, the fallacy of his assertion at page 7, respecting the necessity of having an uneven number of archstones in the face.

As for all that part of his book which contains such problems as the following, viz.: "Given the three sides of a triangle to construct the triangle," and "from a given point near the middle of a straight line to draw a perpendicular;" it is, to say the least of it, most arrant twaddle. He might with equal propriety have added, given a pair of compasses with a point at one leg and a pencil at the other, to describe a circle.

However, I will say no more. For this time I have, as he observes, "done with him;" and I hope enough has been said to show Mr. Nicholson that his ideas have got a twist in their beds by no means adapted to skew-bridges, and that no species of brow-beating or invective on his part will be of the slightest use to him, while his book remains so very imperfect.

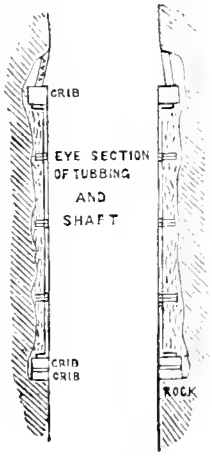
I am, Sir, your obedient servant,
W. H. Barlow.

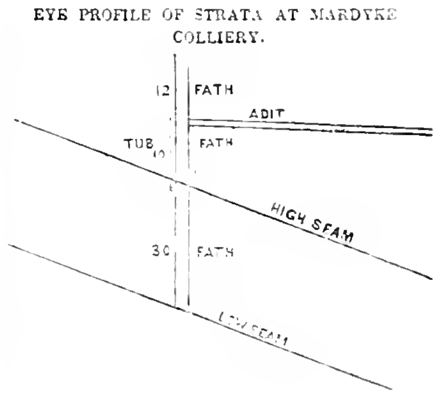
Brenton, August 16, 1841.

* The mode of obtaining the formula and construction is too long for insertion in this letter, but I will supply it if required.

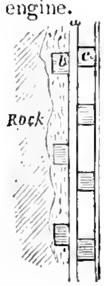
CAST IRON TUBBING.

In the Mining Journal there are some useful communications on Engineering Works connected with Mining, from which we select the following on "Tubbing of Shafts:" the first description is the application of a cast-iron tub, for the stopping back of water at Mardyke Colliery, the property of the Irish Mining Company, by Mr. Dunn, of Newcastle-on-Tyne, the first attempt in Ireland. The colliery contains two principal seams of coal, lying at an angle of one in three. The upper one, lying at the depth of 22 fathoms, is exhausted; and in order to win the second seam, at the depth of 30 fathoms further, the waters of the upper seam were required to be either pumped up to the natural adit (12 fathoms from surface), or to be forced up to that





point of discharge by tubbing. In order to give this project a fair chance, a piece of fire-clay, lying below the first seam, was taken advantage of as a foundation, and the shaft was rounded out to ten feet diameter. The base of tubbing is made to rest upon a pair of oaken cribs, fitted closely to the fire-clay foundation, and wedged from behind as long as ever a wooden wedge can be driven. This done, the cast-iron tub begins to be built, consisting of cast iron segments, four feet long, two feet high, and three-quarters of an inch thick, with a rectangular flange all round, of three inches; between each of these segments are placed half-inch (end ways) fir deal, wherein to wedge; the space between the segments and the rock is also stuffed with small stones, and tightened with wood. The top of the segments was completed by a wooden crib, which was stayed fast against the superincumbent rock, and then the whole fabric underwent the most severe wedging so long as any leak continued; and, when finished, the shaft was laid perfectly dry, with the feeder of water discharging out at the adit 12 fathoms above, and the sinking of the shaft resumed perfectly dry. The pressure against every square inch of the lower range of tubbing is equal to two and a half atmospheres, or about 37 lb. per inch, and, taking the average altitude at 36 feet, the whole tub is sustaining a pressure of about 81,200 tons; and so complete is the job, that the sinking has been since carried on without any pumping apparatus, whilst sufficient water is discharging at the adit as would give employment to a heavy engine.



It is often found convenient to surmount these tubs with a sufficient quantity of stone walling, to enable the wedging to be made effective.

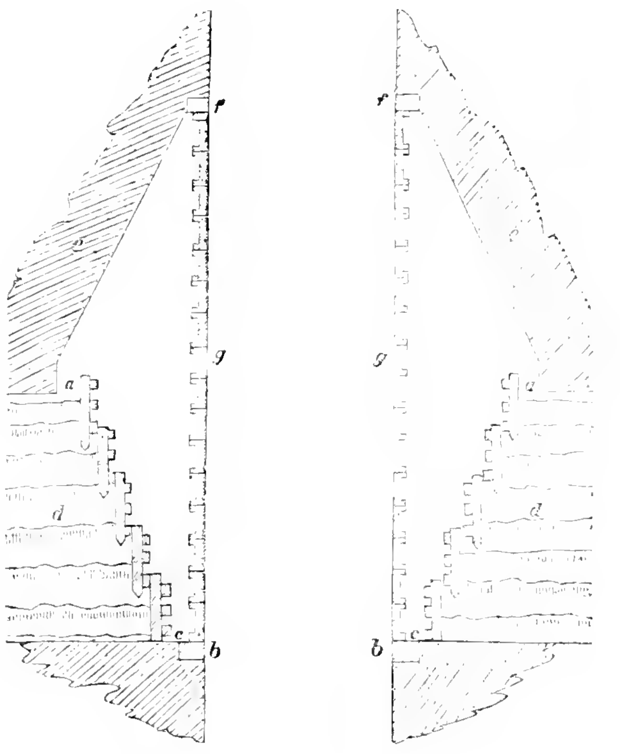
Some years ago Mr. Dunn effected the "winning" of a shaft, 30 fathoms deep, at Castle Comer, in the same county, by means of a plank tubbing, of 10 fathoms in length, constructed of three-inch planks, a, spiked against wooden cribs, b, and supported again by a range of inside cribs, c, which were in their turn clead with common deals; this mode of stopping water was practised for many years previous to the invention of cast iron tubbing.

ACCOUNT OF SOME PLANS ADOPTED IN THE NORTH OF ENGLAND OF SINKING THROUGH QUICKSAND.

By EDWARD STANLEY, Engineer, Sunderland.

When a "winning" numbers amongst its contingencies an encounter with a formidable quicksand, the preparations are, or ought to be, well digested as to power and appliances to overcome it. The viewer, engineer, and master sinker, each in their respective departments, take a retrospect of the means used on former occasions at other places, selecting the improvements that each adopted from previous works, which give every new "winning" an opportunity of profiting by the experience of the past. Boring by rods having determined the distance the sand is situated from the surface, and also the thickness of the sand previously; this operation is requisite, as the pit has to be chambered or bevelled like the frustrum of a cone, for the purpose of driving the spiling and laying cribs, each length and round in the descent being within the previous one. Supposing, for instance, the pit is 15 feet diameter, and the sand five fathoms, or 30 feet, in depth, and the spiling and cribs averaging each six inches thick, and the length of the spiles six feet, it remains now to examine what must be the diameter of the base of the frustrum of the cone, bevelled out so as to have the pit of sufficient size at the bottom of the sand as to admit the metal tubbing, and preserve the size of the pit. It will be, of course, premised that in six feet lengths it will require for the 30 feet, five lengths; if fewer lengths could be driven through the sand, the less the frustrum of the cone bevelled out in the rock; but long lengths, when driven, if the deviation is small, are like the trifling inaccuracy of an angle, which, if produced, are a long way out at the far end; it is, therefore, advisable to keep the lengths short, and in the annexed diagram are five. The five rounds of spiles and cribs, according to the former dimensions, will take up 10 feet of the diameter of the pit. We must add a clear space round at the surface of the sand, *a a*, of 18

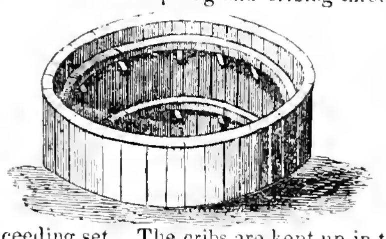
Fig. 1.



inches, which will add to the former diameter three feet, making it 13 feet. Further, we have to add the breadth of wedging crib, *b b*, cut at the bottom, and the space between its outer circumference and the lowest crib of the last spile, *c c*, together two feet each, which, added again to the 13 feet, makes 17 feet. This summary is the extra diameter over and above that of the pit, which we took at 15 feet, which gives 32 feet as the diameter of the base of the frustrum of the cone.

The height of this frustrum will depend upon the soundness of the limestone in contact with the sand. If not very sound, it must be carried further up, both for the safety of the sinkers and efficiency of the wedging crib at the top of the tub. The stratum of quicksand is shown by the letters *d d*, and the superincumbent limestone, *e e*, the top, or closing crib, *f f*, and the metal tubbing, *g g*; the manner of putting in which is by an intervening layer of deal sheathing, at the vertical and horizontal joinings, and subsequent wedging, has already been given in the *Mining Journal*. No letters of reference are put to the spiles and cribs, as they will easily be recognized, each spile having three cribs, at a distance apart of about two feet.

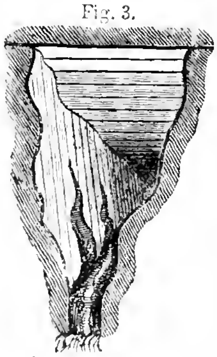
The following figure in perspective may give a more general idea of the mode of spiling and cribing through the sand:—It will be perceived that the spiles are driven round the pit in the sand, and considerable attention and care is required on the first round—and the reason is, that when it is accomplished, and the three cribs inserted, the last of these acts as a guide for the circular insertion and driving of the succeeding set.



The cribs are kept up in their proper position by cleats or brackets (see fig.) till a sufficient external pressure keeps them tight. The spiles may be lighter near the surface of the sand if thought proper, and increase in thickness in the succeeding lengths with the pressure, but some consideration should at the same time be made for the large diameter requiring increased strength. It may, therefore, be considered a prudent error to be too strong instead of too weak. A bird's eye view of the spiling, when complete, presents in principle an analogy to the elongation of a telescope.

It may appear paradoxical to a person unacquainted with the district, to be told that the quicksand sometimes presents itself in the form of a hard rock, requiring the liberal use of gunpowder to detach it. This stone is very porous, through which immense quantities of water filter, and which, by a continuous, running, increase the size of the apertures, along which are at the same time conveyed a large quantity of sand to the pit. This result is technically called "guttering," and, on any cessation of pumping, and consequent rising of the water, it increases to a great extent. As the water is being drawn out of the pit, its receding from the gutters brings along with it sand, and hence their enlargement.

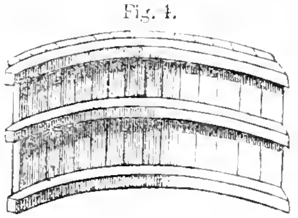
Fig. 3.



The annexed fig. shows a gutter fallen on to the limestone roof. At the bottom will be perceived a stream proceeding from the far end, having tributary ones from each side. These, in some cases, keep filling up the bottom of the pit with sand, nearly as fast as it can be sent to bank. With a sand of this kind, the general aim is, to keep the water always down if possible, for it has been found that its rising invariably increases this guttering, which proceeds in long irregular chasms radiating from the shaft.

As "spiling" cannot be driven under circumstances of this kind, the cribbing and lathing is put into the pit in sections, as shown in the annexed fig., varying in depth according to circumstances, and as the sand can be excavated. These sections, when the round is complete, are kept together vertically by hanging deals, which are planks spiked to the previous rounds, or if it be the first round, to some suitable provision in the shaft; external pressure soon binds them horizontally. In some cases the sand becomes soft towards the bottom, and the sections are abandoned for spiling.

Fig. 4.



The foregoing details are enumerations of the resources hitherto applied, which appear, and, indeed, have been found in practice to answer best. In cases of difficulty, parties having works of this kind in hand are frequently favoured with friendly suggestions, the most popular of which appears to be the suspension of a cylindrical iron vessel, of proper diameter, which it is proposed to lower and lengthen at the top as the excavation proceeds. This suggestion has certainly feasibility about it, though it is said to have originated from an amateur.

The present article may not inaptly close with a brief notice of the Datton "winning," which is going on slowly but surely. The most determined and persevering spirit is shown by the owners (Messrs. T. R. G. Bradyll and Co.), and the viewer. The outlay of money is immense, and the conviction is, that the colliery will be eventually "won." The engine power is ample, cancelling accidents, which have not been frequent. The settling of the sand on the bucket on one occasion was so dense as to be the means of lifting a column of 33 fathoms, of 22-inch pumps, by the spears on the starting of the engine. The sand is hard, and the feeder flowing principally from the south, has occasioned great delay and expense by guttering. Fig. 4 is a representation of the wooden segments that are being put in to get through the sand previous to metal tubbing, which is now about half penetrated. The liberality and public spirit of the owners deserves the most complete success, which all parties earnestly wish may be the case.

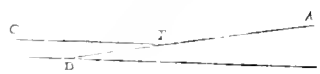
Another "winning" is now being made at Shotton, belonging to the Haswell Company, under the management of Mr. Thomas Foster, where the quicksand is very nearly arrived at. Should "any thing fresh" be brought into play at this place, either in getting through the sand, or the surface arrangements, it will appear in the Journal, with suitable illustrations, so far as it can be done without injury to the proprietors.

DREDGE'S SUSPENSION BRIDGES.

Sir—May I request the favour that the following remarks (on an anonymous communication, signed G. F. F., which appeared in your last Journal), may be inserted in your next.

The curve of a taper chain either connected or unconnected with the platform, is not a catenary, but one of very different properties; it might be easily demonstrated, but let that pass—for your correspondent makes as great a mistake in regard to the action of the oblique suspending rods in connection with the chains, and which is the only part of his letter I shall notice.

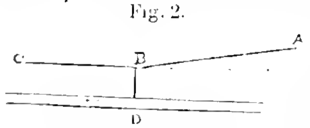
Fig. 1.



C, the centre of the bridge.

Let A B C represent a portion of the chain of a suspension bridge, B D an oblique suspending rod having the same inclination with the horizon as that portion of the chain B A; then will the strain upon B D, and of course upon B A, be proportional to the secant of the angle D A makes with the horizon, and there being no resolution of forces from the point B, there can be no tension in the direction B C.

Fig. 2.



C, centre of the bridge.

Again, put A B C part of the chain of a common suspension bridge, B A forming the same angle with the horizon as A D did in the former curve; then will the strain in the direction B A be proportional to the secant of the angle which it makes with the horizon (or the same as before), but by a resolution of forces, there would be a tension in the direction B C, α as the radius, which tension must be borne by a sufficient quantity of iron, and that iron causing a strain on the curve α as the secant of the angle B A makes with the horizon.

I shall take no further notice of this anonymous communication, but if your correspondent wishes further information, he must affix his name to his next letter, and then be careful what he says, for though the diagram he shows is totally different from the form proposed, his demonstration if carried out, would only tend to support that principle he is attempting to refute, and the several structures either in course of, or about to be erected in various parts of the kingdom, will at once silence every futile objection that can be raised against it.

I remain, Sir, your humble obedient servant,

J. Dredge.

Bath, August 16, 1841.

P.S. I would refer your readers who may be interested in this subject, to the drawings which have appeared in your Journal, and they will at once perceive that there is not the slightest similitude between them and that represented by your correspondent in the last number.

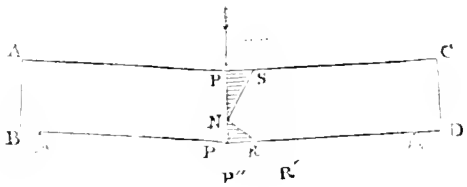
*** We know not what right Mr. Dredge has to make the insinuation which he has done in the above letter, with regard to an "anonymous communication." The article of G. F. F., was written without the slightest taint of presumption or slur upon Mr. Dredge's invention, it was a fair scientific enquiry into its merits, and such a one as every inventor must be ready to encounter, if he be desirous of introducing to the scientific world any new form or invention. For the purposes of free and open discussion, we do not see the necessity of correspondents giving their names—and we shall leave it to G. F. F. to reply to Mr. Dredge's remarks.—Editor.

ON THE TRANVERSE STRAIN OF BEAMS.

By Herbert Spencer, C.E.

The following paper is an outline of a new system of investigating the laws of the transverse strain, differing from the usual method, in as much as it depends solely upon the position of the neutral axis. The results as here given, will probably not be considered sufficiently concise for practical application; but they are published in the hope that something useful may be elicited.

Fig. 1.

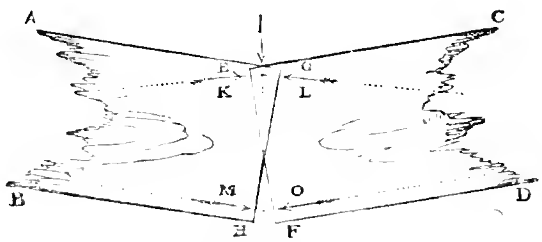


1. Let A B C D be a piece of timber, subject to the transverse strain in the direction shown by the arrow; and let P P′ be assumed as the plane of fracture, and N the position of the neutral axis. Take any line P′ R, to represent the resistance to fracture of all the fibres in the bottom lamina, then by the theory of the lever, if N, R, be joined, and any line be drawn parallel to P′ R, and terminated by N P′, and N R, it will represent the relative effect of all the fibres in its latitude, and therefore the whole triangle N P′ R, will denote the resistance to fracture of all the fibres in tension. In the same manner, a triangle N P S may be assumed, which shall represent the resistance of all the fibres in compression.*

2. Now the mode of action of the fibres in resisting the force impressed, involves the necessity of the equilibrium of the compressive and tensive resistances, about the transverse line through N, that is the neutral axis; for suppose a saw-gate made down the line P N as far as N, and the force to be then applied; a deflection will immediately take place, and the surfaces of the opening will come into close contact. Carrying out the idea it would appear, that the deflection would continue, until the resistance to compression in the upper portion P N of the plane of fracture, is equal to the resistance to tension in the lower portion; or that in the uncut beam, the neutral axis arranges itself so that these forces are in equilibrium.

As it is this theory upon which all that follows depends, and which if disproved, will invalidate the succeeding calculations, it may be well to give a further illustration.

Fig. 2.



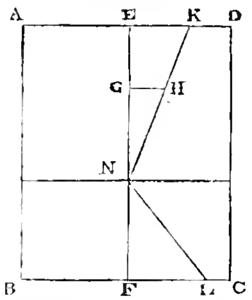
Let A B C D be a piece of wood as before, subject to transverse strain, and let E F and G H be the planes of fracture; (the diagram being necessarily greatly exaggerated to make the action clear) draw the arrows K, and O, perpendicular to E F, and L, and M, perpendicular to G H; then K, and L, will represent the direction of the resistances of certain fibres to compression, and M, and O, those of the resistances of other fibres to tension; (the forces extending the fibres are acting from H towards B, and from F towards C, and the resistances will obviously be in the reverse directions)—now K, and O, being perpendi-

* This theorem affords a simple demonstration, that the strength varies as the square of the depth; for if the depth be increased, (the neutral axis remaining constant) so that N P′ becomes N P″, the original supposition being carried out, the triangle N P″ R′ will denote the new tensive resistance; but the triangle N P″ R′, is to the triangle N P′ R, as $(N P'')^2$ to $(N P')^2$; that is the resistance of the fibres in tension, varies as the depth square, and the same will be true of those in compression.

cular to E F are parallel, and the same may be said of L, and M; hence if produced they will form a parallelogram, and the resultant diagonal of K, and L, will be equal, and in the opposite direction to that of M, and O; that is, the forces will be in equilibrium; but if K, and L, be greater than M, and O, their resultant diagonal will also be greater, and motion must ensue, that is such a state of things cannot exist. And what is true of these single forces, will be true of the forces of all the fibres collectively; or the resistances to compression and tension will be equal. It may be said that this explanation, involves the necessity of the centre of motion N, being midway between the contending forces, and that that does not obtain, in the case in point; but this does not prevent its application, for the resistances to tension though exercised nearer to the neutral axis, are greater in amount, so that the effect is practically the same.

3. The position of the neutral axis therefore, depends upon the ratio between the tensive and compressive resistances of the material, and by the application of the above principle, with the necessary data, its situation may be found. The next step will be to develop the general expression for obtaining it in simple cases.

Fig. 3.



Let A B C D be a transverse section of a rectangular beam; assume N as the middle of the neutral axis, and through it draw the central line E F, and in F C take any line F L, to represent the resistance of all the fibres in the line B C; join N L, and the triangle N L F will denote the resistance of all the fibres in tension. Make N G, equal to N F, and draw G H perpendicular to it, and let G H, be to F L, as the resistance to compression, is to the resistance to tension in the material in question; join N H, and produce it to K, then the triangle N E K will represent the resistance of all the fibres in compression, and will consequently be equal to the triangle N F L. Let x equal N F, the distance of the neutral axis from the bottom; take d for the depth, and let p and q stand for F L and G H respectively; that is, let them denote the tensive and compressive resistances.

Now by similar triangles N G : G H : : N E : E K,

or $x : q :: d-x$: E K, or $\text{E K} = \frac{q\,(d-x)}{x}$,

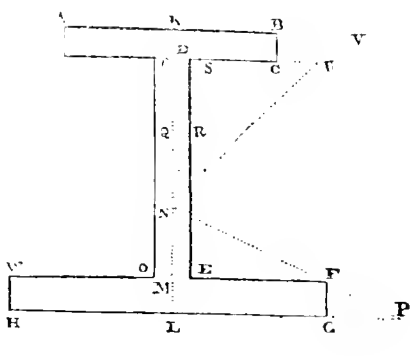
$\therefore \dfrac{(d-x)\times\dfrac{q\,(d-x)}{x}}{2}$ = area of triangle N E K; and $\frac{p\,x}{2}$ = area of triangle N F L; hence we have the equation,

$\frac{p\,x}{2} = \frac{q\,(d-x)^2}{2\,x}$ or $p\,x = \frac{q\,(d-x)^2}{x}$, hence $p\,x^2 = q\,(d-x)^2$ or $\frac{p}{q}\,x^2 = d^2 - 2\,dx + x^2$. dividing by x^2, $\frac{p}{q} = \frac{d^2}{x^2} - 2\frac{d}{x} + 1$ and extracting root

$$\frac{d}{x} - 1 = \sqrt{\frac{p}{q}} \text{ or } \frac{d}{x} = \sqrt{\frac{p}{q}} + 1, \text{ and } x = \frac{d}{\sqrt{\frac{p}{q}} + 1} \qquad (1.)$$

4. The application of the principle to the common form of girder, is the next case that suggests itself.

Fig. 4.



Let A B C D E F G H be the section, assume N to be the middle of the neutral axis, and through it draw the central line K L, and in the line E O, take a line M E, to represent the resistance to fracture of all the fibres between E, and O, and for the sake of convenience, let M E be equal to half E O; join N E, N F, and let N F, and H G, produced, meet in P.

Make N Q, equal to N M, and draw Q R perpendicular to it, and let Q R, be to M E, as the compressive resistance in cast iron, is to the tensive resistance; join N R, and produce it to S, and as T S : T D, so make T U : T C; join N U, and let N U, and A B, produced, meet in V.

Then in accordance with the principles as applied in the last case, the figure N L P F E, will represent the resistance to fracture, of all the fibres below the neutral axis; and the figure N S U V K, the resistance of all those above, and these will be equal.

Now let x = N L the distance of the n. a. from the bottom.

d = the whole depth.
d' = depth of top flange.
d'' = depth of bottom flange.
b = breadth of top flange.
b' = ditto of middle rib.
b'' = ditto of bottom flange.

And as before, let p and q represent M E and Q R respectively.

Then N M : M F : : N L : L P or $x - d'' :: \frac{p\,b''}{b'}$* $:: x$: L P

or $\text{L P} = \dfrac{x \times \dfrac{p\,b''}{b'}}{x-d''} = \dfrac{p\,b''\,x}{b'\,(x-d'')}$. Therefore the area of the figure N L P F E will be represented by,

$$\frac{p\,(x-d'')}{2} + d''\left(\frac{\frac{p\,b''}{b'} + \frac{p\,b''\,x}{b'\,(x-d'')}}{2}\right) =$$

$$\frac{p\,(x-d'')}{2} + \frac{p\,d''\,b''}{2\,b'} \times \left(1 + \frac{x}{(x-d'')}\right)$$

Again, as N Q : Q R : : N T : T S,
that is $x - d'' : q :: d - d' - x$: T S,

$$\text{or T S} = \frac{q\,(d-d'-x)}{x-d''}.$$

But T D : T S : : T C : T U or $p : \frac{q\,(d-d'-x)}{x-d''} :: \frac{b\,p}{b'}$† : T U

$$\text{that is T U} = \frac{\dfrac{b\,p\,q\,(d-d'-x)}{b'\,(x-d'')}}{p} = \frac{b\,q\,(d-d'-x)}{b'\,(x-d'')}.$$

And N T : T U : : N K : K V or

$$d - d' - x : \frac{b\,q\,(d-d'-x)}{b'\,(x-d'')} :: d - x : \text{K V},$$

$$\text{hence K V} = \frac{\dfrac{b\,q\,(d-d'-x)\,.\,(d-x)}{b'\,(x-d'')}}{d-d'-x} = \frac{b\,q\,(d-x)}{b'\,(x-d'')}.$$

And the area of the figure N S U V K, will therefore be represented by

$$\frac{d-d'-x}{2} \times \frac{q\,(d-d'-x)}{x-d''} + d'\left(\frac{\frac{b\,q\,(d-d'-x)}{b'\,(x-d'')} + \frac{b\,q\,(d-x)}{b'\,(x-d'')}}{2}\right)$$

---

* As $\frac{b'}{2}$ represents the resistance of all fibres between O and E; $\frac{b''}{2}$, will denote that of all those between W and F; and $(\frac{b''}{2} \div \frac{b'}{2})$ that is $\frac{b''}{b'}$, will express the multiple, that the number of fibres between W and F, is of the number between O and E, and if p equal the resistance of fibres between O and E, then $p \times \frac{b''}{b'}$ will equal that of all fibres between W and F. It is necessary that the quantity should be put in this form, instead of the simple fraction $\frac{b'}{2}$, in order that the value of L P, should involve the term (p).

† The last note explains this also.

But, area N L P F E = area N S U V K.

Hence we have the equation,

$$\frac{p\,(x-d'')^2}{2}+\frac{p\,d''\,b''}{2\,b'}\times\left(1+\frac{x}{(x-d'')}\right)=\frac{q\,(d-d'-x)^2}{2\,(x-d'')}+$$

$$\frac{q\,d'\,b\,(2\,d-2\,x-d')}{2\,b'\,(x-d'')}.$$ And multiplying by $2\,(x-d'')$,

$$p\,(x-d'')^2+\frac{p\,d''\,b''}{b'}\times(x-d''+x)=q\,(d-d'-x)^2+$$

$$\frac{q\,d'\,b\,(2\,d-2\,x-d')}{b'},\ \text{or}\ \ p\,b'\,(x-d'')^2+p\,d''\,b''\,(2\,x-d'')=$$

$$q\,b'\,(d-d'-x)^2+q\,d'\,b\,(2\,d-2\,x-d').$$

Expanding the squares we have

$$p\,b'\,(x^2-2\,d''\,x+d''^2)+p\,b''\,d''\,(2\,x-d'')=q\,b'\,(d^2+d'^2+x^2+$$
$$2\,d'\,x-2\,d\,d'-2\,d\,x)+q\,d'\,b\,(2\,d-2\,x-d'),\qquad\text{or}$$
$$p\,b'\,x^2-2\,p\,b'\,d''\,x+p\,b'\,d''^2+2\,p\,b''\,d''\,x-p\,b''\,d''^2=$$
$$q\,b'\,(d^2+d'^2-2\,d\,d')+q\,b'\,x^2+2\,q\,b'\,d'\,x-2\,q\,b'\,d\,x+$$
$$q\,d'\,b\,(2\,d-d')-2\,q\,d'\,b\,x.$$

And by transposition,

$$(p\,b'-q\,b')\,x^2+(2\,p\,b''\,d''-2\,p\,b'\,d''+2\,q\,b'\,d-2\,q\,b'\,d'+$$
$$2\,q\,d'\,b)\,x=p\,b''\,d''^2-p\,b'\,d''^2+q\,b'\,(d^2+d'^2-2\,d\,d')+$$
$$q\,d'\,b\,(2\,d-d'),$$

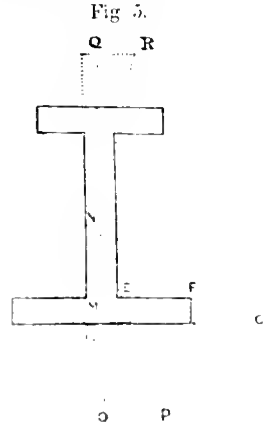
$$\text{hence}\ x^2+\frac{2\,(p\,d''\,(b''-b')+q\,b'\,(d-d')+q\,d'\,b)}{p\,b'-q\,b'}\,x=$$
$$\frac{p\,d''^2\,(b''-b')+q\,[b'\,(d-d')^2+d'\,b\,(2\,d-d')]}{p\,b'-q\,b'}$$

And completing the square, extracting the root, &c., we have

$$x=\sqrt{\left\{\frac{p\,d''^2\,(b''-b')+q\,[b'\,(d-d')^2+d'\,b\,(2\,d-d')]}{p\,b'-q\,b'}+\left(\frac{p\,d''\,(b''-b')+q\,b'\,(d-d')+q\,d'\,b}{p\,b'-q\,b'}\right)^2\right\}}-$$
$$\frac{p\,d''\,(b''-b')+q\,b'\,(d-d')+q\,d'\,b}{p\,b'-q\,b'}\qquad(2.)$$

And thus we obtain the situation of the neutral axis. It must be admitted that the equation is rather forbidding in appearance, but the reduction of the value of x, will not be found so tedious as may at first be imagined, since the quantities are simple, and the same combinations often repeated.

Fig. 5.



5. Assuming that N L, the distance from the centre of the neutral axis, to the bottom of the girder, has been found by equation 2; we shall at once be able to determine the dimensions of a rectangular beam, whose strength shall be equal to that of the girder.

The figure being constructed as before, produce N L to O, and N E to P, and let O P be drawn at right angles to N O, the distance L O being supposed to be such, that the area of the figure M E P O, may be equal to that of the figure M L G F, and consequently, that the triangle N O P, and the figure N L G F E, may have equal areas. Since therefore the area N L G F E, which represents the resistance to fracture of that portion of the girder below the neutral axis, is equal to the triangle N O P, which will indicate the resistance of the middle rib, produced to an imaginary point O: by finding the distance L O, we shall obtain the dimensions of a simple rectangular rib, having a strength equivalent to that of the portion of the girder below the neutral axis N.

Let the known distance N L, be represented by (a), and L O by (x), and the other dimensions remain as before.

Then $a-d''\,:\,\frac{b''}{2}\,::\,a\,:\,$ L G or L G $=\frac{a\,b''}{2\,(a-d'')}$,

and $\dfrac{d''\left(\frac{b''}{2}+\frac{a\,b''}{2\,(a-d'')}\right)}{2}=$ area of figure M L G F.

Again, $a-d''\,:\,\frac{b'}{2}\,::\,a+x\,:\,$ O P or O P $=\frac{b'\,(a+x)}{2\,(a-d'')}$.

And $(x+d'')\times\left(\dfrac{\frac{b'}{2}+\frac{b'\,(a+x)}{2\,(a-d'')}}{2}\right)=$ area of figure M E P O,

hence, by the construction we have the equation,

$$d''\left(\frac{b''}{4}+\frac{a\,b''}{4\,(a-d'')}\right)=(x+d'')\times\left(\frac{b'}{4}+\frac{b'\,(a+x)}{4\,(a-d'')}\right)$$

$$\text{or}\ \frac{d''\,b''}{4}\left(1+\frac{a}{a-d''}\right)=\frac{b'\,(x+d'')}{4}\left(1+\frac{a+x}{a-d''}\right)$$

Multiplying by $4\,(a-d'')$ we have,

$$d''\,b''\,(a-d''+a)=b'\,(x+d'')\times(a-d''+a+x)$$
$$\text{or,}\quad d''\,b''\,(2\,a-d'')=b'\,(x+d'')\times(2\,a+x-d''),$$
$$\text{and,}\quad d''\,b''\,(2\,a-d'')=b'\,(x^2+2\,a\,x+2\,a\,d''-d''^2)$$
$$\text{hence,}\quad\frac{d''\,b''\,(2\,a-d'')}{b'}=x^2+2\,a\,x+2\,a\,d''-d''^2$$

$$\text{by transposition,}\ \frac{d''\,b''\,(2\,a-d'')}{b'}+d''^2-2\,a\,d''=x^2+2\,a\,x,$$

$$\text{completing the square,}\ \frac{d''\,b''\,(2\,a-d'')}{b'}+d''^2-2\,a\,d''+a^2=x^2+2\,a\,x+a^2$$

$$\text{extracting the root,}\ x+a=\sqrt{\frac{d''\,b''\,(2\,a-d'')}{b'}+(d''-a)^2},$$

$$\text{or,}\quad N\,O=\sqrt{\frac{d''\,b''\,(2\,a-d'')}{b'}+(d''-a)^2}\qquad(3.)$$

The points Q and R, having been assumed in the same manner as O and P, we shall have the proportion, O P : Q R :: p : q, and as the triangles N Q R, N O P, are equal,

O N : N Q inversely as p to q,

that is, N Q $=\frac{p\times O\,N}{q}$,

and the whole depth, O Q $=$ N O $+\frac{p\times N\,O}{q}$ (4.)

It will be seen therefore, that by applying the equation No. 2, to ascertain the position of the neutral axis, and subsequently Nos. 3 and 4, we obtain the depth of an imaginary rectangular beam, having the same thickness as the middle rib, whose strength shall be equal to that of the girder, thus bringing us within the reach of the usual formula.

It may be as well to repeat the remark made at the commencement, that this system is not proposed for practical application in common cases; the essay being merely intended, as an exposition of another mode of viewing the action of the transverse strain, and as affording a means, should the principles be found correct, of testing the accuracy of the common approximate methods.

Derby, August 11, 1841.

Pacific Steam Navigation.—Extract of a letter received by the Directors of the Company from Mr. Wheelwright, dated Lima, April 28, 1841.—"Captain Peacock arrived here on Saturday, the 24th, having consumed nothing but Chili coal during the voyage:—his calculations have been most beautifully carried out, for he has not been 15 moments out of his time, on arriving at and sailing from each port in the voyage, from Talcahuano to this place, a distance of nearly 1,700 miles: and it affords me pleasure to remark, that his zeal in the cause of the Company merits the highest praise. His ship is, am happy to state, well regulated with a due regard to economy, and the several departments are most judiciously arranged."

CANDIDUS'S NOTE-BOOK.

FASCICULUS XXX.

"I must have liberty
Withal, as large a charter as the winds,
To blow on whom I please."

I. It is a most fortunate circumstance that the Croakers, and Screech-owl school of philosophers, both contradict each other, and are contradicted by experience; else we should have a most woful time of it, were we to pay attention to all their notable advice in regard to the *hygeine* regimen of architecture. At one time the public —at least the *nervous* public—are scared by being told that St. James' Park is the seat of malaria, and by being made to believe that Queen Victoria actually dwells in the midst of pestilence, although she does so only metaphorically, like all sovereigns, amid the moral malaria of a court. Next come the ventilation folks, who would fain persuade us that we are now all suffocating ourselves in rooms whose atmosphere is incapable of supporting animal life, owing to our present defective modes of construction. And indeed were the atmosphere in our houses as oppressive and suffocating as their doctrines, it would be so deadly, that I question if any sort of ventilation could correct it—except it were the ventilation occasioned by a hearty laugh. It was certainly a very great piece of presumption on the part of the Old-Londoners to presume to exist, as they did, cooped up in narrow lanes and alleys, where the different stories of the houses, projected over each other, so that the occupiers of the garrets could *Pyramus-and-Thisbe* with their opposite neighbours. No less impertinent is it that even nowadays, people will presume to fancy they can contrive to exist huddled together in the cabin of a steamer, in an atmosphere reeking with frowsiness!—and sleeping in boxes, not very much bigger than—and certainly not so well aired as, an ordinary dog-kennel. Did I wish to set up a fussy doctrine of my own, I should say that sea-sickness is chiefly occasioned by the horrible agglomeration of impurity condensed between the decks of a ship. Nevertheless instead of keeping quietly at home in their own comfortable rooms, many people are seized every season with a desperate fit of fidgetiness, until they can regale themselves with fresh air in a steamer, and squeeze themselves into poking little rooms in crowded lodging-houses, peopled from Cockney-Land, in a place that looks just like a suburb of it.—Well if the Ventilation folks can frighten them a bit, they may so far do good. If too, their doctrine be worth anything, an act ought to be passed making it a cognizable offence, for any one to get a genteel *squeeze*, especially if their "saloons," as the newspapers call them, consist of no more than two ordinary-sized upstair parlours, with a little cabin beyond them, made to perform the part of Boudoir—for that 'night only'. As for that, it matters very little how many or how spacious the rooms themselves may be, if more persons are to be crammed and jammed into them than their area can well contain; for it is no less absurd to attempt to pour a gallon into a quart mug, than a quart into a pint one. "Was not the squeeze, last night at ——'s actually insupportable?" was a question once asked, and produced the following reply: "It was, indeed, tremendous, but not insupportable, since the gentlemen supported the ladies, and the ladies supported the gentlemen."

II. Though the first has been a long one, I must give a second act to the farce of Ventilation. If the Terrifiers be in the right, ought not all under-ground kitchens, servants' halls and other rooms, to be strictly prohibited?—or does it not matter whether the High-Life-below-stairs part of the creation are suffocated or not? We are told that those whose avocations compel them to be chiefly in the open air, are proportionable healthier than others; and in proof of this we are perhaps referred to the striking difference between a ploughman, and a weaver;—a gamekeeper ranging about the woods, and a tailor doomed to sit all day upon the piece of wood called his shop-board. In all such arguments the stress is laid exclusively upon the single circumstance that happens to make for it. Here, the difference is attributed entirely to air,—to exercise, diet, &c., nothing. Should a tailor chance to drink himself into his grave, the "Ventilators" would seize upon him —not exactly after the fashion of body-snatchers,—but as an instance of the deplorable consequences of the want of fresh air. Well but put exercise to fresh air, and good appetite and its wherewithal, to them both, and they achieve wonders.—Yet, your jolly, jovial, foxhunter dies at the venerable age of forty, while some poor feeble, sickly, bookworm who immures himself almost constantly within his study, outlives another foxhunting generation, keeping among the living for fourscore years.—It is unnecessary to repeat so well known an anecdote as that of Fontenelle's "slow poison;"—which, by the by, is only one of the slow poisons which certain ingenious gentlemen have from time to time invented for the laudable purpose of alarming their neighbours. I remember once reading an awful medical invective against carpets,—the general use of which was said to have rendered people less healthy and long-lived than their ancestors who were unacquainted with such foolish luxuries. Yet I make no question but that the Doctor himself had his rooms carpetted, as well as his neighbours.

III. The author of the World of London, in Blackwood's Magazine, speaking of the building at the corner of Downing-street, observes that it is by "Sir John Soane, of Bæotian celebrity, who, together with Nash, has done so much to deprave our metropolitan taste in architecture, that another invasion of the Goths and Vandals were more to be desired than deplored." Indeed it is truly wonderful, and not a little scandalous also that two such Bæotians as Soane and Nash should have obtained fat-headed patronage to the extent they did, and been permitted to play their tasteless and extravagant pranks, while John Bull paid the piper. Both of them were addicted to the expensive practice of experimentalizing with their buildings, constructing, pulling down again, and reconstructing afresh, as if alterations of that kind cost no more time or money than they would have done in a drawing. Such was notoriously the case with Buckingham Palace, such too was it with the Downing Street edifice, which after all is unfinished, and doomed never to be finished, it having been commenced so Bæotianly and bunglingly that it cannot possibly be continued Northwards without either being twisted, or else projected into the street, so as to extend across the foot-pavement. Therefore it is likely to remain as long as it lasts, in statu quo,—a monument of its architect's taste, and his great affection for the "scored pork" style, and likewise of his extraordinary ingenuity, the entablature being most artfully contrived to block up a series of mezzannie windows just behind, and separated from it merely by an interval of three or four inches. It is lucky for Soane that this fault has escaped the notice of his friend Gammon, who has just found out what he might have discovered many years ago that Soanean Gothic is very *so-soish* stuff. But poor little Gammon's esteem for Soane, has steamed itself quite away, and is now utterly evaporated.

IV. One of the least exceptionable samples of Soane's taste is the basement of the State Paper Office, St. James' Park, where he has introduced a rather novel mode of rustication, which is at once rich and sober in effect. There are also one or two other good points about that building, although as a whole it is not particularly happy. It appears to be no more than a private house, and even as such by no means a large one. Most certainly there is nothing whatever in the exterior to indicate, or even remotely suggest for what particular purpose the building was erected. In regard to Soane's works generally, it is somewhat remarkable that they have been so very little noticed by foreigners, either for approbation or the contrary. The venerable architect's affection or appetite for his "scored pork" was so inordinate, that he did not scruple at times to employ that singular species of decoration even internally.

HINTS ON ARCHITECTURAL CRITICISM.—Part I.

It is a very delicate thing to insist on primary principles, when the very suggestion that a knowledge of those principles is necessary, seems almost like a whisper of insult. Thus, to intrude with an alphabet for the critic, in an age when men have grown grey in criticism, becomes scarcely pardonable;—nay it would be almost dangerous, but for the suggestive attitude the writer would assume, in pleading anew those elemental truths, by which alone the critic can arrive at an equitable conclusion. If therefore, out of regard perhaps for one or two, (who have viewed the vision of Palladio's family with horror, as if the harmless race of a Banquo had been passing in review,) I draw for a little a veil upon the past to introduce a new subject, and appear on a new scene, the spectator must judge me mildly; for I am no literary coxcomb, pulling myself into notice, but anxious,—deeply anxious, to remove some of those weeds, which entangle around to choke the beautiful flowers of a still more beautiful art.

The subject of consideration, is criticism, which, like politics, betrays many currents of opinion, and many hostile enthusiasts.

It is right that there be enthusiasm, for without it art would slumber, but it is also right that every persuasive argument be adduced, to free the mind from certain prejudices, which lead the enthusiast astray; and it is a commendable task, to try at turning these various currents of opinion into one deep channel, the original source of which shall be "truth."—This preface must suffice. I am satisfied after this attempt at beckoning the attention towards what I would present, to leave it to the reader to judge, whether I quibble merely for indefinite purposes, or strive with the noble and the proud aim of ameliorating my country's art.

First, what is criticism?—Criticism is a branch of polite science, and when found in union with art becomes an index to its position. From this arises its importance. It is also a court, where the several disputes of art are brought to issue, and upon the decisions of which the public opinion stands: hence arises its influence. The foundation of its laws, is based on sense, imagination, and judgment, as the three natural powers it attempts to move. Its laws of adjudication vary according to the claims of art, and according to the nature of appeal; and from the labour necessary to frame these laws, and to apply them, is inferred the necessity of their adoption. An appeal to the judgment of criticism, is based upon plausibility, and implies public assent to certain principles; these however, critics as counsel in the social contentions of art, quarrel upon, whilst the judge "nature" sits to disentangle and apply them. The arguments vary first, according to the art, and secondly, accordingly to the nature of its claim,—its claims being always in the shape of some emotion, (emotion being the aim of the affecting arts) the fitness, or unfitness of which, for the present is immaterial. The institution of the court itself, is founded upon presumed error, as implying an uncertain acquaintance with those laws, which are the philosophy of our taste. It follows then, in order to meet the wisdom of such an institution, that the principles which detect the propriety, or expose the error of appeal, should be free from arbitrary application. It is first then, upon the necessity of a judgment in matters of art, secondly,—upon the required clearness of the laws of judgment, and, thirdly, upon the arbitrary interpretation of those laws, which interpretation, I for the present assume to exist, that I am induced to throw out a few hints on criticism, which I hope will be received by the reader with a politeness due to the subject, however in exhibiting this politeness, he may disguise a dislike to what may appear officious interference in the writer. However these hints may be generally received, the man of correct taste knows that it is not an irrational task, to dissect those principles which aid us, or ought to aid us, as we either feel or affect a love for the great examples of art. He knows that about architectural excellence there is an air of mystery: so that without any implied reproach upon the elegance of any choice hitherto made, or which may be made, he would prefer our being guided by principle, rather than by instinct, in our search after the beautiful, and that instead of wrangling over fragments, like beasts over carcases, he would choose an explanation of the real basis of choice, of which a noble profession cannot be ashamed. The very circumstance of our choice being a habit, requires that some effort be made to enlarge and unfetter the mind, so that by infusing into it those ideas which are the very key to effective design, we may stand in rivalry with the ancients;—adopting if we please their beauties, but adopting them from choice, not from necessity.

I feel strongly on the subject, because it is so important that architecture should rank amidst the poetic arts, and that the attainment to architectural excellence, shall be only by the acknowledged effort of genius. I feel strongly too, because I conceive it is owing to our negative character as artists, and our supine imitation, that critics rise no higher in their views. The architect of original bent, feels the incompetency of ordinary men to discuss his claims: a critic in his idea, being a man who has only read through Creasy or Stewart, or if learned in Christian architecture, has his dictionary of reference only in some convenient examples. He is unfamiliar with the man of that severe yet elegant mind whose opinion he covets. He has been deceived in fancying architecture an art, where conception, the inseparable companion of genius, might alight. The root of the defect at once appears in criticism, which is confined to certain laws inimical to invention. The evil of this criticism is, that it limits that range of mind which every other poetic art allows, and is either founded on a presumption against the poetry of the art, or against the ability of its students. If in the former ground it is inconsistent, because that combination of parts, with the ancients so fortuitous, being deemed by many the monopolist of beauty, shows an argument then against the poetry of the art, for poetry is confined to no set disposition of forms. If on the latter ground it is a libel upon the genius of our nation, and stagnates by its mean policy, those efforts which might introduce fresh beauties amongst us. I admit that our rules are protective, and exclude many incongruities; but would it not be more honourable to make the antique amenable only to fresh creations? very possible if as artists we catch the spirit of our masters. It being evident then, that our art for inventive beauty is far behind the other arts, with which it claims sisterhood, and that however good this claim to equality may be, it does not appear either from the pen of the critic, or the example of the architect, to be so dignified; it follows, as a natural consequence, that to maintain this kindred claim, there should be shown a similarity of laws, by which the composition is governed, and by which the emotions are engaged: it follows too, if this be the case, that then, our laws of criticism are erroneous, or capricious, being essentially at variance with those of other arts.

In watching the progress of a design, in either art, to its completion, that is in observing that anatomy of thought out of which the composition is formed, we may perceive a relationship existing, although we do not yet admit its existence. We read an able critique upon poetry, music, sculpture or painting, and the mind responding with ready fidelity to truth, becomes at once conscious that it hears in that criticism, but the echo of its own suggestions: but architectural criticism we do not feel in this way, and purely because its compositions are not criticized on the same ground, the mechanical being ever judged as in partial skirmish with the poetical. Architecture however, is not more mechanical than the other arts, for the conception which occupies the brain of the poet, or the painter, can only acquire a correct and tangible shape by a process of adjustment. Calculation enters into the design; associations are dwelt upon: and the sentiment which is to appear is only featured by a careful arrangement. Music, amidst all its sweetness and harmony, has its mechanism. The rush of chords, the softer modulation, independent of the art, which, if I may so speak, can embody for the ear its anticipations, is but the sale of a passion, or a sentiment, shaped and tutored in the mind, with reference to situation, circumstance, time and probability. Each art is alike too in its finished performances: they are so many appeals to the mind through the senses; music, through the ear, sculpture, painting, and architecture through the eye, poetry through the eye and ear, and it is upon this beautiful and exquisite web of sensation, that the power of art moves. But supposing that architecture be equally with the other arts, a mirror where the eye can seek objects, which the mind may enjoy, a barrier intrudes itself at once, in the shape of that word, "taste," (which like the ghost of Junius assumes a variety of shapes) to make it doubtful after all, whether there can be shown common grounds, upon which the feelings are moved. It will be necessary then, to define this word "taste," because if this be unexplained, we may be only right by chance.

It has been deemed a fruitless task, to reconcile to a principle the varying opinions current upon the same object in arts, each of which is termed the opinion of taste, because of the different degrees of sensibility and imagination found in different minds, and because it has been observed, that the same object, which is viewed carelessly by one man, fills another man with exquisite delight. Strange as these differences may appear, they are all to be traced to one source. The taste of a man which is a progressing principle, receives its perfect development only from time. Taste which in infancy is mere sense, becomes improved as imagination and reason blend to assist it.—Taste resulting not from a simple idea, but from the union of reason and imagination, varies then not according to that chance inseparable from a simple notion, but according to the effort of the imagination and the exercise of the judgment, the latter quality of the mind being a determinable thing, whose degree of ability is proportioned to the attention and care bestowed. Imagination too, though a power extremely elastic, resembles when engaged with architecture, either more or less that faculty we denominate "taste," for its essential power then lies in tracing resemblances, and it is either perfect or advancing towards perfection, according to the degree of judgment in simultaneous exercise. Thus taste is subject to degree, and according to this degree of taste in different individuals, we find the degree of refined pleasure which a work of art produces. Taste which is a habit is therefore imperfect taste, because inimical to progression. Hence habit which is the origin of our views in a great measure, may explain the source of our architectural taste.

Independently of this definition of taste, and the grounds of its support, there is a further difficulty attendant upon its application to architecture, from the circumstance of there being little or no direct appeal to the sympathies, which the painter, the poet, and the sculptor, so powerfully affect, and which the rudest mind intuitively feels, without previous study, to acquaint him with the source of his emotion. This is one reason why public opinion varies so much; men untaught, with their judgments unassisted, feeling that emotion is the object of the art, are precipitated into hasty conclusions, just because their sympathies cannot be awakened. A correct taste in architecture is more difficult than in any other art, because the ideal resemblances affecting the mind are more remote: and this is the reason why the taste is pleased by figures, pictures, statues or striking ornaments, to the prejudice very often of a taste strictly architectural:—the mind being conducted towards familiar objects.

The essential difference between architecture and the other poetic arts, consists then in this suggestive character, whilst the poetry it exhibits, appears in expression, attitude, or relative position. It has however, all the attributes of the other arts at command, and which it makes subsidiary; and thus its claims to criticism are as strong and as important, as the noble art of the painter, or the sculptor. Having then endeavoured to state that architecture is equal to the other arts, in its claims to liberal criticism, I shall reserve it for my next to show the origin of its effects upon the mind, by a definition of that faculty, inherent in us, by which we extract emotion from attitude, proportion and position, even when these three essentials have no counterpart in nature.

FREDERICK EAST.

August, 1841.

ENGINEERING WORKS OF THE ANCIENTS, No. 8.

DIONYSIUS of Halicarnassus who lived in the time of Augustus, is the next author who contributes to our series, having extracted from his Roman Antiquities the following accounts of Roman works.

BRIDGE OVER THE TIBER.

Ancus Marcius, the 4th King of Rome (B. 3, ch. 14,) is said to have been the first who built over the Tiber the famous wooden bridge, which is considered as sacred. It must only be made of wood, and neither iron nor copper may be used in it. When any damage occurs it is the duty of the pontiffs to see to the repair, and to perform certain sacrifices prescribed by law during the progress of the works.

Ancus Marcius greatly enlarged the city of Rome, and built the port of Ostia at the mouth of the Tiber.

SEWERS.

TARQUINIUS PRISCUS, the 5th King (B. 3, ch. 20), built the walls of Rome of large squared stones, and commenced the sewers, by which the waters are collected in the streets of the city, and carried into the Tiber. The work is admirable, and beyond anything that can be said. For my own part, I believe that Rome has nothing more magnificent, nothing which better shows the grandeur of her empire, than her aqueducts, streets, paved roads, and sewers: I judge thus not only on account of their utility, but still more on account of the immense outlay which they have required. To prove what I assert, I will only instance the sewers. According to Caius Aquilius, having been for some time so neglected that they were stopped up, the censors concluded a bargain with a contractor to clean and repair them for a thousand talents.

We cannot pass over this tribute of the old historian without remarking that while the temples of Greece are scattered in ruins, and their proudest ornaments become the trophies of barbarians, the roads, aqueducts, and sewers of the Romans still minister to the wants of nations, centuries after the power of their founders has ceased to exist. The English emulate the Romans in the useful nature of their enterprises, and we trust that the labours of our engineers may minister as long to the service of the world as those of their predecessors.

GREAT CIRCUS.

Tarquin also embellished the Great Circus between the Aventine and Palatine mounts, and was the first who constructed around this circus covered seats, whereas the practice formerly was to place scaffolding around.

TARQUINIUS SUPERBUS.

Tarquin the Proud (B. 4, ch. 10,) the seventh and last king of Rome, employed the people on the public works in order to occupy them and prevent them from plotting. He continued to the Tiber the sewers begun by his grandfather, and carried out several of his unfinished works.

STRABO.

Having thus dismissed Dionysius of Halicarnassus, we come to Strabo, one of the most celebrated of the geographical writers of the ancients, and from whom, as from Diodorus Siculus, much information is to be gleaned as to ancient mining, a most important branch of engineering, as bearing upon earthworks. We shall first take the third book.

MINES IN SPAIN.

A chain of mountains, (the Sierra Morena), parallel to the Betis (Guadalquivir) extends towards the north, approaching more or less the banks of the river; it contains a great many mines. Silver is found every where in the neighbourhood of Ilipo and Old and New Sisapone (Almaden). Near the place called Cotinas, gold and copper are worked together. The mountains on the banks of the Anas (Gaudiana) also contain mines.*

* B. 3. ch. 2.

From Turdetania is exported cinnabar equal to that of Sinope. There is also found fossil salt.

What renders Turdetania particularly remarkable is its excellent mines. In fact all Iberia is full of them; but Turdetania unites all the advantages of a mining country to a degree which surpasses any praise. In no country in the world do we find gold, silver, copper and iron in such quantity or of similar quality. Gold is obtained not only from the mines but also from the rivers and streams, in which it is contained mixed with sand. It is also to be found in many dry places, but with this difference, that in these it cannot be distinguished at sight, whilst it shines when covered with the water. This is the reason why water is made to pass over sandy places, to make the particles of gold shine. Wells also are dug, and many means have been invented for separating the gold from the sand by washing, so that there are more gold washing works in the country than mines. The Gauls assert that their mines, as well those of the Cevennes as those of the Pyrenees situated on their side, are better: but, nevertheless, the mines on the Spanish side are generally more esteemed. Among the particles of gold are sometimes lumps of gold weighing half a pound, which are named *pales*, and require very little refining. In cutting stones of ore, small lumps of this metal are sometimes found. After having roasted the gold intended to be purified, by means of an aluminous earth mixed with it, the result of the operation is the alloy of gold and silver known under the name of *electrum*. It is again placed in the fire, which separates the silver, and leaves the gold pure: for this latter metal is easily fused, and is not of much hardness. It is also fused sooner by the flame of straw, which, being milder, agrees better with the nature of gold, which obeys its action, and dissolves easily, while charcoal, being stronger, consumes a great part by liquefying it too soon, and converting it into vapour. As to the beds of rivers, the particles are extracted, washed in buckets, or in wells or holes made near, and the earth is washed. The furnaces for melting silver are generally made higher, to enable the pernicious vapour of this metal to rise and be dispersed. Some mines of copper have the name of gold mines, whence it is presumed that they formerly supplied this metal.

Posidonius, in speaking of the number and excellence of these mines, uses all the exaggerations of an enthusiast. The Turdetanians, says he, use the greatest industry and labour in digging winding galleries far into the earth, and often in draining, by means of Egyptian spirals, the subterranean streams with which they meet. But their lot, he observes, is very different from that of the miners of Attica, to whom may be applied the ancient enigma, "They have not taken all that they have drawn from the earth, and they have left there what they possessed." The Turdetanians, on the contrary, draw from their mines enormous profits, since the fourth of the earth which they extract from the copper mines is pure copper; and the silver mines furnish private individuals in three days with a quantity of this metal equivalent to a Euboic talent. As to tin, according to the account of Posidonius, it is not found on the surface of the earth, as some historians assert, but it is also extracted from mines. Mines of this metal are found among the barbarous people who inhabit beyond the Lusitanians and in the Cassiterrides Islands, and tin is also brought from the British islands to Marseilles. Among the Artabri, in Gallacia, the last people of Lusitania, on the north and west, there is earth covered with a dust of silver, tin, and of the metal, known under the name of white gold, on account of its alloy with silver. This dust is brought down by the rivers, raked up by the women, and then washed by them in sieves placed upon baskets. This is what Posidonius says as to the mines of Iberia.

Polybius, in speaking of those of silver which exist near New Carthage (Carthagena) says that they are 20 stades from the city, that they are so great that they extend over a district of 400 stades in circumference, that they habitually employ 40,000 workmen, whose labour brings to the Roman people 25,000 drachms per day (about £350,000 per annum). I do not enter into the detail of all the other operations, which would be too long, I confine myself to what Polybius says as to the manner in which the silver is treated, which is contained in the rivers and torrents. After having pounded and sifted it over water, what remains is separated from the water and pounded again: after having been sifted again, it is pounded and sifted five times in all. After this the pulverized matter is melted to separate the lead contained in it, and the silver remains pure. These mines of silver still exist, but there and elsewhere they belong to the state no longer, but have been taken possession of by private individuals; those of gold on the contrary mostly belong to the state. Here as well as at Castalon (Caslona) and in other places are mines of lead, which contain silver, but in too small quantity to defray the expense of separation.

* B. 3. ch. 2.

A little way from Castalon is the mountain whence the Betis (Guadalquivir) springs; it is named the Silver Mountain, on account of the mines of that metal which it contains.*

Lusitania is watered by great and small rivers which contain many grains of gold. Although the country abounds in gold, the inhabitants preferred living by plunder.†

The mountains in the neighbourhood of Malacea (Malaga) contain in several places mines of gold and other metals.

Not far from Dianium (Denia) are very fine forges.‡

WORKS IN SPAIN.

In the neighbourhood of Asta (Mesa de Asta), Nebrissa (Lebrisa), Onoba (Gibraleon), are canals dug in several places to facilitate the navigation.§

Near Cadiz is to be seen the Tower of Cæpio built on a rock, washed on every side by the sea. This admirable work was constructed in imitation of the Pharos of Alexandria.‖

SCILLY ISLANDS.

The inhabitants trade in the tin and lead which they dig from their mines. Publius Crassus, who went there, found that their mines are not very deep.

WORKS IN GAUL.

The extracts which follow are from various books.

Marius, perceiving that the mouth of the Rhone was becoming gradually shoaled up, had a new channel dug, which received the greater part of the waters. This canal he gave to the Marseillese in recompense for their service in the wars, and it became to them a great source of riches on account of the dues which they levied on those who went up or down.¶

The road from Iberia to Italy passes through Nimes. It is good enough in summer, but very bad in winter and spring, on account of the rivers overflowing and depositing mud. This road passes several rivers by boats, or by bridges of stone or wood.**

The territory of the Cevennes abounds with gold mines.††

The Tarbelli, a people of Aquitaine, are in possession of the most esteemed gold mines: for without digging deep, lumps of gold as big as the hand are sometimes found, requiring only a slight washing. The rest of the mine consists of grains and lumps, which do not either require much work.‡‡

BRITAIN.

Britain produces gold, silver, and iron.§§

LIPARI.

Lipari has very productive mines of alum.‖‖

ROMAN ROADS AND BRIDGES.

The Romans, says Strabo, have principally employed themselves upon what the Greeks have neglected—I mean paved roads, aqueducts, and those sewers which drain the city of Rome. In fact, by cutting through mountains and filling up vallies, they have every where throughout the country made paved roads, which serve to convey from one place to another the goods brought by sea to the ports. The sewers of Rome, arched with dressed stone, are broad enough in some places for a cart laden with hay to pass; and the aqueducts bring water in such abundance as to form streams running across the city, cleansing the sewers, and are sufficient, as it may be said, to supply all the houses with great fountains, canals and reservoirs. This last advantage is principally owing to the cares of Marcus Agrippa, who has decorated Rome with many other public monuments.¶¶

The principal of the great roads which traverse the country are the Appian Way, the Latin way, and the Valerian Way.***

According to modern accounts, the Valerian way was about 100 miles long; for the first 15 miles are found ruins of bridges, causeways, &c. Beyond, the remains of it are not so evident, but the boldness with which it is carried across three mountain chains is surprising.

Near the city of Como, to master the people disposed to robbery, roads have been constructed, which are as practicable as it is possible for art to make them. Augustus, not content with clearing the roads of the banditti, has made them as convenient as possible, although the country is very difficult.†††

M. Emilius Scaurus constructed the Emilian Way running to Sabbata and Darthon: and there is another Emilian Way, which continues the Flaminian Way, and was the work of M. Emilius Lepidus, colleague of C. Flaminius* (This is an error of Strabo in attributing the Flaminian way to this Flaminius.)

The Salarian Way is a great road very short.† To it joins the Nomentan Way.

The Appian Way is paved from Rome to Brendisium (Brindisi), and is the most frequented of all the roads made in Italy. Beyond Terracina on the Roman side, the Appian way is bordered by a canal, which receives the water of the marshes and rivers. It is particularly by night that this way of the canal is preferred; upon it people embark in the evening, and leave it in the morning, and take for the rest of the journey, the Appian Way, but even in the day-time the boats are towed by mules.‡

Near Baiæ is an isthmus of a few stades, through which a road is tunnelled. Near Naples is a similar one, which, in the space of several stades, crosses the mountain situated between Neapolis and Dicearchia. Its breadth is such that carriages which meet find no difficulty, and light is admitted by several openings pierced internally from the surface of the mountain through a great thickness.§

The Aternus (Pescara) in the country of the Peligni is passed by a bridge 24 stades from Cortinium.‖

CANALS.

The greater part of Transpadane Italy is full of lagunes, and therefore the inhabitants have made canals and dykes as in Lower Egypt, a part of the inundated ground being drained and the rest navigable.

Epiterpum, Concordia, Atria, Vicetia, and some other small places in the neighbourhood of Ravenna, by small navigable canals communicate with the sea.

The Cispadane was for a long time covered by marshes, which arose from the superabundance of the waters of the Po, but Scaurus, by having navigable canals dug from Placentia to Parma, drained the plain.

Ravenna is a great city built on piles in the midst of the marshes, and intersected with canals, which are crossed by boats or bridges.¶

DYKE.

The Locrine Gulf in its breadth extends as far as Baiæ, and is separated from the external sea, in a length of 8 stades by a dyke broad enough for a great waggon to pass. This dyke it is said is the work of Hercules; as in rough weather the waves flowed over it, so as to make it impassable for foot-passengers, Agrippa had it raised higher.**

TIMBER.

From Tyrrhenia (Tuscany) is obtained timber for building, of which is made very long and straight beams.

Pisa supplies timber for building much used by the Romans.††

CEMENT.

Dicearchia or Puteoli has become a place of great trade, on account of the works by which it is sheltered, having in the sand of the neighbourhood (puzzolana) great facilities for such constructions. This sand employed in a certain proportion with lime, makes a body, and becomes very solid.‡‡

MINES AND QUARRIES.

The Salassi have gold mines, the working of which was facilitated by the Durias (Doria) which supplied the water required for the washings; so that, by diverting the courses by numerous branches, they often dried up the main bed, which was the cause of constant war with the neighbouring people, whose agriculture was affected. The Salassi, although conquered by the Romans and dispossessed of their mines, being masters of the mountains, continued to sell water to the mine contractors.

Polybius relates that in his time among the Taurisci Norici, (people of Corinthia, Istria, &c.) were mines of gold so rich that by digging the ground only two feet deep gold was met with, and that the ordinary works were not more than fifteen feet deep; that a part was native gold, in grains the size of a bean or a lupine, which in the fire only diminished an eighth, and that the remainder, although requiring to be more purified still, gave a considerable product. [He adds] that the Italians having entered into agreements with the barbarians for working these mines, in the space of two months the price of gold fell throughout Italy a third, and that the Taurisci having perceived it, turned out their foreign colleagues, and sold the metal themselves. At the present day the Romans possess these mines. The rivers, also, like those of Iberia, contain grains of gold, although in smaller quantity.§§

Near Acyleia (Aquileia) are mines of gold and iron easy to work.‖‖

Cisalpine Gaul has mines which are not worked so much as they used to be, perhaps because they produce less than those of the Transalpine Celts and of Iberia, but formerly they were worked very much, since a mine of gold was wrought even in the territory of Vercelli.*

In the territory of Poplonium (Capo di Campana) are some abandoned mines, and the forges in which is wrought the iron of Elba, which, as it can only be reduced in the furnaces, is transported to the continent, as soon as it is brought out of the mine. Strabo says that the excavation of these mines grew up.†

Pithecusa (Procida) has gold mines.‡

Near Luna in Tyrrhenia are the quarries of marble, white, and spotted with green, of which tables and columns are made of a single block. These quarries are so numerous and so well supplied, that they are sufficient for most of the fine works which are made at Rome and throughout Italy.

The Pisan territory has an abundance of marbles.§

Gabii near Palestrina is in the midst of the quarries most used by the Romans.

At Tibura (Tivoli) are quarries of those different kinds of stones known under the names of Tibnrtines, Gabians, red stones, of which most of the Roman buildings are constructed.||

ON THE FORMS AND PROPORTIONS OF STEAM VESSELS.

Sir—Among the numerous opinions which have been advanced, as to the causes of the failure in point of speed which has attended the voyages of the British Queen and President, a subject to which the non-arrival of the latter vessel has given a most painful interest, I have not met with one which appears at all conclusive or satisfactory. Deficiency of power is always the first reason assigned; and a writer in a professional periodical, assuming that the models of these vessels are as perfect as any in existence, has gone the length of asserting that the power necessary to produce the same speed in vessels of similar form, but different dimensions, must increase in a larger ratio than the tonnage. His first position as to the forms of the vessels could, I think, be easily proved untenable, and his conclusion tends to subvert a plain physical principle; as he would make it appear that to overcome the resistance of the water, in which the *surface* of the immersed portion of the vessel alone is concerned, requires power increasing in a greater proportion than is requisite to conquer the inertia; the latter being always directly as the *mass*. Yet similar opinions are avowed by most persons who place reliance on the popular notions prevalent respecting the models of these steamers.—The nearest approach to the true manner of considering this question which I have yet seen, is, I think, made by a correspondent signing himself E., in the number of your Journal for last January; where he remarks that of the vessels he mentions, the best have the most beam in proportion to their length; and afterwards, that more seems to depend on model than power. Taking somewhat similar ground, I shall endeavour to show that as regards the several points of speed, capacity for carrying fuel to advantage, efficient working of the paddles, good qualities as seaboats, and power of carrying sail on an emergency; one essential requisite for seagoing steamers is a good breadth of beam in proportion both to their length and depth; and out of these considerations will arise others as respects the most advantageous modifications of form in the fore and after body. On all these points I shall confine myself, as much as possiible, to such remarks as arise from known facts, my intention being merely to state opinions resulting from a good deal of observation, on a subject which I do not think has ever received the attention it deserves, from those more practically interested in it than myself. The first point to which I would call attention is that of speed. In all the comparisons which I have ever seen drawn as to the relative merits of different steam vessels, the principal data have always been the power of their engines, and the sectional area of the immersed parts of their bodies; and the comparison so far as regards the latter particular has always proceeded simply on the superficial area of these sections, no regard being paid to the increased pressure of the water with an increased depth: so that supposing two vessels have their immersed sectional surfaces parallellograms severally 40 feet wide by 15 feet deep, and 30 feet wide by 20 feet deep, these giving the same result as to area, their resistances are in the abstract considered equal, and any advantage which one such vessel may have in point of speed over the other, supposing their power, speed of engines, &c. to be equal, is always referred to some supposed superiority of form in the entrance and run of the faster vessel. Such a mode of calculation is founded, I believe, on the experiments of M. Bossut, who gives as a rule that any plane surface moving with a given speed perpendicularly against a fluid, suffers a resistance equal to the weight of a column of the fluid, with a base equal to the area of the moving surface, and of such a height as a body must fall to acquire the given velocity. I have never seen the details of these experiments, nor do I know whether they are within my reach, but I feel pretty certain that the surfaces made use of must have been immersed in all cases the same depth in the fluid, and the difference of dimension must have been made in breadth only, or such results could never have been arrived at. Suppose the two above named surfaces were those of flood gates; to ascertain the pressure of water on each, 600 square feet, the common result of 40×15, and 30×20, must be multiplied into the pressure at the mean depth of each. The pressure of water at the depth of $7\frac{1}{2}$ feet, the mean of 15, may be taken as 3·75 lb. per square inch; and that at 10 feet, the mean of 20, as 5 lb. These numbers multiplied into 86400 the number of square inches in each surface give the results of 325000 lb. = 145 tons 1 cwt. 88 lb. for the first named, and 432000 lb. = 192 tons 17 cwt. 6 lb. for the second, being about as 7 to 9; and yet if the rule applied to calculate the resistances of vessels be correct, these two surfaces when put in motion at the same speed, immediately have their amounts of resistance equalized, because their areas are equal!—Such a result is manifestly absurd; and as the increased pressure of water in the proportion of its depth is an established fact, I shall proceed on these premises to inquire into the manner in which these vessels would be affected by the alteration of form necessary to reduce their resistance in moving through the water. We will suppose, for simplicity of argument, that their transverse sections are uniform throughout, and that both in plan and elevation they are also parallellograms: that they are each of the length of 200 feet, and their cubic contents consequently the same, viz., 120,000 feet.

Fig. 1.

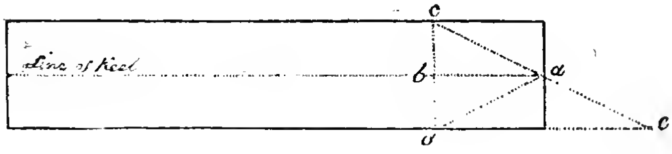

Fig. 2.

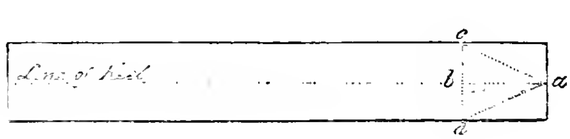

Suppose it were required to reduce their resistance by one half, preserving to the wider vessel her advantage of 7 to 9. Let fig. 1 represent the vessel of 40 feet beam, and fig. 2 that of 30. To effect the required reduction, we have simply to employ the principle of the wedge, and making $a\ b$ in each figure equal to $c\ d$, in the same we have $b\ a$, the velocity of the vessel, equal to twice $b\ c$, the velocity of the weight which represents the resistance of the water to the motion of the vessel in the direction $b\ a$. For the weight or resistance of the whole surface $c\ d$ is divided into two equal parts on the surfaces $a\ c$, $a\ d$, and these two halves being each moved the distance $b\ c$ or $b\ d$, while the vessel moves the distance $a\ b$, a power is shown exactly equivalent to that of a wedge $c\ a\ e$ in fig. 1. I state this thus fully because some writers on mechanics, as Emerson for example, make it appear that though the direction of the power be that of the line $a\ b$, it is to be calculated on the proportion which $c\ d$ bears to $a\ b$, instead of that borne by $c\ b$ or $b\ d$, the half of $c\ d$.

The vessels are thus reduced in their bulk or tonnage by the amount of a rectangular prism equal in its upper surface to the parallelogram $c\ b$, $b\ a$, and, (as we are at present considering only the immersed portion of their hulls,) of the immersed depths of each, viz., 15 feet in fig. 1, and 20 feet in fig. 2. Now $a\ b$ is in each equal to the beam of the vessel, and $c\ b$ equal to half $a\ b$, therefore the cubic contents of the parts removed are in fig. 1, $40 \times 20 \times 15 = 12,000$ cubic feet, and in fig. 2, $30 \times 15 \times 20 = 9000$ feet, giving a difference of 3000 feet, which divides exactly 40 times into 120,000, the total cubic contents of each vessel; thus by the sacrifice of $\frac{1}{40}$th part of the immersed portion of her body, we preserve to the vessel of greatest breadth her advantage in point of speed of 7 to 9, together with the other good qualities which I shall hereafter show to attend her proportions, by the alteration of form in the horizontal direction alone. We have next to consider how the relative merits of the two vessels will stand if it be required to give the same speed to both with the same power. Their relative resistances being as 7 to 9, we will suppose that the velocity attained by the narrower vessel with a given power is sufficient for the wider; to reduce the latter to the speed of the former, we again have recourse to the principle of the wedge, by making *a b* bear the same proportion to *c d*, or 10 feet as 7 to 9. We thus find as 9 : 7 : : 40 : 31·11; then *b c* 20 × 15 (the depth) × 31·11 = 9333 cubic feet, the amount by which the bulk of the wider vessel is decreased to attain the same speed as the narrow one. But the latter was shown to lose only 9000 cubic feet of her bulk by this means, and she has still therefore an advantage of 333 feet over the wide vessel, 333 will divide about 360 times into 120,000, therefore the wide vessel sacrifices 1-360th part of her bulk more than the narrow one to attain the same speed by alteration of her horizontal form; but this amount is so small as to be quite inconsiderable, for in a vessel of 2000 tons burthen the difference will be but $3\frac{1}{18}$ tons.

Thus much as to the diminution of resistance by alteration of the horizontal form; let us now inquire how the same effect may be produced by altering the vessels in their vertical section. Let fig. 1* represent the vessel of 40 feet beam, and fig. 2* that of 30, in elevation, or longitudinal section. The depth *a b* equals 15 feet in fig. 1*, and 20 feet in fig. 2*. To reduce their respective resistances as before to one half, we make *b c* equal to twice *a b*, viz., 30 feet in fig. 1*, and 40 feet in fig. 2*. They are then reduced in bulk as follows: fig. 1* by 15 × 15 × 40 = 9000 cubic feet, and fig. 2* by 20 × 20 × 30 = 12,000 cubic feet, showing a difference of 3000 cubic feet in favour of fig. 1*, being exactly what was lost when reduced in her horizontal form to give the same results. Again, to reduce the speed of fig. 1* to that of fig. 2*, make *b c* : 30 : : 7 : 9, thus *b c* = 23·33 feet, and $\frac{23{\cdot}33}{2} \times 15 \times 40 = 6999$ cubic feet, making a difference in bulk of 5001 cubic feet in favour of fig. 1*, at the same velocity as fig. 2*. Comparing these results we see that giving the wider vessel the same speed as the narrow one, she lost 333 cubic feet more of her bulk than the latter, by doing the same by change of form vertically she has an advantage of 5001 cubic feet.* As it is almost always necessary to employ both these methods of reducing a vessel's resistance, I shall suppose them equally applied, and deducting the loss from the gain we have still 4668 cubic feet of bulk remaining for buoyancy or stowage in favour of the wider vessel when the two have the same velocity: and as the loss in preserving her advantage of 7 to 9, by change of horizontal form exactly equalled her gain in doing so by the vertical alteration, if both means are equally employed we find she preserves her advantage in speed without any loss of bulk whatever beyond the narrow vessel, and, as I think can be proved, with many points of superiority in other respects. I have considered these effects as applied to bodies of simple parallelogramic forms in the first instance for the sake of simplicity of illustration, but the principle is applicable to all forms; and as regards vessels with sharp bottoms, and of a breadth of beam say equal to the wider vessel supposed above, and of a draught equal to the narrow one, their resistance may be resolved into that of parallelograms depending in their proportions of depth and width on the acuteness or obtuseness of the angle which their bottoms make at the keel, and on the depth of their bilge or union of the sides and bottom below the water line. I shall have occasion again to refer to this part of my subject when I come to speak of the comparative stability of vessels of different transverse sections. At present I shall only remark that the results of the above calculations are fully borne out by all the seagoing steamers I am acquainted with. For instance, the Gorgon and Cyclops of 1200 tons burthen and 320 horse power, having good beam, have performed excellently; while the Liverpool, in her first state of 1042 tons burthen, and 460 horse power, through great deficiency of beam, was a miserable failure; but since her alteration, though greatly increased in tonnage by the addition of 7 feet beam, she gives more satisfactory results with the same power than any of the large steamers built for crossing the Atlantic. The Great Western registering 1340 tons, and of 450 horse power, having pretty fair beam, was the only one of the New York steamers which could be said to answer, until the Liverpool was altered, since which time the latter seems to have the advantage. The British Queen and President have completely nullified the calculations of their projectors, and Mr. Cunard's steamers, almost equally deficient in this respect, employ about 500 horse power to do what, judging from past experience, the Gorgon* and Cyclops would in all probability easily effect with 320. I think these results, independently of others which, with your permission, I shall hereafter adduce, are sufficient to prove the fallacy of the almost universal belief among shipbuilders and others that narrow vessels are necessarily faster than those of greater beam. So strongly however is this opinion held, that I know that shipbuilders of considerable experience and ability have declared that no steamer should have beam in a larger proportion to her length than as 2 to 13; or in other words should have no less than $6\frac{1}{2}$ breadths to her length; a proportion which has proved insufficient in most of the points which I named as necessary for a seagoing steamer: and for the sake of this dogma though sometimes giving their vessels very good horizontal lines, they sacrifice all the advantages they might obtain by a proper application of the reduction of body vertically, and are obliged from their want of beam, to trust to the enlargement of their bows above water to prevent their constantly shipping water forward, involving defects which I shall endeavour to make clear if I continue the subject. The subject of long narrow steamers of small draught in proportion to their beam, which have had many advocates, will occupy another part of our consideration, and I refer to it here merely to say that it is not overlooked. I believe the late system of computing tonnage for shipping has had a great share in producing the defect in point of beam which is to be observed both in our sailing merchant vessels and in our mercantile steamers; for in consequence of the gross absurdity of assuming a fixed proportion of depth for every vessel, namely, half of their measured breadth, and 94 as the divisor for reducing the cubic result of the three dimensions to tons, however different in form the vessels might really be. Merchants and shipbuilders universally endeavoured to gain as much as possible on their registered tonnage, by giving depth beyond the imaginary standard, and a form fore and aft which should give an absolute amount of bulk much above the $\frac{4}{10}$ths of the parallelogramic solid which were supposed, by the use of 94 as a divisor, to remain after reducing the vessel by the sharpening of her bottom, entrance, and run. This style of building has been frequently carried, as too many fatal instances have proved, far beyond the limits of safety, while vessels of really good proportions and fine form being registered by this method of a much greater tonnage than their real burthen, had an absolute fine in the shape of duty imposed on their good qualities.—In the fruit trade and others especially requiring speed, this has led to the building of deep narrow vessels sharp forward, and lean and hollow abaft, gaining somewhat in tonnage, but wanting in all really good qualities, being the wettest and most uneasy vessels which leave our ports. The numerous beautiful models which have fallen into the hands of our merchants as slave prizes have for the same reason, almost without exception, been lengthened and raised upon, have had all their fine points destroyed, been greatly reduced in speed, and frequently become exceedingly unsafe vessels, as was the case with a most beautiful slave schooner sold for the turtle trade in this port a few years ago, which having been raised upon, lengthened, and square rigged, went to the bottom on her second voyage. Since the passing of the New Tonnage Act, which assigns as nearly as possible the real contents of a vessel for her register, it might have been expected that some improvement would have taken place in the models leaving the stocks in our merchant builders' yards, but so strong is habit, especially bad habit, and so rooted is prejudice, particularly in matters where expediency and not principle has been the ruling power, that hardly any use has been made of the advantages offered by the new act, and our

newly built merchant ships, in general, present no more satisfactory aspects than their predecessors; and the proportions published as those of the new steamers building in Scotland for Government, are a further illustration of this position.* Unfortunately this defect has influenced the docks intended for the reception of merchant steamers, and unless the gates of those in this port were increased in width they would not admit steamers of the same tonnage as those now using them, but of greater beam.—Having trespassed at so great length on your space, I beg to observe in conclusion, that my reason for having cited no authority in support of my views is simply that I have met with none taking the same ground; and of those treating on this subject under any aspect, the older ones are generally very vague and general in their statements; and the more modern, though entering at great length and with much pains into particular forms, are so partial in their manner of considering the matter, that of the two whose opinions have latterly carried most weight, I have found one advocating the construction of seagoing steamers twelve times as long as they are broad, and the other predicting the time when masts and sails would be considered mere useless incumbrances, and our line-of-battle ships be used only as coal transports for steamers. Such ideas indicate any thing but a comprehensive mode of viewing this subject, and not trusting much to the assistance to be derived from such sources I have preferred merely stating the result of my own observations, relying on the candid consideration of those who are practically interested in this matter.

I am, &c.,

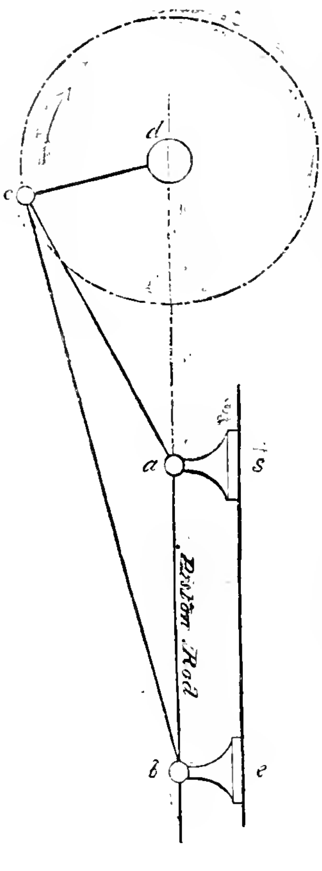
ON LONG AND SHORT CONNECTING RODS.



Sir—Perceiving in your excellent Journal for this month, an article respecting long and short connecting rods, wherein it is stated that the short connecting rod is as effective as the long one, I take leave to send you a diagram, which will perhaps show that there is a greater amount of friction with the short connecting rod.

The accompanying figure represents the direct connection with the piston of a long and short connecting rod. In this case it is clear that the long rod *c*, *b*, is working always nearer the *parallel line* of the piston than the short rod *c*, *a*, or that the short rod is pushing against the slide *s*, *e*, at a much greater angle than the long one, and consequently that there must be less friction at *e*, than at *s*, therefore as the angle *c*, *a*, *d*, is greater than the angle *c*, *b*, *d*, so is the friction at *s*, greater than the friction at *e*. The same results will be found with common marine and all other engines, only that where slides are used there is always a much greater amount of friction than upon centres. I am however of opinion, that a short connecting rod, with a direct connection with the crank, might be used with greater effect than a longer one in the common marine engine, where heavy side levers are kept continually reversing their motion, besides the extra weight which the boat has to carry.

I am, Sir, your most obedient servant,

J. F.

London, July 12.

Sir—In your July number you have a letter from Mr. Daniel Clark on "Long and short connecting rods," in which he arrives at the conclusion that "upon the whole, then, short and long connecting rods on the same length of crank must be equally effective, whatever peculiarities there be." In this, however, I do not concur with him and would recommend him to re-consider the subject and see if really the force (see Mr. Clark's first figure) D C or E M be of no consequence; I think he will find it to be of the greatest consequence, and to be together with the analogous force of pressure on the other journals, the reason why long connecting rods always have been and always will be preferable, and why, moreover, an engine, the connecting rod of which bears to the length of the crank a ratio less than a certain quantity, would not work at all. Mr. Clark would find it very interesting to consider minutely the case in which the length of the connecting rod is equal to the length of the crank, he will find that the strength required for the paddle-shaft, the connecting rod, all the journals, the framing, and in fact the whole engine, is what may probably startle him.

I am, Sir,

Greenock, July 5. Your obedient servant,

J. G. L.

MR. PARKES NEW THEORY OF THE PERCUSSIVE ACTION OF STEAM.

Sir—Feeling some interest in Mr. Parkes' new theory of the percussive action of steam in the Cornish engines, might I offer a few remarks on the former part of a paper which appeared in your Journal for this month. The writer of that paper appears from his remarks at the beginning, to have an opinion that Mr. Parkes has rather favoured the Cornish engines, in considering that the percussive force of steam is only developed in them; and he remarks that if such a property does exist in the steam, we might expect to find it more fully developed in the case of the locomotive engines; for he says, "though why he considers it to operate in these engines only, we know not; we are of opinion that if it obtains in them, it should obtain *à fortiori* in locomotives, where the density and velocity of the steam entering the cylinder are so much greater."

The object of the following remarks is to try to show that the Cornish single-acting engines are the only ones at present in which the percussive force of steam could act with any very great advantage; and that the locomotives are the very worst engines in which it could be used as a moving force.

We will first of all take the case of a common double-acting rotative engine. In these engines the slide is so adjusted as to let the steam into the cylinder when the piston is either at the top or bottom of its stroke; and consequently, when the crank is just passing the centre. Now this being the case, it is evident that any percussive force of the steam striking upon the piston would be injurious rather than benefit the engine, as it could not by any means have any effect in turning the crank, but, on the contrary, only create an additional wear and tear of the different working parts, on account of the violent jerk which would be the effect of its striking upon the piston while the crank is in such a position as not to let it recede before the blow. In this engine, then, as at present constructed, we must not expect to find any very great economy by bringing this force into action.

In consequence of the rapidity with which the strokes of the piston in a locomotive follow one another, it is found necessary to admit the steam into the cylinder before the piston has finished its stroke, for two reasons: 1st, it is found necessary to admit the steam into the opposite side of the piston before it has finished its stroke, in order to bring it gradually up to the stop, and to diminish the violent jerk that would be occasioned by its motion being so rapidly changed, and 2ndly, so that it may be ready to act as soon as the piston has finished its stroke. This being the case, the percussive force of steam would act still worse here than in the before-mentioned case, as it would, instead of helping to impel the piston, actually impede it, if not stop it altogether. In this case, as well as in the former, the percussive action is altogether avoided by the gradual motion of the slide, for as soon as the slide begins to open the steam way, the steam rushes into the cylinder and strikes upon the piston, but with very little effect, on account of its being so much wire drawn in consequence of the small size of the opening at first.

In order to render the percussive force of steam available to its fullest extent as a moving power in single acting pumping engines, it would be necessary to have some medium interposed between the direct action of the steam on the piston and the pumps; so as to convert the ever-varying pressure on the piston into a regular and steady pressure on the plunger of the pump. This I think will be clearly seen, for if we suppose for an instant this medium not to exist, such as

* The Forth has lately arrived in Liverpool, and fully confirms the above opinion; proving with two steamers lately sent hither from Hamburg, that the examples of the Liverpool, British Queen and President have not influenced their builders in assigning the proportions of breadth and depth.

the momentum of the different parts of the engine, the pump rod, and the column of water set in motion; we must come to the conclusion that as the pressure on the piston varies without any medium to equalize its effect, the resistance opposed to the pump plunger ought to vary also.

In the common single acting pumping engine this medium is in a measure supplied by the weight of the pump rod, which is made sufficiently heavy to overcome the friction of the engine, and to raise the piston at the return stroke, and by the momentum of the beam and other parts of the engine; and also by the momentum of the column of water before it enters into the air vessel; these however would form but a very small reservoir for the immense pressure at the commencement of the stroke, so that in these engines the application of the percussive force must be very limited, in consequence of the pump rod not being of a sufficient weight to accumulate all the overplus power at the commencement of the stroke, so as to impart it to the plunger when the pressure on the piston, in consequence of the expansion of the steam, falls below the resistance on the plunger so that the percussive force would be in a great measure entirely wasted. Again on the other hand, if the rod which generally weighs from 8 to 9 tons, were made heavier, so as to equalize to a great extent the pressure on the plunger, it would be more than necessary to overcome the resistance of the engine at the return stroke, and so occasion a loss of power.

The action of the Cornish single acting engine is somewhat different from that of the common one, the pressure of the steam on the piston instead of being applied directly to work the pumps, is applied to raise a pump rod of sufficient weight to work the pumps at the return stroke. The result of this difference of arrangement is that instead of having a pump rod of 8 or 9 tons weight, we get one of from 20 to 70 tons weight according to circumstances. Here then we get an immense mass of matter amply sufficient to accumulate all the overplus power at the commencement of the stroke, and to return it as required at the end of it. The action of it is this: the steam being admitted suddenly into the cylinder strikes upon the piston at rest with a considerable force above what is due to its elastic pressure alone, and sets this massive pump rod in motion; the steam in the cylinder expands, and consequently acts with less force on the piston, and the pump rod after the pressure of the steam on the piston, becomes insufficient of itself to raise it any higher, assists to carry itself through the remainder of the stroke, by means of the power that it accumulated at the commencement. When the rod is thus as it were thrown up to the top of its stroke, the equilibrium valve is opened and the weight of the pump rod descending acts upon the plunger of the pump and raises the water. In this engine then we have the means of applying the percussive force of steam to almost any extent in cousequence of the weight of the pump rod, which acts as a reservoir for the power that would otherwise be wasted.

These remarks I think have clearly shown that in the common double acting engine the percussive force of steam could not be made to act with any advantage, but would, on the contrary, occasion an additional wear and tear; that in the locomotive it would act still worse, and would actually impede the engine, if not stop it altogether; that in the common single acting pumping engine it could only be brought into useful action in a small degree; and that in the Cornish engine we might use it as a moving force to a very considerable extent.

When we consider the amazing quantity of work done by the Cornish engines as compared to any other, we are perfectly at a loss to account for the difference, and are brought to the conclusion that there must be some force in the steam which can only be applied to any considerable extent in those engines, and which will not allow of being so applied in any others. The elastic force of steam can be applied in any sort of engine, the expansive force can be applied economically in all, but more so in the Cornish than any other engines; but still this is insufficient to account for the difference of the amount of duty done. The only other force that we can conceive the steam to possess is that which Mr. Parkes has denominated its percussive force. If the conclusion drawn from the preceding remarks be just, we see that the Cornish engines are the only ones in which this force could be applied to any considerable extent.

It also stands to reason that if this force does exist in the steam, and if it was usefully applied it would increase very considerably the duty done. It is also now a fact well ascertained that the Cornish engines will do three times the duty of any other with the same expenditure of fuel.

Is it not then reasonable to infer that as the Cornish engines are the only ones in which the percussive action could be employed to any considerable extent, and that they alone perform that additional work that would be the effect of this force if usefully applied, we may safely conclude (if all other evidence was wanting), that this percussive force does actually exist in the steam, and that it in a great measure will account for the quantity of work done by these engines.

Hoping that these observations may help to throw a little light on the subject, and may induce some of your readers who may have the means, to pay a little attention to the subject.

I remain, Sir, your's, respectfully,

C. S.

Bankside, Southwark,
August 13, 1841.

ON THE MOMENTUM PROPOSED BY MR. JOSIAH PARKES, AS A MEASURE OF THE MECHANICAL EFFECT OF LOCOMOTIVE ENGINES.

By the Count De Pambour.

In the *Transactions of the Institution of Civil Engineers*, vol. III, Mr. J. Parkes has published a paper *On Steam-boilers and Steam-engines*, in which the object s to propose, as a new measure of the mechanical effect of locomotive engines, what he calls the *momentum* produced by the engine, that is to say the product of the mass, in tons, of the engine, tender and train, multiplied into its velocity, in feet per second. According to him, this momentum being measured at one velocity, for a given engine, the effect of the same engine, at any other velocity, will be immediately deduced from it by a single proportion (page 130), without troubling one's head about the inclination of the road, the friction of the wagons or the engine, the counter-pressure due to the blast-pipe, the resistance of the air, or, in fact, any of the resistances really encountered by the engines.

To establish this new idea, Mr. Parkes' first step is to represent as altogether faulty and impossible every calculation or experiment made by others, to take account of the divers resistances offered to the motion of the engines. With this view he enters into a long and malevolent discussion on the experiments of our *Treatise on Locomotive Engines*, and on all the experiments on the same subject published by different engineers; and to demonstrate the difficulties insurmountable, in his opinion (page 124, 129), and the uncertainty attending such researches, he indicates several verifications which, as he says, these experiments ought to satisfy, and which they do not satisfy. As Mr. Parkes gives on the subject a great number of arithmetical calculations, the errors of which are protected against detection by the heap of figures presented, we shall first enter, with some detail, into the examination of his pretended verifications, and afterwards shall discuss the value of the new measure proposed by him to represent the mechanical effect of locomotive engines.

On seeing the *fundamental* errors on which his reasoning and his calculations are grounded, the inaccuracy of his criticisms and of the results at which he has arrived, will be at once recognised.

1st. Mr. Parkes proposes to calculate the pressure at which the steam was necessarily expended on the cylinder of each engine submitted to experiment, in order afterwards to compare that pressure with the pressure resulting from the sum of the different determinations of resistances exerted against the piston, according to the *treatise on locomotive engines*. With this view, he seeks, from the velocity of the engine, the number of cylinders full of steam which were expended per minute. Comparing the volume thus obtained to the volume of water vaporized in the boiler, he concludes the *relative* volume of the steam during its passage into the cylinder; and finally, recurring to the table of the relative volumes of steam under divers pressures, contained in our *Theory of the Steam Engine*, he concludes the pressure which the steam must necessarily have had (page 82, &c.) This is conformable to our theory developed in the *Treatise on Locomotive Engines*, which, in fact, Mr. Parkes entirely adopts. But to perform this calculation, Mr. Parkes takes the *average* velocity of the whole trip from Liverpool to Manchester (page 85, and table viii., col. 10; table xiii., col. 9; table xvi., col. 2, &c.), and from that velocity he pretends to deduce the *mean pressure* of the steam in the cylinder during the same trip. Now it will be easy to prove by an example that this mode is altogether faulty.

Suppose, in effect, the engine Atlas has travelled a distance of 30 miles in an hour and a half, vaporizing 60 cubic feet of water per hour. As the wheel of the engine is 5 feet in diameter, or 15·71 in circumference, as there are two double cylinders-full of steam expended at every turn of the wheel, and as the capacity of those two double cylinders, including the filling up of the steam ways, amounts to 4·398 cubic feet, it follows that the volume of the steam which passes into the cylinders per mile performed, or per distance of 5280 feet, is

$$\frac{5280}{15{\cdot}71} \times 4{\cdot}398 = 1178 \text{ cubic feet.}$$

This premised, when Mr Parkes refers to the average velocity of the whole trip, to value the pressure in the cylinder, as that velocity is 20 miles per hour, and as the vaporization at the same time is 60 cubic feet of water per hour, he finds, for the ratio of the volume of the steam expended to the volume of water, $\frac{1478 \times 20}{60} = 492{\cdot}7$. Consequently, recurring to the table of the relative volumes of steam under different pressures, he obtains for the corresponding total or absolute pressure 56·66 lb. per square inch; and deducting the atmospheric pressure, he obtains for the effective pressure, 41·95 lb. per square inch.

But to show that this mode of calculating, from the average velocity, can only lead to error, let us suppose that, by reason of the divers inclinations of the portions of the railway, the first 15 miles have been traversed in half an hour, and the other 15 miles in an hour, which still makes 30 miles in an hour and a half; as 30 cubic feet of water will have been vaporized in the first half hour, or during the passage of the first 15 miles, and 60 cubic feet of water during the next hour, or in the passage of the last 15 miles, it is plain that the volume of the steam will have been respectively in each of those times $\frac{1478 \times 15}{30} = 739$ first, and afterwards $\frac{1478 \times 15}{60} = 369{\cdot}5$. Whence results, according to the table, that the effective pressure of the steam will have been successively 21·62 and 62·95 lb. per square inch.

Thus, during the first half hour the effective pressure will have been 21·62 lb.; during the second half hour it will have been 62·95 lb., and during the third again 62·95 lb. Consequently, taking account of the time during which the pressure has had these respective values, it is plain that the mean effective pressure in the cylinder will really have been $\frac{21{\cdot}62 + 62{\cdot}95 + 62{\cdot}95}{3} = 49{\cdot}17$ lb. per square inch, and not 41·95 lb. per square inch, as given in Mr. Parkes's calculation; which, by the fact, supposes all the portions of the trip to have been performed in equal times. In this case, therefore, which has nothing in it but what is very ordinary, there would be an error of 7·22 lb. per square inch out of 41·95; that is an error of more than $\frac{1}{6}$ on the effective pressure of the steam. It is evident that the calculation, such as Mr. Parkes makes it, is exact only for portions of road composed of one inclination, or travelled with *uniform* velocity, and that it cannot apply to the total passage of a line composed of different inclinations. For further elucidation on this head, we refer to chapter XVII., relative to inclined planes, of our *Treatise on Locomotive Engines*, 2nd edition, and to chapter XII. of the same work, in which all the experiments considered by Mr. Parkes are calculated.

2nd. We have just shown the first error which Mr. Parkes introduces, as a fundamental basis, in his calculation of the pressure of the steam in the cylinder. But he does not stop there. In the table of experiments on the vaporization of the engines (*Treatise on Locomotive Engines*, page 175 of first edition, and page 253 of second edition), we have given the average velocity of the engines during each trip; and that velocity is obtained simply by dividing the whole distance performed, by the time employed in performing it, as is seen in the table in question. It would be natural then for Mr. Parkes, who, as has been said, is satisfied with average velocities in his calculations, to take those which are given in the table; but instead of that, he augments almost all the velocities about $\frac{1}{5}$. Thus, for instance, the VULCAN, which travelled 29·5 miles in 1 hour 17 minutes, and whose average velocity in consequence was stated to be 22·99 miles per hour, had, according to Mr. Parkes, a velocity of 26·90 miles per hour. The velocity of the VESTA rises from 27·23 to 31·60 miles per hour, and so of the others (table viii., col. 10; table xiii., col. 9; table xvi., col. 2). The critic falls into this new error because, in the *Treatise on Locomotive Engines* (page 324 first edition, and page 311 second edition), in speaking of fuel, it is said that, when the engines ascend without help the inclined planes of the Liverpool and Manchester Railway, the surplus of work, thence resulting for them, equals, on an average, the conveying of their load to $\frac{1}{5}$ more distance, and Mr. Parkes logically concludes from this that the *velocity* of the engine must be by so much increased (pages 86, 112). So that if an engine perform 1 mile in 4 minutes, ascending a plane inclined $\frac{1}{89}$, which renders nearly five-fold the work of the engine, it would follow, from this calculation, that the velocity would not have been 15 miles per hour, but $15 \times 5 = 75$ miles per hour, since the quantity of work done would have been five-fold! Mr. Parkes's error proceeds from his having applied to the velocity a correction which refers only to the *work* done, and, as a consequence, to the corresponding consumption of *fuel*.

But on examining what effect results from this substitution of the imagined velocity of Mr. Parkes for the observed velocity, it will be remarked that whenever an engine is obliged to ascend without help one of the inclined planes of the Liverpool and Manchester Railway, it exerts at that moment, as we have said, an effort five times as great as upon a level, and draws its load less rapidly. One would deem it then allowable to conclude, that the average pressure of the steam in the cylinder must be augmented, since during a certain portion of the trip, the effort required is greater, and that the *useful* effect per unit of time must be diminished, since during the same time the useful load is drawn at less velocity. But no. Mr. Parkes's calculation, by augmenting, then, the apparent velocity of the engine, demonstrates that, in this case, the average pressure in the cylinder becomes on the contrary much *less*, and that the useful effect becomes much *greater*. So that the error committed produces itself here in the two opposite ways.

With these elements Mr. Parkes establishes the *whole* of his calculations and tables, to the very end of his paper (table viii., col. 10; table ix., col. 19; table xiii., col. 9; table xiv., col. 2; table xvi., col. 2); and as, to augment the evil, this pretended correction is made only on one portion of the experiments, namely those in which the engines were helped up the inclined planes, without being made in the other cases, there results an inexplicable confusion in all the calculations. Thus, it happens that Mr. Parkes's determination of the volume and pressure of the steam consumed by the engines (table ix., col. 26, 29), the horse power produced per cubic foot of water vaporized, or the quantity of water employed to produce one horse power (table x., col. 44, 45, 49, &c.), the momentum generated per pound (table xiii., col. 11, 12; table xiv., col. 9, 10, 11), and all the consequences thence derived are in every way erroneous.

To show by a particular example, the fallacy of the results to which Mr. Parkes has been led by this wholesale and faulty way of calculating, we need only refer to the two experiments of the FURY, which he extracts from our work on locomotive engines. He pronounces, "with certainty," (page 128), these two experiments to be erroneous, as exhibiting an engine performing more work at 23 than at 21$\frac{3}{4}$ miles per hour, in the ratio of 21 to 19. Now, to arrive at this conclusion, Mr. Parkes first takes the velocity of the engine, not at 18·53 and 19·67 miles per hour, as given from actual observation, page 175 of the first edition, and pages 253 and 392 of the second edition of our Treatise on Locomotive Engines, but at 21·79 and 23 miles per hour (table xiii., col. 3). Secondly, in comparing the work done in the two trips, he does not take into account that the first of the two trips has been made from Manchester to Liverpool, and the second on the contrary from Liverpool to Manchester. But there is a general rise of the ground from Manchester towards Liverpool, and from that circumstance, the gravity opposes more resistance in that direction than in the contrary one. Thus it happens that a less train carried on the line from Manchester to Liverpool, may require from the engine, a greater quantity of labour than a heavier train carried in the opposite way. In effect, by referring to pages 501 and 504 of the second edition of our work on locomotives, it will be found that in the two experiments under consideration, the work done by the FURY, in carrying the two loads of 43·8 and 51·16 tons, besides tender, from Manchester and from Liverpool respectively, to the other end of the line, was

43·8 tons, from Manchester to Liverpool, equal, gravity included, to - - - 1964 tons to 1 mile.
51·16 tons, from Liverpool to Manchester, equal, gravity included, to - - - 1837 tons to 1 mile.

We see, therefore, that when we take an account, as we ought to do, and as Mr. Parkes has not done, of the surplus of labour caused by gravity, the work required of the engine is in reality more in the first case than in the second, although the load itself is less. Consequently the engine ought to have accomplished the second trip in less time or with a greater average velocity than the first, which in fact it did, and which had led Mr. Parkes to pronounce with such "certainty" the experiments to be erroneous.

This example shows that the calculation of Mr. Parkes, made with an erroneously averaged and exaggerated velocity, in which, moreover, he omits the gravity on the inclined planes, the resistance of the air, the friction of the engine, and all the other resistances really opposed to the motion, leads him to a *very inaccurate* measure of the work performed by those engines; and this refers to the whole of the results obtained, table ix., col. 29—32; table x., col. 41—50; table xiii., col. 11, 12; table xiv., col. 9, 10, 11; table xvi., &c., and also to his comparison of locomotive and stationary steam engines, which we shall notice further on.

3rd. After having calculated *very exactly*, as we have shown, the pressure of the steam in the cylinder, Mr. Parkes compares the result which he has obtained, with the total pressure on the piston resulting from the partial resistances suffered by the engine, according to the *Treatise on Locomotive Engines;* and as, in the first edition of that work, the author had confined himself to mentioning the pressure against the piston due to the action of the blast-pipe, without making any experimental research on the subject, Mr. Parkes, without noticing the results presented since in the *theory of the steam engine*, (page 161), takes the difference between the two results, as necessarily expressing the pressure due to the blast-pipe (pages 82, 83); and he demonstrates the inaccuracy of it. Here we perfectly agree with him; for, besides the errors already pointed out in his research of the pressure of the steam in the cylinder, every thing variable that can occur in the different data of resistance, now passes to the account of the pressure due to the blast-pipe, and must necessarily come to falsify the calculation of it. Thus, for instance, in the experiments, a great deal of water was lost by *priming*, and there resulted an apparent vaporization greater than the true one. A part of the difference between the calculated and the observed pressure was therefore to be attributed to that cause, though it could not be accurately measured; but, by the calculation of Mr. Parkes, it all passes to the account of the pressure due to the blast-pipe. Similarly, the resistance of the air, then imperfectly computed in the total resistance for an average velocity of about 12 miles per hour, is found, in all cases of greater velocity, to augment considerably the pressure due to the blast-pipe, and on the contrary to diminish it in all cases of less velocity. A favourable or an unfavourable wind necessarily produce similar effects. Thus, circumstances, combined with the fundamental errors already introduced in the calculation, raise or lower that pressure to all imaginable degrees (pages 87, 88, 90, 91); and it will be readily imagined that such a determination cannot be exact.

4th. Mr. Parkes has observed, in the experiments of the *Treatise on Locomotive Engines*, and particularly in two of them, made with the LEEDS engine, and quoted in the *Theory of the Steam Engine*, that the useful effects produced by the same quantity of water vaporized varies according to different circumstances, and he is amazed at it; for, as he affirms, the useful effects produced by the same quantity of water vaporized, in the same time and under the same pressure in the boiler, ought in all cases to be identical (pages 104, 119). But this again is merely an error of the critic; for if we suppose a locomotive engine drawing a heavy load at a small velocity, since it is only at a small velocity that the engine has to overcome its friction, as well as the atmospheric pressure against the piston, and, above all, the resistance of the air against the train, it follows that out of the quantity of total work executed, there will be but a trifling portion lost in overcoming those resistances; but if, on the contrary, we suppose the same engine performing precisely the same quantity of *total* work, but drawing a light load at a great velocity, it is obvious that a much greater part of the work done will be absorbed in moving, at that velocity, the resistance which represents the friction of the engine, as well as the atmospheric pressure against the piston, and in overcoming the resistance of the air, which increases as the square of the velocity; and consequently there will remain a much smaller portion of it applied to the producing of the useful effect. Hence, in the two cases considered, the useful effects produced by the same quantity of water vaporized, so far from being identical, will, on the contrary, be very different from each other. Mr. Parkes may, besides, satisfy himself on this point, by perusing the *Theory of the Steam Engine*, in which he will find numerous examples of steam engines, in which the useful effect of one cubic foot of water varies in very wide limits, according to the velocity of the motion or the load imposed on the engine; and he will find it explained theoretically in chapter XII. of the *Treatise on Locomotive Engines*, or in chapter III. art. II, of the *Theory of the Steam Engine*. Thus Mr. Parkes's reasoning errs again by the basis itself.

5th. But there is another principle to which Mr. Parkes would subject all the observations of vaporization of locomotive engines. He remarks that in the two experiments above cited, the total resistance opposed to the motion is different in the two cases. Consequently, says he, the quantities of water vaporized by the engine in the same time must be in proportion to the pressures in the cylinder, and the experiments ought to satisfy this condition (pages 90, 100). Upon this point he is merciless.

To establish this new principle, Mr. Parkes recurs to the *Treatise on Locomotive Engines* itself. He quotes a passage in which, supposing same engine travelling the same distance with two different loads, the author says positively that the distance travelled being the same in both cases, the number of turns of the wheel, and consequently the number of strokes of the piston given by the engine, that is to say, the number of cylinders full of steam, or finally the total volume of steam expended, will also be the same in both cases; whence results that the same volume will successively have been filled with two steams at different pressures, or in other words, at different densities; and consequently the quantities of water which have served to form those steams will be in proportion to their respective pressures (page 310—312 of the first edition). Thus, this passage establishes very distinctly that the quantities of water vaporized, *for the same distance*, are in proportion to the pressures of the steam in the cylinders. But what does Mr. Parkes conclude from this? Why, that the quantities of water vaporized *in the same distance* are in proportion to the pressures in the cylinder. Now it happens to be just the contrary; for, if we suppose, by way of example, the two pressures to be in the ratio of 2 to 1, the volumes of water vaporized for the same distance traversed, will also be in the ratio of 2 to 1; but if the time employed in performing the distance in question be two hours in the first case, and one hour in the second, it is plainly the quantities of water vaporized in two hours and in one hour respectively, which will be one to the other in the ratio of 2 to 1, so that the vaporizations per hour, or *in the same time*, will be equal instead of being in the ratio of the pressures. Thus it is clear again that Mr. Parkes's principle rests but on a new error, which consists in making a confusion between the vaporization for the same distance and the vaporization for the same time.

6th. A final observation of Mr. Parkes (pages 89, 90, 98), is this, that in some experiments, the locomotive engines produced, for the same quantity of water vaporized, a greater useful effect than several stationary high-pressure steam engines, or even than several condensing steam engines; and he considers this result as a proof of the inaccuracy of those observations; for, says he, the locomotive engines having to contend with the pressure arising from the blast-pipe, which the high pressure engines have not, and also with the atmospheric pressure, neither of which resistances the condensing engines have to contend with, it is incontestable that they cannot even produce equal effects, much less superior ones (page 104). But this reasoning is as unfounded as those we have already noticed; for, since the useful effect of steam engines, for the same vaporization, diminishes as the velocity of the motion increases, which has been already explained above, and which is found developed, either in chapter XII. article II. of the *Treatise on Locomotive Engines*, second edition, or in chapter III. article II., section 1, of the *Theory of the Steam Engine*, it is easy to conceive that a locomotive working, for instance, at its maximum useful effect, that is to say, with its maximum load, and consequently at a very small velocity, at which the pressure due to the blast-pipe and the resistance of the air are nearly null, can produce a useful effect greater, nay much greater than a stationary high pressure engine, working on the contrary with a light load and a great velocity. The same inferiority of effect may also occur in a condensing engine, because an engine of that system working, for instance, at 16 lb. pressure per square inch in the cylinder, and condensing the steam to 4 lb. per square inch *under the piston*, where the pressure is always greater than in the condenser, loses, by that fact alone, a quarter of the power which it applies: whereas a locomotive, working at 5 atmospheres in the cylinder, and at a very small velocity, which renders almost null the pressure due to the blast-pipe, suffers, by the opposition of the atmospheric pressure, a loss equal to only $\frac{1}{5}$ of its total power. Hence, definitively, in the latter engine, the counter-pressure against the piston destroys a smaller portion of the total power applied, and consequently, without even noticing the difference of friction of the two engines, or entering into any other consideration relative to the velocity, it is conceivable that the useful effect of the locomotive may be found greater.

But if a more complete calculation be desired, it will be easy to furnish it; for the relative volume of the steam at 16 lb. pressure per square inch, being 1672 times that of water, it is plain that if S represent the number of cubic feet of water vaporized per minute in the boiler, and if a represent the area of the cylinder expressed in square feet, $1672\ S$ will be the volume of the steam generated per minute, whence results that $\frac{1672\ S}{a}$ will be the velocity, in feet per minute, assumed by the piston of the engine working at that pressure. Moreover, the *effective* pressure of the steam or the load which the piston can support, is $16 - 4 = 12$ lb. per square inch; which gives $12 \times 144\ a$ for the total resistance, in pounds, supported by the piston. Thus, in the condensing engine, the effect produced by the number S of cubic feet of water, expressed in pounds raised one foot per minute, is $1672 \times 12 \times 144\ S = 2{,}889{,}216\ S$. Calculating in the same manner the case of the locomotive engine, we find that the effect it produces for the same vaporization S, working at the total pressure of 75 lb. per square inch, or at the effective pressure of 60 lb. per square inch, and expressed in pounds raised 1 foot per minute, is $381 \times 60 \times 144\ S = 3{,}291{,}840\ S$. Therefore, finally, its useful effect, per cubic foot of water vaporized, will exceed that of the condensing engine, and this again is a circumstance, examples of which will be found in the *Theory of the Steam Engine*.

Thus this new peremptory condition which the experiments ought to satisfy is as unfounded as the former ones; and, in fact, Mr. Parkes contradicts it, himself, a little further on (pages 157, 158), so that we might have referred his first argument to his second, for refutation. But, besides the foregoing observations it must be borne in mind that the velocities employed by Mr. Parkes, for locomotive engines, being nearly all considerably augmented, as has been explained above, he must necessarily arrive (pages 85, 87, 89, 92, and tables x., xiii., xiv., xvi.), at exaggerated results, for the effects which he supposes to have been produced by those engines; and therefore his comparison between locomotive and stationary engines, is altogether founded upon false calculations.

It is remarkable, finally, that in applying the preceding considerations to all the experiments published on locomotive engines, by different engineers, namely, Messrs. R. Stephenson, N. Wood, E. Woods, and Dr. Lardner (pages 102, 117, 118, 159), Mr. Parkes finds that the conditions to which he proposes to subject those experiments are not verified in them. Such a result ought to have put him on his guard against the validity of his own arguments; but the want of knowledge in the principles of Mechanics and of habit in mathematical reasoning (the author tells us that he is more accustomed to handle the hammer than the pen), causes him to heap errors on errors, combining and complicating them unawares, till he arrives at a point where he does not produce a single result that is not erroneous.

There is a matter of surprise in the numberless errors contained in the paper of Mr. Parkes, and of which, for the sake of brevity, we have noticed merely the principal ones, reserving the rest for another opportunity if necessary. But on inquiring what was the end he had proposed to himself, what was to be definitive consequence of his labour, one is yet much more surprised.

His object is to propose a new measure of the effect of locomotive engines; and this *new* measure is what he calls the "momentum" generated, that is to say, "the product of the mass, in tons, of the engines, tender and train, multiplied into its velocity, in feet per second." This standard is to "represent the repective mechanical effect produced per second by each engine" (page 128).

Now, the true mechanical produce includes the whole of the resistances and frictions really overcome by the engines; that is to say, the friction of the carriages, the friction of the engines, the gravity of the mass on the different inclines traversed, the atmospheric pressure, the pressure due to the blast-pipe, the resistance of the air, &c.; and in multiplying the sum of all these resistances, by the velocity of the motion, we shall have the mechanical effect produced. But, if among all those divers resistances, we take account *only* of the friction of the carriage, and the engine, omitting all the rest, and if we suppose, for an instant, that friction to be 6 lb. per ton, as well for the engine as for any other carriage, we shall have the effect produced, in multiplying the weight of the train, tender and engine included, first by 6 lb., and afterwards by the velocity of the motion. Now, it is evident that in calculating thus, we shall have exactly the same number given by the computation of Mr. Parkes, excepting that all of them shall be multiplied by 6. Therefore, the new measure proposed comes merely to this, that the effect of the engines will be calculated by the friction of the carriages only, and that of the engine considered as a mere wagon, and the results divided by 6.

But, as this pretended "standard" comprehends only a portion of the resistances really overcome; as it does not include the gravity of the train, which may, according to circumstances, offer a resistance exceedingly great, or null, or even act in favour of the motion; as it does not include the counter-pressure due to the blast-pipe, which varies according to the velocity, the rate of vaporization and the size of blast-pipe; as it does not include the total friction of the engine, but only the friction of its wheels, as a single wagon; as, above all, it does not include the resistance of the air, which, from experiments of which Mr. Parkes is "utterly ignorant" (page 124), varies according to the bulk of the train and the square of the velocity, so that the quantity neglected, on that account, in the calculation may, at times, be quite trifling, and at other times, exceed the *momentum* of Mr. Parkes itself; as in fact this pretended *new* measure is nothing more or less than the common *useful effect* of the engine, as given in many works and particularly in our *Theory of the Steam Engine*, and *Treatise on Locomotive Engines*, with these differences only that in Mr. Parkes's calculation, it includes also the weight of the engine, and that it is erroneously computed, inasmuch as, in multiplying the weight of the train, in tons, by the velocity, the calculation is made as if the whole weight were raised up in the air by the engines, instead of being dragged or rolled along the rails; as, finally, this pretended standard, instead of being constant, varies with the velocity, just as well as what Mr. Parkes calls the *commercial* and *useful* effects, so that it is not more easy to know the one than the others, or that the rule of Mr. Parkes, which we are going to quote, refers to the one just as well as to the others; for all those reasons, then, we see that the aforesaid measure is not new, that it does not measure the mechanical effects of the engines, and finally that it is nothing more or less than the common useful effect (weight of engine included), calculated in considering the whole train raised up in the air and the engine as a mere wagon.

After having thus found upon *reasoning* the accuracy of his new measure of the mechanical effect of the engines, Mr. Parkes proceeds to show the "powers of this method of analysis" (page 131). Collecting all the erroneous results which he has obtained in his tables, and admitting then, as accurate, the experiments of the *Treatise on Locomotive Engines*, which he thought of demonstrating false before, Mr. Parkes forms a table in which he sets in view, on one side, the vaporization effected by the engine, and on the other side the useful effect produced, giving it only the name of *momentum* when it includes the weight of the engine besides that of the wagons. Then comparing the vaporization to the effect produced, and taking an average, not upon his own experiments, *since he has made none*, but upon all the experiments which he has collected from the divers works published on the subject, he presents (page 130), as the result of his labours, the following conclusion, which he proposes to substitute in place of every other kind of research on locomotive engines.

When the velocity of a locomotive engine is augmented in the proportion of 1·52 to 1, the vaporization necessary to produce the same effects varies in the following proportions:

To produce an equal *momentum* (an equal useful effect, weight of wagons and engine included), in the proportion of 1·42 to 1, or in a proportion something less than that of the velocities; to produce an equal *commercial* gross effect (an equal useful effect, including the weight of the wagons), in the proportion of 2·43 to 1, or nearly as the square of the velocities; to produce the same *useful* effect (the same useful effect, net weight), in the proportion of 3·41 to 1, or nearly as the cubes of the velocities.

This is the definitive result which Mr. Parkes has attained, and the help of which seems to him to render it needless henceforward to seek to determine either the friction of the wagons, or that of the engines, or the resistance of the air, or any thing in fact that may influence the effects produced; researches which appear to him to offer insurmountable difficulties. Possessed of the *wholesale* result of Mr. Parkes, nothing more will be needed. Does any one wish, for instance, to know what load a given engine will draw at 25 miles per hour, on a given inclination? to know what velocity it will assume with a load of 60 tons? to know what is the maximum of useful effect that it is capable of producing? to know what proportions must be given to it, in order to obtain desired effects? Why, having recourse to Mr. Parkes's result, the solution of all these questions is self-evident!

It is evident, on the contrary, that Mr. Parkes's result, even were it exact instead of being founded on erroneous calculation, could lead to but one thing, namely, to find the useful effect produced by an engine at the velocity of 30 miles per hour, when the same effect, in quite similar circumstances, is known at the velocity of 20 miles. But, even then, making use of so rough an approximation, in which all is thrown in the lump: friction of the wagons, friction of the engine, resistance of the air, resistance owing to the blast-pipe, &c., the result could never be depended on. Assuredly, calculations like these do not tend to the progress of science; they would rather lead it back to its first rudiments. For this reason we persist in our belief that the only means of calculating locomotive engines, is to endeavour to determine, as exactly as possible, each of the resistances which oppose their motion, and by taking an account of the value of those forces in the calculation, we may then in every case attain a valuation really founded in principle, of the effects of every kind that are to be expected from them.

MR. RANKIN'S WOOD PAVEMENT.

(Abridged from the Polytechnic Journal.)

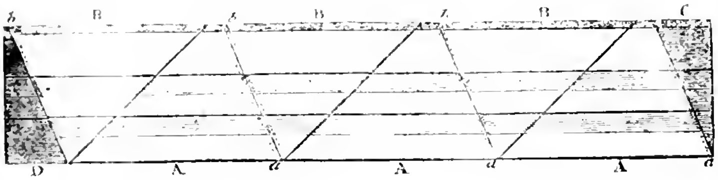
This new wood pavement is the invention of Mr. Rankin, and manufactured by Messrs. Esdailes and Margrave at their City saw-mills. We will first proceed to describe the process of its manufacture from the beginning. A square-sided piece of timber, of a proper length, is provided, each side being four inches across. By the application of the steam machinery at the saw-mills, two equilateral *grooves* are rapidly cut along the whole length of the piece. As soon as this operation is performed, the piece is turned completely over, and on the side immediately opposite to that previously grooved, two *tongues* are cut, in like manner, along its whole length.

The length of timber, thus prepared, will have two sides opposite to each other with plain surfaces, one of the remaining sides *grooved*, and the other *tongued*: and in this state it is ready to to be cut into blocks, to be laid down as street pavement.

Simple as this grooving and tonguing may appear to be, they constitute, in fact, a principal part of the merit of the invention. The fundamental principles of geometry have been strictly attended to in their construction, and the result is consonant with an adherence to scientific laws. The tongues of one piece of timber fit into the grooves of another: and when two pieces are thus united, the are not *flush* with each other, but the side of the second piece projects beyond the side of the first to which it is fastened, exactly half its own width. If a third length were attached to the second, in the same way that the second was to the first, the edge of this third length would again project beyond that of the second, half its width, and the same effect would be produced with any number of pieces.

The lengths, first prepared in the way described, will then have to be cut into blocks. In order to facilitate information on this part of the plan, we here introduce a diagram.

Fig. 1.



It will be observed there are two shaded parts, C and D, one at each end of the length. These are cut to waste: but the amount of loss is so small as hardly to be worth consideration in any estimate of prime cost. With this trifling exception, the whole of each piece, no matter how long it may be, is brought into use. The dotted lines, which intersect the length, indicate the direction of the saw when it is converted into blocks. A A A are base-blocks, and B B B the key-blocks. Let us, for the sake of an example, suppose that one length is cut into six blocks. Of these, three are intended to be laid upon the ground with their bases downward, and the other three to form the surface of the pavement by reversing this position, and placing their bases upward; and this is the only distinction between the blocks of which Mr. Rankin's pavement is composed. The lower blocks are called base-blocks, and these support the others; the upper blocks are called key-blocks, and these firmly interlock the under blocks and themselves together. The annexed drawing, fig. 2, represents the *grooved* side of a base-block, *a* and *b* being the grooves: and the engraving opposite fig. 3, presents the *tongued* side of the same base-block, *a* and B A being the tongues. The two similar sides of the key-block are also exhibited in the accompanying diagrams; *a* and *b* in fig. 4, representing the grooves, and *a* in fig. 5 the *tongue*. Such is the shape of the blocks of this most ingenious pavement; and begging our readers to bear in mind that there are but two sets, upper and lower, and that the individual parts of every block of each set are geometrically alike, we proceed to the proof of its advantages, with the promise of which we started.

Fig. 2.

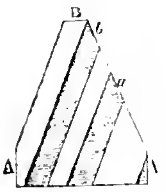


Fig. 3.

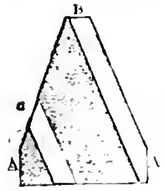

Fig. 4.

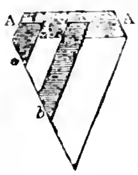

Fig. 5.

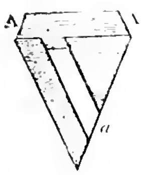
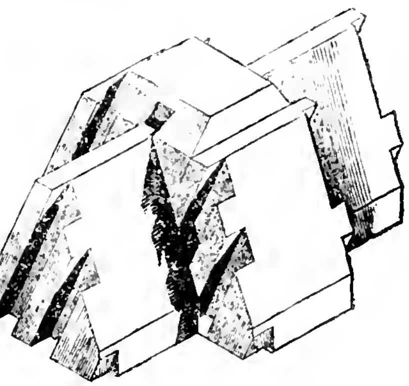


As "UNCHANGEABLENESS OF POSITION" is a primary and most important quality of this pavement, we will first explain how this is secured. Fig. 6 is a representation of five blocks locked together. It will be noted that four of these are base-blocks, and but one a surface block. If examined in detail, it will also be found that the key or surface block is supported by the others, and by all equally; and that no surface pressure can separate them laterally, or drive them asunder; so that any weight applied at the surface, is distributed over a base nearly four times its area; but these four base-blocks likewise respectively lock in with four other different series of the same kind, and so on continuously from side to side of the street, where they rest on the kerbs, and longitudinally from end to end of the pavement; and thus

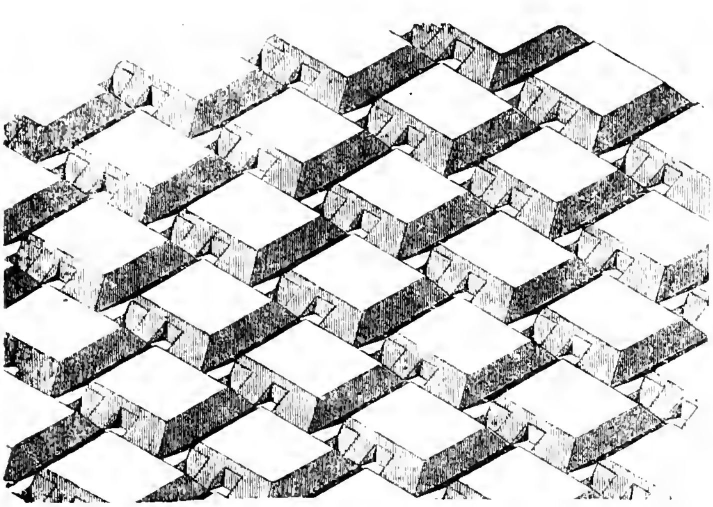
Fig. 6.



the weight applied to an individual surface block is not confined to the four base-blocks, its immediate supporters, but is transmitted throughout the whole structure, and no one part can yield to the superincumbent pressure, without causing a general deflection from kerb to kerb; and as this is manifestly impossible, except to a small amount, it must be granted, that the base of the pavement can never be affected, or dislocated, by any traffic whatsoever: no inequality of surface, from the sinking or depression of individual blocks, can consequently arise, until the surface blocks themselves are fairly worn out, a result which is assuredly much more remote in wood than the public are yet prepared to believe. The construction of this pavement, therefore, as regards uniform stability of base, places it beyond all comparison with any stone paving now in use, because it includes the principle of the arch, the kerbs representing the abutting piers, and the upper or surface blocks the key-stones: and the greater the weight, the more solid does the structure become by the tightening process of the wedge-shaped key-blocks, with their grooves and tongues. If our readers will again examine figures 1 and 2, they will observe that the angular terminations on two opposite sides of the base of every substratum block (A A) are chamfered or squared; and if, furthermore, they will suppose a row of these blocks to be placed on the ground between two piers, or abutments, with their chamfered edges together, and the upper blocks afterwards introduced in their proper place, it will at once be evident that no sinking can take place without complete destruction of the parts. In truth, by this arrangement of shape, unchangeableness of position is absolutely obtained.

But, after all, the most important consideration in the adoption of wood as a substitute for stone in the street-paving of the Metropolis, will ever be the providing an effectual REMEDY AGAINST SLIPPERINESS. No pavement of wood, that does not offer a firm foothold for the horse in all states of weather, will ever become generally adopted in London. In every situation, whether in continuous motion, in backing, in being abruptly pulled up or suddenly started, the horse must be able to maintain his feet in precisely the same place in which he places them down, otherwise wood pavement will not have realised the grand advantage of which it is susceptible. That nothing of the kind has been hitherto accomplished, needs but a five minutes' examination of any public street paved with wood immediately after and during the existence of a passing shower. The plunging and sliding about of the animals are then awful. If an omnibus going at the usual speed were suddenly required to be stopped to take up a passenger, its momentum would force the horses along the pavement several yards, in spite of all their efforts to prevent it. In starting too, their feet rapidly slip from under them for several moments before they can succeed in moving the vehicle. Frequently they fall down and are injured, and the greatest precautions are necessary under such circumstances to prevent accidents. These things happen because there is no foothold for the horse in damp weather upon any of the wood pavements hitherto introduced. We can testify, of our own knowledge, that the reverse of this is the fact in the case of Mr. Rankin's pavement. Indeed, it speaks for itself; no argument is required to prove that the foot of a horse cannot slip over its surface. At the same time it offers no resistance to the uninterrupted progress of the wheel, and therefore a remedy against slipperiness is not obtained by any sacrifice of facility of traction. A general character of the paving may be gleaned from the annexed engraving.

Fig. 7.



Here, then, as the licencees fairly remark, is a pavement, removing at once the great and hitherto insurmountable evil attending the use of wood, the insecurity of the horse's foothold: and offering a facility of removal equal to the present stone paving, and an evenness of surface, and combination of construction, together with an absence of noise and increase of cleanliness, which wood alone can give.

We have felt great pleasure in thus calling the attention of the public to the invention of Mr. Rankin, because we know it to be very ingenious, and believe it to be, for all seasons, by far the best wood pavement hitherto made public. The government ought to allow an experiment upon an extended scale to be made with it duty free, for the question of wood pavement is one of metropolitan, if not of national, convenience.

PROFESSOR FREUND, DANISH SCULPTOR.

If not in the fine arts generally, the north of Europe has distinguished itself in sculpture—that one of them, on which the fame of Greece now chiefly rests, and which more especially demands a critical study of beautiful forms and proportions. The eminent and excellent sculptors Sweden and Denmark—and we may add Russia—have given birth to, sufficiently vindicate their pretensions and character in that branch of art. The names of Martos (+1835) and Boris Orlovsky (+1837), of Sergell, Bystrom, and Fogelberg (belonging to Russia and Sweden), may be said to be European ones, while that of the great Danish master almost dims that of Canova himself. Neither is it of her Thorwaldsen alone that Denmark has cause to be proud, since she can boast of having given to the world another highly gifted sculptor in Hermann Freund, who died at Copenhagen in July 1840.

Of this last-mentioned artist we are not as yet prepared to give any biographical sketch, nor even to enumerate his principal works. We are enabled, however, to state a few particulars relative to some of his subjects from ancient northern mythology, which had been a favourite study with him, and of whose imagery and traditions he sought to avail himself for plastic and sculpture, in like manner as his countryman Oehlenschläger has done for poetry and the drama. It was here that he displayed poetical conception, a noble simplicity, a characteristic yet graceful severity, free from aught like mannerism, and from those mere conventionalities upon which so much stress seems to have been laid by most modern sculptors, to the exclusion of either originality or feeling. Among the works of the class above referred to, is a bas-relief representing the three Nornas or northern Fates, who are consulted by Mimer, Baldur, and the Valkyrias, in consequence of Iduna, the goddess of youth, having been carried off by the evil spirit Loke, and thereby both gods and mortals subjected to the infirmities of age and decay. In this dilemma Baldur, the Apollo of the Scandinavians, solicits the counsel of Mimer, the god of wisdom, and he, being unable to assist by his advice, they both proceed to solicit that of the Nornas. These last form the centre group in the composition, and represent Veranda, she who presides over the *present*, Ur, who presides over the *past*, and is here seen recording its events upon a tablet; and Skulda, or the *future*, with her finger upon her lips. To the right of these figures are those of Mimer and Baldur, the former with a long beard and arrayed in a bear's skin, the other a beautiful youth, vying in form with his classical prototype. To the left of the centre group are the three Valkyrias (whose office it was to tend upon the souls of the blest in Valhalla, the Scandinavian Elysium), who are here represented as attired in long under garments, and with wings growing from their temples.

Among Freund's single figures and statues are many representing personages belonging to the same mythological system: viz. Odin, Thor, Freya, Iduna, Bragur & Loke. The first-mentioned of these is seated on a throne, and wears a diadem inscribed with Runic characters. He is the Scandinavian Zeus, and like the Grecian one, is distinguished by majesty of appearance, but his features are more aged, his form less expressive of strength: for though superior in power to the rest of the deities, Odin was supposed to be himself under the control of Fate—an arbiter more awful and tremendous than even the sovereign of the gods. His attributes are two ravens, seated on the arms of the throne, which were the messengers commissioned to bear his orders to gods and mortals—and two wolves couched at his feet.

Thor or the Thunder-god, is a standing figure, with his right foot advanced forwards, and looking earnestly on one side. He is here supposed to have just hurled forth his lightning, and to be striking a thunder-peal with his hammer. This figure—which is somewhat between that of a Jupiter and a Hercules—is quite naked with the exception of a wolf's skin, hanging upon one arm, and reaching to the ground. Beside him is a coat of mail, which serves to support and balance the statue. In a second figure he is somewhat differently represented—in a more composed attitude, with his hammer in his right, resting upon his armour, and a thunderbolt in his left.

In the group of Freya, the goddess fabled to preside over sexual passion, that figure is represented veiled, resting her chin on her right hand, and holding a wreath of flowers. On one side of her is Siofne (under whom was typified the first emotion of love), endeavouring to draw aside her veil and behold her countenance; while on the other is Hnos, or Enjoyment, with her left arm around her mother Freya's neck. Both Siofne and Hnos are naked figures. So far the allegory seems well conceived, but there is one circumstance which, though it may be significant enough as a symbol, is far more associated with the ludicrous, than with either the sentimental or poetical, according to modern ideas; for instead of turtle-doves, the northern Venus has at her feet—two cats! as images of the potent influence of *la belle passion!*

Iduna, the Scandinavian Hebe, is represented by a graceful youthful figure, holding in her left hand a patera filled with apples, and in her right a cup of mead. Her luxuriant tresses fall from beneath a long pointed cap, similar to that still worn by the maidens of Iceland, which hangs down behind, where it terminates in a tassel.

Bragur, her consort, and the Scandinavian deity of poetry and minstrelsy, and whose office it is to recreate the indwellers of Valhalla with his songs, is shown in the act of playing upon his harp, which is attached to a riband that crosses his shoulders.

The evil malicious spirit, Loke, is characteristically described—under a shape speakingly expressive of the disposition attributed to him. There is something stealthy in his very attitude, as he creeps along resting his chin upon his left hand, while brooding upon mischief. His other claw-shaped hand is partly concealed beneath his mantle, as are likewise his long and ugly ears, and his bat-wings.

However admirable may be the talent manifested in those productions, it is with us a question whether it might not have been more advantageously employed. If heathen mythology is now worn out, if it does not address itself to our sympathies, especially when served up—as it necessarily must be in modern sculpture, at second-hand; that of Scandinavia has to contend with the additional disadvantage of being less known, consequently less intelligible. All attempts to revive it, to bring it again into vogue, either in poetry or the graphic and plastic arts have proved comparative failures. Did the fame of Gray rest chiefly upon his productions of that class, it would be much less than what it actually is; or rather, he would share the fate of Sayers, whose northern poetry has been descanted upon and praised by critics, to be forgotten—supposing it ever to have been regarded—by the public.

A new Paving.—M. Polonceau, the engineer of Paris, proposes a new mode of paving for Paris, consisting of artificial stones made of clay, sand, and pulverized charcoal. This mixture stood heat well, and became vitrified; it also dried without cracking. The stones were made in an hexagonal form, and could be put down or taken up one by one. Government had given leave for an experiment to be made of this system in one of the streets of the capital.

COMPETITION DESIGNS.

(Benevolent Institution for the Relief of Aged and Infirm Journeyman Tailors.)

The mal-administration of competitions for designs becoming every day more apparent, the indignities and imposition practised upon architects who are foolish enough to yield to importunity and submit the result of their labours to the decision of men not merely unfitted for the task, but in most cases *prepared* to decide in a certain manner even before the reception of the drawings, becoming additionally glaring, it surely only needs that some few more home-cases should be brought forcibly before the public eye to induce the entire abandonment of the present scandalous system, and to enforce from committees an honest decision and something like consideration for the time and talents of the professional men applied to. With this view we proceed to lay before our readers the particulars of a recent competition which have come to our knowledge in the hope that the statement may aid in rousing public indignation against such proceedings: furthermore, we have a latent hope that by putting the whole matter fairly before the parties interested they may be led, as it is not yet too late, to retrace their steps.

Some few months ago the Committee of the Institution named at the head of this article, requiring designs for an asylum which they propose to erect in the Hampstead Road, invited a limited number of architects to forward drawings, namely Messrs. Lee and Duesbury, Mr. Jones, Mr. Vulliamy, Mr. Thomas Meyer, Messrs. Winterbottom and Sands, Mr. George Godwin, and Mr. E. H. Browne.

It being understood that one of the competitors, namely Mr. Meyer, was brother of a member of the Committee and had already sent in a design, some of the other architects inquired pointedly whether or not this gentleman was to be in any degree considered more than the rest, and were informed by various members of the committee that the best design would positively be accepted whether made by Mr. A. or Mr. B. Designs were accordingly sent in by all the gentlemen we have named. A building committee was appointed by the general committee to examine the drawings, and recommend for adoption that which they considered the best. They accordingly met various times, gave a long consideration to the matter, and ultimately selected Mr. Godwin's design as the fittest for their purpose; a written report to this effect was drawn up and the matter was talked of out of doors as a thing settled. Several weeks having elapsed after this had reached Mr. Godwin's ears accidentally, without his receiving any special communication, he applied to know how the competition had terminated, and the following letter was shortly afterwards sent to him:

Benevolent Institution, &c.
32, Sackville Street,
14th July, 1841.

SIR—I beg leave to inform you that, by a decision of the Board of Directors, their choice of an architect has fallen on Mr. Meyer.

I am, Sir,
Your obedient servant,
George Godwin, Jun., Esq. T. P. DAVIDSON, Sec.

The gentleman to whom this was addressed accordingly called the next day to fetch away his drawings, and being shown into the room of meeting, saw there five of the seven sets of designs, including those selected as the best. In consequence of this examination he immediately addressed a letter to the Board, which, as it puts the whole matter in the fairest point of view possible we here annex

To the President and Directors of the Institution for the relief of infirm Journeyman Tailors.

Brompton, July 17, 1841.

GENTLEMEN—I have the honour to acknowledge a note from your Secretary, stating "that the choice of an architect has fallen on Mr. Meyer."

Some time previously I was told, in three different quarters, that *my* plans had been selected by the Committee as the most approved, and I felt, therefore, a little disappointed on receiving official intimation to the contrary; still, considering that I must have been misinformed, I was of course quite disposed to bow to the decision in silence, and to believe that a better plan than my own had been chosen.

Applying, however, a few days back in Sackville Street to regain the drawings, I there saw the various designs of the other competitors. Amongst them were those of the preferred candidate, and an examination of these led me to the conviction, that such a decision had not been come to as those architects who had given their time and attention to the subject at the request of the Board, had every right to expect. I make this remark with the greatest deference to every member of the Board, for many of whom personally I have great respect.

Far be it from me to deny that the Board had right to appoint any architect they pleased: what I would very deferentially submit is, that having induced six or seven architects to make plans for the proposed asylum, at an expense of both time and money, in the full persuasion that the author of the best design would be appointed to execute the building, the Board were bound to make that selection solely on the ground of *superiority*, and without reference to the name of the author of the plan.

That such has not been the case, referring solely to the designs submitted, and without the slightest intention of disparaging Mr. Meyer's fitness for the task, I venture without hesitation to assert.

Apart from private grounds (and even in this respect, as my plan was selected by the Building Committee after due consideration, as the best adapted to your purpose, I am, perhaps, authorized to address you,) I am induced to this step by strong public motives—by that desire to obtain a just administration of competitions for designs which is felt at this time by all those who wish the prosperity of the arts in England.

On this ground then, gentlemen, I appeal to your sense of justice, and the desire which, I will venture to believe, you all have to maintain the good opinion of the world, to give this matter re-consideration.

I hope sincerely that you will not deem any thing I have said disrespectful in the slightest degree, and that you will permit me to subscribe myself, gentlemen,

(Waiting your decision),
Your humble servant,
GEO. GODWIN, Jun., Architect.

The result of this letter was that the Board, at their next meeting, refused to confirm the appointment of Mr. Meyer, and it was proposed that the whole of the designs should be referred back to the decision of one or more architects. A subsequent meeting, however, influenced in a manner one would hardly venture to hint at, overturned this intention and confirmed the original appointment. Here the matter stands. We have seen the various plans, and without stopping to inquire whether Mr. Godwin's plan is the best (a point we don't in the least care for), we have no hesitation in saying that not merely is the selected design *not* the best, but that it is perhaps the least entitled of any one of the seven to claim for its author the appointment. If the Board desired to employ Mr. Meyer, why did they not do so in the first instance? No one would have questioned his fitness, or their right to appoint. But having given seven gentlemen the trouble, and led them into the expence, by special invitation, of preparing designs, we assert that the Board were bound, by every feeling of honesty, to appoint the author of the best plan, without the slightest reference to his name or his connexion with the society. We hope even now it is not too late for redress.

COMPETITION.

SIR—If your readers will refer to the Athenæum for the last month, they will find an account of a highly entertaining squabble arising out of the competition for a new church in the parish of Paddington.

When this competition was announced, I applied for the particulars, and subsequently for further information on a few points which did not appear to my humble comprehension to be quite explained in the instructions. Without troubling you with the whole list, I will mention one question, viz. How many of the prescribed sittings were to be in pews, and how many in free seats? to which I took the liberty to add the further inquiries, whether any member of the vestry would be permitted to compete, and to whose judgment the designs were to be submitted. To which answer was made, to the first question, that many architects had applied for the like information, but that the instructions already given were considered sufficient—to the second, that no member of the vestry *could* have an interest in any parish work—and to the third, that it was calculated to give great offence! and that it was quite enough for the architect to know that the parties concerned were "all honourable men."

Of course all applicants were obliged to be content with the same answers, for, *of course*, nobody gave, or profited by, private information—nobody ever does. I submit, therefore, that any one who competed after receiving such answers, got what he deserved, whatever he may have or may think he has to complain of, and I trust that none of the profession who lend themselves to the system of scrambling for jobs in the dark, will ever be better treated.

I am, Sir,
26th August. Your obedient servant,
T. J.

ON RAILWAY CARRIAGE WHEELS.

SIR—In your number for June last, there is a paper, page 197, professing to contain accounts of improvements in Railway Carriage Wheels.

The writer's first two heads of method contain two different modes of constructing the axle of a pair of wheels, to allow these to turn independently. One would infer from his manner of stating the modes, that they should be united in one pair. They evidently cannot. At all events, he implies that, on either plan, the independent rolling of the wheels, together, I suppose, with the additional flanges, would entirely prevent the engines being thrown off the line by an obstacle. Now the *independence* of their rates of motion cannot facilitate the prevention of such an accident.

In his third head he tells us that his wheels should be of cast iron, preferably to malleable iron. But why this preference? It is universally agreed that malleable iron is superior to cast iron for all wheels of the kind now in use. Why are the writer's wheels to be an exception? Is it on account of spreading? The writer himself says that malleable iron wheels spread out only on the bare side. And, therefore, now that they are to be flanged on both sides, the spread will be checked, therefore let us yet use malleable iron. There is no other new circumstance requiring this change of metal. The jolts, strains, and every thing else will be the same. Again, therefore, let us yet use malleable iron. His preference for cast iron is of a kind with the dislike of Dr. Pell versified in the immortal quartet so often quoted. Again, he says that the wheels as they are double flanged will not require to be so strong as at present, because side jolts will be divided between the opposite wheels. The consummation of lateral strains and jolts would be both wheels rising on the rails, which case, therefore, we must consider in judging of the required strength. Admitting the writer's assumption that both wheels share the strain equally, (which however cannot always be, as in cases of variation of gauge, which fact itself is an argument against his conclusion), it is clear, as Telford has it, that the engine on being raised, is elevated on both rails through the depth of flanges, and that therefore its centre of gravity also rises through the mean depth of flanges. Now with the single-flange wheels the engine would be raised only on one side, through the depth of flange, and therefore its centre of gravity rises through only one half this depth. It is clear again, then, that double flanged wheels would have as tight work each as the single flange wheel, and therefore *would* require to be as strong. What right has he to deny this, who never proved the contrary? He again says that the face of the wheels ought to be in outline a circular segment instead of conical. Now the face of a wheel, as he views it, is not conical; it is a straight line inclined to the axis. He proceeds to mention by wholesale the great saving in his plan. Particularly, he says, no attention will be required in laying the rails to an angle in straight parts. What although, there will be the same attention altogether in laying them horizontally? At all events, he allows that the angular position is required at curves. But under the fifth head, he says that railways are all curves together; therefore he must conclude against himself that the saving in straight parts is just nothing, since he supposes there to be no straight parts at all.

Again, he says that the inclination of the rails the same way on curves instead of towards each other, as now set, will enable gravity to act more forcibly. This can be only on the ground that the comparative virtual velocity in the direction of gravity is greater in the first case than in the other. The writer has evidently not troubled himself as to the truth of this gratuitous statement. It would be easy to prove that the centre of gravity moves through equal depths for the same horizontal movement, in both cases. And therefore is he entirely wrong.

Again, he says that the inclination of the rails to one another in present plans causes great friction on the journals. How so? The pressure on the journals must be the same. Nor is there any twisting or other adverse action of the kind. In fact, the only sources of friction by this cause would be at the contact of wheels and rails, owing to the wedge-like action of the conical wheels, which is utterly insignificant. Again, each wheel cannot possibly press the other against the rail, for their action is equal and opposite, and therefore nothing.

In his fourth head he has asserted all, proved nothing. How did he know the exact saving of power he mentions? It is evident that his improvement was never in operation. What right had he then, when he knows nothing about it, to pronounce so decisively as he has done, and that not only in this paragraph, but throughout the whole paper.

His last notable and most ridiculous statement is set down in the fifth head. He tells us that railway curves do all differ in intensity, and they must therefore be of various radii. But this evidently requires wheels of various diameters to suit them, and to produce that sweetly-gliding motion which he loves. This exigence is beautifully provided for in conical wheels. Now he proposes to set his engine running upon the flanges of the wheels forsooth when they enter upon curves. By this exceedingly quick plan, the wheels are evidently adapted to only one kind of curve, and would therefore, on any other curve, grub up the rails most sweetly indeed.

I am, your's, respectfully,

D. C.

Glasgow, July 9, 1841.

QUESTIONS FOR THE OPINION OF THE EDITOR.

Sir—I shall feel obliged if you will inform me if I could sustain a charge in a court of law under the following circumstances. In the early part of the year I was applied to, amongst other tradesmen in the parish, to tender for certain alterations and additions required to a building, in the erection of schools, and in due course I was informed that my tender was accepted, and that a delay of a week would most likely take place, but from that time to this, a period of six months and upwards, I heard nothing of the matter until a day or two since, when I received a letter (certainly a polite letter), stating circumstances prevented the design from being carried into effect, and that they were sorry I could not have an opportunity of carrying my contract into effect.

Do you not think, Sir, I should be fully justified in charging two per cent on the amount of my tender, as some judgment was necessary and much time taken up in making the estimate.

I am, Sir,
Your obedient servant,
Aug. 9. T. O. M.

In all cases when our opinion is required, we should be furnished with full particulars; for instance, in the above case, a copy of the advertisement should have been forwarded. Taking for granted that there is nothing very special in the wording of the advertisement, and that there was nothing personally objectionable to the tradesman making the tender as to his general way of doing business in point of construction, or for want of pecuniary means to fulfil his contract, we are then of opinion that a claim could be legally substantiated against the parties advertising.

We have some recollection of a case being tried about six months since, either in the Sheriffs' or Secondaries' Court in London, of a builder suing a person for the trifling sum of about 3*l*. for his loss of time in making an estimate of some works; after receiving the tender, the defendant declined employing the plaintiff, without showing any reasonable excuse; in this case the plaintiff recovered the sum sued for. Our impression is that there are other cases which might be cited; probably, before our next number appears, some of our readers will be able to furnish us with some information regarding this question, which is one of very great importance, not only to the builder, but also to the profession.—Editor.

Sir—I thank you for your reply respecting the legal arrangement of chimney flues, and from which I gather that the termination at top, if of different materials from the stack, may be of any size that one pleases; but suppose I choose to have nothing resembling a chimney-pot, is it your opinion that the law will forbid such a contraction for the last two or three feet of the brick or stone, as is now effected by the addition of the cement or pottery abominations?

I am, Sir,
Aug. 10. Your obedient servant,
A subscriber.

If the chimney be built as our correspondent suggests, it will be necessary, in our opinion, to construct it with an aperture not less than 14 in. by 9 or 12 inches diameter, agreeably to the Act. We hope that the legislature will see the necessity for altering the clause in the act before it comes into operation; the Architects' Institute or Society should interfere and obtain a repeal or modification of the objectionable clause before the act comes into operation.—Editor.

Sir—I have lately had an opportunity of seeing the Illustrations of Ancient Halls by Nash. Now it struck me at the time, that though they were certainly very pleasing to the eye, how much more *useful*, simple but correct outline elevations and plans would have been to the architect and others, as it would be the means not only of preserving a true delineation of the subject, but would also be the means of furnishing numerous data in erecting similar edifices, which I know to be useful to all. Now as many very beautiful specimens still exist in this part of the country, I have it in contemplation to bring out a work of this kind. The only question is, whether architects will patronize it as they ought to do, as I am sure plans, elevations, &c., of such buildings must be very acceptable to them. If you will be kind enough to give your opinion in your next number, I shall feel greatly obliged.

A Subscriber.

Such a work as our correspondent describes has already been commenced, but not proceeded with. We think a work got up at a moderate price, suitable for the architect, might stand a chance of meeting with support, but we are afraid to recommend the publishing of it, as it is very doubtful if our correspondent would be remunerated for his labour.—EDITOR.

MOVEABLE FURNACE BARS.

SIR—With your permission I beg to make the following remark respecting an article which appeared in your valuable Journal of last July, under the head of "New Inventions and Improvements." The article in question is one which I suppose to be an extract from the specification of Mr. C. W. Williams's patent improvements in furnaces and boilers.

If there be any credit due to the discovery of the method therein described, for producing the continual up-and-down movements in the grate bars, that credit is most certainly due to the late Mr. Mathew Murray of Leeds, who had the furnace of an eight horse steam engine, so constructed as to keep the grate bars continually in motion, by means of small eccentrics formed on a horizontal shaft, which revolved beneath, and supported the ends of the grate bars next to the furnace bars. This was done with an intention to prevent the formation of clinkers, and to keep the fire perfectly clear; but, as the plan did not prove perfectly satisfactory to the inventors, the whole system was very shortly taken out, and replaced by that then most commonly adopted. It appears to me somewhat singular that this contrivance, though upwards of fourteen years old, should at length become the leading feature in a specification of patented improvements.

I am, Sir, with great respect,
Your humble servant,
FLORENTINE.

Holbeck, August 16, 1841.

REVIEWS.

A Series of Original Designs for Churches and Chapels in the Anglo-Norman, Early English, Decorated English, and Perpendicular Styles of Ecclesiastical Architecture, including also designs for Rectory Houses and Schools in the Domestic English and Tudor Styles. By FREDERICK J. FRANCIS, Architect. London: John Weale, 1841.

This forms the first part of a series of original designs, which are divided into four classes. 1. The Norman. 2. The Early English. 3. The Decorated English, and 4, the Perpendicular English. We do not think however from the specimens before us that Mr. Francis is so happy with his pencil as with his pen, neither are we of opinion that these designs are likely to induce the Church Building Commissioners to abandon their "Barn Church Architecture." We might instance several defects, for instance in design No. 1, we have the principal entrance opening direct into the body of the Church without any lobby, or second entrance; the same again in the side entrance of No. 2, nor do we admire the stunted steeples which have been introduced in designs Nos. 2 and 6, the pedimental parapet of No. 7. and the stepped parapet of No. 12 design, nor the square hood moulding over the pointed windows of the clere-story.

Description of a Series of Geological Models. By T. SOPWITH, M. Inst. C.E., F.R.S., &c. Newcastle: Blackwell.

☞ As a Mineral Surveyor Mr. Sopwith has had excellent opportunities of acquiring practical geological information, and he has been no less successful in imparting it to the public. The models, which this work is intended to describe, illustrate the nature of stratification, valleys of denudation, succession of seams in the Newcastle Coal Field, the effects produced by faults or dislocations of the strata, intersection of mineral veins, &c. These models are very ingenious and useful, and the work before us besides being a necessary companion to them, is of great interest on its own individual account. The illustrations being drawn from actual inspection, and greatly to the merits of the work, which abounds in practical instruction on mining geology.

PARLIAMENTARY PROSPECTS OF THE ENGINEERING INTEREST.

A change in the administration of the country being imminent, it is the bounden duty of the engineers, both civil and mechanical, to profit by the present state of affairs to obtain redress for their numerous grievances. No time can be more appropriate than the opening of a new parliament to canvass for a change in the Standing Orders of the House of Commons, and the formation of a ministry is a good opportunity for securing a sound system of government policy. When we consider the vastness of the interests involved, and the extent of influence at the command of the engineers, we entertain no doubt of a relief from the oppressions by which they have hitherto been afflicted. It may not be in the power of the engineers to meet together at this season and act in concert, but it is at least open to them to exert themselves individually in influencing the members for their several towns and districts, who may be called on to co-operate in a cause, which is nonpolitical, and of the greatest importance to the industrial interests of the country. It is perhaps fortunate that Sir Robert Peel has hitherto shown himself favourable to our interests, and we think that after the formation of a new ministry under his guidance, no time should be lost in ascertaining by a deputation of men of all parties the course he intends to take upon the momentous questions of the Standing Orders, Railways, Steam Navigation and the Irish Railways, so that the engineers might be able to take their measures accordingly.

MR. JOHN SCOTT RUSSELL'S TREATISE ON STEAM NAVIGATION.

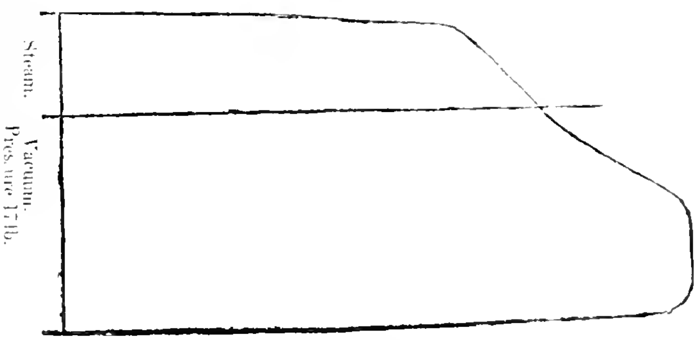
SIR—In a late Treatise on Steam Navigation, by John Scott Russell, I observed a statement regarding a steamer lately constructed on the wave-line principle, which ran thus, page 301, "the next and last vessel is the Flambeau, built in 1840, on the wave principle, by Mr. Duncan of Greenock, with the co-operation of the present writer. This vessel with the smallest proportion of power to tonnage, and with the smallest supply of steam, is nevertheless by far the swiftest vessel on the Clyde." Now I think "the present writer" ought not (although the vessel was constructed on the wave principle), to have allowed himself to go beyond the bounds of truth, I mean in the three last sentences. 1st. "She has the smallest proportion of power to tonnage." This is certainly doubtful, as you will see by the following indicator diagram, taken when at the speed of 21 strokes, (now she has many times made 27 strokes per minute), making 138 horse power: not as Mr. Russell has supposed, or rather wishes to make the world believe to be 70 only. Now taking her at 280 tons measurement, we have $\frac{280}{138} = 2$ tons per horse power. If that is the smallest, pray what may be the largest,—and yet with all this she was not by far the swiftest.

2nd. "With the smallest supply of steam." I understand the first boiler was not capable of supplying steam to the engine the whole length of stroke, so that they expanded one-third or 20 inches, as was intended, and pressed a little higher to compensate; yet so much was Mr. Russell disappointed with the speed of the vessel, that he attributed the deficiency of speed to the deficiency of steam, and accordingly with his usual tact, got the proprietors prevailed upon to put in another boiler that should follow up the steam, which they accordingly did, and pressed at about 6 or 7 lb.; the result was her speed diminished to Mr. Russell's mortification, and time, labour, and money lost to the proprietors.

3rd. "Is nevertheless the swiftest on the Clyde." With her first boilers I grant she was the swiftest last season, only when she made the 27 strokes, but this season she is not classed among the swiftest. Now this is a statement of facts, as Mr. Russell knows very well.

Cylinder 48 in. diam.
Stroke 5 feet.

$$\frac{48^2 \times .7854 \times 14 \times 240}{44000} = 138 \text{ horse power.}$$



Mean pressure 14 lb.

Your insertion of the above in your useful Journal, will oblige,
Your obedient servant,
H.

August 14, 1841.

REMARKS ON RAILWAYS REPORT AND EVIDENCE.—1841.

Sir—The report of the "Select Committee appointed to consider whether it is desirable for the public safety to vest a discretionary power of issuing Regulations for the prevention of Accidents upon Railways, in the Board of Trade: and if so, under what conditions and limitations;" together with the evidence upon which such report has been founded, has fallen under my notice, and with the view of adding my experience and reflections to the general fund of information upon railways, I request the favour that you will lay the following observations before the public at your earliest opportunity.

I am an engineer of 18 years' experience in my profession, and for the last 6 years have been intimately connected with railways, principally in endeavouring to introduce into the system various contrivances by which the public safety will be increased.

It has occurred to me as a matter of great regret that the Committee was not assisted, during its deliberation, by a practical engineer fully versed in the various railway details which were brought under its consideration, a practice which is quite usual in the Admiralty Courts, by which the testimony of the various witnesses would have been checked; for it is just evident, had such been the case, the extraordinary opinions and assertions advanced by some of them, would never have been broached, as it is clear, when the questions of the Committee were directed in such a way as to convict a witness from his own testimony, the party never failed to take refuge behind some technical details, into the peculiarities of which the Committee could not follow. A striking instance of this occurs in (Question 567) Mr. Brunel's evidence, who states as the probable cause of accident, "that perhaps a pair of wheels upon a train is slightly out of gauge, being too narrow, that in passing some guard-rail they get strained, and that when they come to a part of the line which is rather wide in gauge, they get off, and the train is delayed." Now every technical man of experience knows that if a pair of wheels be out of gauge, the fault is in the construction of the spindle, for if every spindle is made with a collar or shoulder, so that the back of the boss of the wheel butts against it, a method I invariably practice, if the wheel run round upon its axle it could never get out of gauge, so that *a regulation* providing that every axle should be made with shoulders would be a very wise and proper regulation, and would apply to all railways whatever.

In another part of his evidence Mr. Brunel states that amongst other causes of accident, "a policeman immediately runs up, and stands right in the way of the tail-lamp of the train, and the next train runs into it. Now the majority of persons would say, that if the policeman had done his duty, and showed a red light, and if the engine-man had seen the red light, there would have been no accident." If the policeman, in the case of accident, received positive instructions to run back 500 yards and hold his red light, so that the engineer of the succeeding train should not fail seeing it, this precaution, one which I have invariably insisted upon, under whatever case or form of accident, is, and would always be, an efficacious and proper *regulation*.

Mr. Brunel states, amongst other minor improvements, it would be better for the wheel not to touch the guard-rail; a man who knew any thing of a railway would then have inquired the use of the guard-rail, because, this being placed purposely to guard the wheel from the point on the opposite rail, if the wheel was not governed by it, it is useless—and there is no secondary use for it, as Mr. Brunel endeavours to make it appear in Ques. 604, and so far as the use and principle of the guard-rails go, it is the same in all cases *on all railways*.

There is another observation in the same answer, so palpably in the teeth of experience, that I cannot fail here to notice it, and that is the denial on the part of Mr. Brunel that railway improvements can be made by any parties excepting by those connected with railways. It would have been a proper question following this assertion, if Mr. Brunel had been asked whether his own father was originally a block maker, and whether the fact of his not being so would have been a proper reason for Sir Jeremy Bentham declining the encouragement due to Sir I. Brunel's very admirable machinery for making blocks by machinery—or whether the illustrious Watt was an engine driver, or before his improvements in steam engines he was actually accustomed to the management of steam engines—or whether Arkwright was a cotton spinner—or Mr. James, the father of railways, previously to his conception of railway extension, was intimately and exclusively connected with railway matters—and lastly the inquiry might have been made, what improvements have been introduced, I will not say invented, by *railway* engineers since the formation of the Liverpool and Manchester Railway, and in what respect this last mentioned railway differs essentially from a colliery railway that had been formed half a century before it.

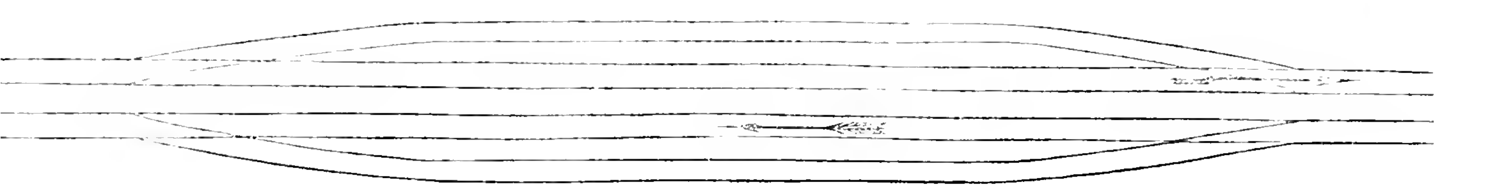
And whence does it arise that the improvement of railways, contrasts so essentially with the advances made by the great branches of trade, and manufactures, since their first introduction, but from the fact of the monopoly of the companies on the one hand, and the disinclination of railway engineers to introduce any contrivance which does not emanate from themselves, on the other: had a liberal spirit prevailed amongst engineers, and had they the judgment to select from the mass of crude suggestions offered to them, railways would have been by this time not only safe by contrast with stage coaches, but absolutely so, there is no reason why the system should not have been so formed as that, by no chance or design could an injury happen to passengers, and no one contrivance would conduce to this result more certainly and more directly than the adoption of the low carriage, upon the principle of those invented by myself, and in use upon the Greenwich Railway, and although Mr. Entwistle takes credit for the arrangements upon the Greenwich line, inasmuch as 6,800,000 passengers have been carried without the loss of life or limb to any one, he had not the candour to admit that this gratifying result is to be attributed mainly to the construction of the carriages, for the accidents from broken axles, &c., have been much greater upon the Greenwich line than upon any other in the country, and but for the low carriages, some most awful accidents would have resulted. I may here mention that the Board of Directors to which Mr. Entwistle belongs, have not only done their worst to disgust the public by the manner in which their carriages are kept, but they would have been long since abolished by the Directors but for the resistance made to that measure by the parties who are in the habit daily of using the line. This fact is one more in proof of the necessity of some supervising power to control the measures of railway managers.

The mode in which Mr. Brunel attacks the recommendation of Sir F. Smith that an engine should not be loaded beyond a certain amount, proves again the necessity that a technical judge should have been in communication with the Committee; in that case I can scarcely believe Mr. Brunel would have indulged in the same arguments. The power of a locomotive is resolvable into two elements, the quantity of water evaporated by it, and the gradients it passes over; therefore, instead of appealing to one of these elements, viz. the gradients, had Mr. Brunel included both, the proposition of Sir F. Smith would have proved a most reasonable one. Had Sir F. Smith's proposition been that the load behind an engine should bear a certain ratio with the area of the cylinders, multiplied by a certain constant, having a ratio with the average gradients of the line, it would have amounted to the very rule of every-day practice upon any railway whatever, and by making either of these ratios fully within the average working condition of an engine, he could have so defined his object as to have ensured the punctual observance of his rule by the railway companies, a rule to which no reasonable objection could be made.

The advantage resulting from massing the trains, by the average power being thus obtained from the engines connected together, is, in my opinion, a very questionable one: supposing a very heavy train has two engines a head, and that the last engine runs so *dry* as to be useless; supposing, likewise, that the train is at a considerable distance from a siding or watering place, or a station whence another engine can be obtained, the power of the engine in good order will be almost entirely absorbed in dragging the defective engine behind it, and thus, the entire load will be retarded, and perhaps dangerously so. Had each engine taken its own load, the defective engine with its load would have been alone delayed: and, talking of expense, it would have been much better economy that a disabled engine and a small load should have been left at the first siding out of Bristol, than that a good engine should be strained and worked violently, and a heavy train delayed a considerable time throughout its journey to London, deranging all the arrangements, and endangering the line throughout. As to the maximum velocity, that could be disposed of in the way before mentioned, for the word power is resolved into the same elements, whether it be employed for draught or flight.

Mr. Brunel states "that with the best assistance of professional men, and others whose whole time and peculiar capabilities are applied to the system, we find it difficult enough to make our regulations sufficiently general to apply even upon our own line, and that the great difficulty in drawing up any code of regulations always is, to make a good regulation which is sufficiently applicable in all cases even on our own line of railway." I will prove that this very desirable system of uniformity can be easily accomplished as regards stations, and that is, to form them in such way that neither trains nor passengers shall ever cross the line. Fig. 1 will explain this method, by which it will be perceived that sidings must be placed on both sides of the line, and the crossings in such way that a train enters and departs from the siding without *backing*, backing into a siding being unquestionably most gothic and unskilful, the only apology for it being

Fig. 1.



the incapacity of the engineer to construct a safe switch and point. The passengers will enter into the offices by a bridge over or under the railway, as the case may be: it will not be out of place here to remark upon the most injudicious and unscientific practice adopted upon the Great Western Railway, in common with many others, of laying all the crossings along the line in one direction, by which means it is indispensable to back the train across the line, and bring it consequently to a dead halt twice before it can pass upon the wrong line; the apology for this is, that the peculiar switches adopted require such an arrangement, in order that the train may pass over them safely, and in the case of the switch being placed improperly, the train not being liable to be thrown off the rails. My patent switches are formed in such a way as to meet this latter case, and have this additional value attached to them, that a train may pass over them in both directions at full speed with perfect security, the switch being so made as to form a perfect and unbroken line, whether laid for the main line or cross line; my patent point or crossing is likewise so made as to require no cut in the line, nor a guard-rail in the main line; both these contrivances are in use, and when they are more generally known, the practice under discussion will be, it is trusted, altered.

It is likewise self-evident, that if sidings of this form be placed at intervals along the line, swift trains may pass slow ones with perfect facility by the slow train entering the siding, and leaving the main line open to the fast train; thus neither train need stop, nor would there be any further delay than a slight retardation of the slow train whilst the switches were altered; but supposing a man kept on the ground on purpose to effect this alteration of the switch, there would be no necessity to reduce the velocity of either train.

Here, again, therefore, a very general and very judicious regulation might be introduced applicable to all railways.

Admitting the deep interest which railway engineers *ought* to have, and the deep breeches-pocket interest which railway directors *must* have in the perfect working of railways, there is another interest which the Committee was not, perhaps, aware of operating most powerfully against the introduction of improvement, and that is the jealous and selfish feeling of engineers against adopting the contrivances of a contemporary, however useful such contrivance may be, their interest is to let well alone, and to keep without censure.

It is surprising it did not occur to Mr. Brunel that in the case of a public officer recommending to one company the adoption of a valuable improvement made by another, the two parties would be in the same relative position in the event of the compliment being returned, by the first being required to reimprove its own improvement, because, if it were proper in one company to go to an expense to effect a certain object, it is still their duty and interest to incur expence to perfect their arrangements; perhaps he may not be aware how large a comparative amount of profits is sunk amongst manufacturers to perfect their processes, when the spur of competition urges one man to surpass his neighbours, but in the case of railways the same feelings do not operate, which is the most powerful reason of all others why this want should be supplied by the interference of the legislature.

I agree with Mr. Brunel that buffers are matters of secondary importance, and I hold them only useful to protect the carriages from injury when they are knocked about in the station: for any purpose of benefit to a train when in motion, I never could discover, inasmuch as the action and reaction of the engine and trains is fully provided for by the springs connected with the drag links, in fact, were carriages provided with merely two springs acting in reverse ways, so that when the carriages are arranged in trains, a buffer spring connects one end of the links, and a drag spring the other, and supposing the link inflexible, the most perfect ease would be produced in the carriage, and every provision made for any sudden retardation to which the carriage will be subjected. However, a buffer is a buffer, whether formed by springs or hair, or by any other elastic means.

Had Sir F. Smith been simply a man of invention, without any connexion with the Board of Trade, and had he not the means of making his suggestions respected, his treatment from railway companies and railway officers would have been the very reverse of that he has found it, and the fact that his suggestions are treated with respect is a most powerful reason that the public supervisor should be the vehicle through which suggestions should be made, otherwise my experience and that of numberless other men prove that their thoughts and their time will be exerted in vain, in fruitless appeals to railway companies or their agents.

Mr. Brunel's objection to the 15 minutes interval is fair and well-considered; such an arrangement is wholly impracticable, and if adopted might lead to accidents in another point of view than that stated: a train might break down a few minutes after it had left a station, the guards and engine-men might be killed or disabled, then supposing the night dark or foggy, the succeeding train would run upon it, and very sad results would ensue; but if signals such as I have contrived were adopted, and which have been since ably recommended by Sir George Cayley, formed in such a way that the engine should make its own signal, and leave notice a mile behind it, whether it had passed or not the next signal post a mile in advance; the engine man would be thus certain of being informed of the state of the line in advance, and supposing any disarrangement of the signal, no delay or embarrassment would arise beyond the caution necessary in proceeding a mile forward, or perhaps one or two minutes in that distance. This objection is, I conceive, conclusive against any signals acting by time, as it would most infallibly fail at those times it was wanted, viz., in cases of accidents in bad weather. Whilst upon the question of signals, I cannot but advert to the evidence of Mr. Entwistle on this subject; that more accidents have not happened upon the Greenwich Railway is indeed a most providential circumstance; what would become of the trains in the case of a foggy night, with a bleak driving storm of rain or snow and wind from the north-west, and what security would there be that the men would hear the approach of a train and pass it, supposing a Croydon train was coming from London, time enough for either the Croydon train to pull up, or the Greenwich train from Greenwich to do so, or both; because, assuming that Mr. Entwistle's 15 men were most advantageously disposed of, placing 5 men from the junction towards London, and 5 towards Greenwich, the other 5 towards Croydon, the men on the London side would have to pass the word 400 yards towards Greenwich before the Greenwich train could be advised, and then either the one or the other would require to be brought to a dead halt within 200 yards, or a collision would ensue. I very much doubt whether Mr. Entwistle would not have been puzzled had the question been put to him, when was the last occasion that he was aware that this plan had been adopted, and how many times since he had been a director of the Greenwich Railway?

My experience tells me that if Mr. Brunel employs a break to his tender and engine-wheels of sufficient power to drag or stop the wheels, he will very soon destroy both the wheels and engine and railway. If any one thing has been settled in the management of a railway, it is this very fact, that, to block the wheels is to wear a flat place in the circumference, which, whenever the break is applied, allows the wheel to revolve until this flat place comes in contact with the rail, and which, by every successive operation, becomes worse, then, when the break is released, the flat side strikes the rail with a violent blow, and to such an amount that I have known one case on the Greenwich line when nearly a dozen rails were broken, on one occasion, by a bad wheel, the cause of which arose from this most vicious practice; if, therefore, Mr. Brunel realizes his notion, he will have good reason very soon to alter his plan. It is unquestionably a good plan that a large rubbing surface should be opposed to the momentum of the train, but that this should be sought, not by blocking, destroying the wheels, but by an independent method, similar to that I have already patented, and published in your Journal.

Mr. Brunel's opinion of the class of men for engine drivers, and his disposal of book principles amongst them, is most excellent, both in its substance, and in the way he defines it. I cordially and fully assent to all he says on the subject, and only wish, for his own reputation, he could always see his position as clearly and state it as cleverly as he has done in this instance.

In thus fully and freely criticising the evidence of Mr. Brunel, I trust that gentleman will do me the justice to believe that the importance attached to his opinions is my apology for subjecting those opinions to rigid review, and the object of the Committee, viz. to provide for and secure the public safety, renders it a duty of every well-wisher to railways to use his best efforts to assist such object. I purpose continuing my observations in your next paper; meanwhile

I remain, Sir,
Your obedient servant,
W. J. CURTIS.

July 22.

REMARKS ON MR. BARRETT'S OBSERVATIONS ON BARS, &c.

SIR—I have read in the July number of your Journal some observations by Mr. Barrett, on Mr. Brook's New Theory of Bars. Not having had time to peruse the work of the latter gentleman, I shall not presume as yet to form any opinion upon it; nor do I mean at present to make any remarks on Mr. Barrett's paper further than relates to a particular passage. Mr. Barrett says, "at the Neva, Gulf of Finland, the Narva, Dantzic, the Danube, the Nile, and many other places, the current without intermission (there being no *flood tide*) is perpetually running out at the rate of six, seven, or eight knots per hour, and yet the old entrances to these rivers have been blocked up by impassable bars, &c."—On this passage I will take the liberty to observe in the first place, that it presents one among too many examples of the confusion arising from hasty writing. Thus the names of rivers are mixed up with those of places in a way to render the writer's meaning rather doubtful. I presume, however, Mr. Barrett means to say—the Neva, at its effluence into the Gulf of Finland, the Narova, (not the Narva, which is a town) also at its egress into the Gulf of Finland, the Vistula (not named) at Dantzic, the Danube and the Nile at their entrance severally, into the Black Sea and into the Mediterranean.

And again, when Mr. Barrett says, "the currents of these rivers (at their embouchures understood) is perpetually running out at the rate of six, seven, or eight knots per hour, there being no *flood tides*," we are at a loss to understand whether the six, seven, or eight knots, refer severally to any three of the five rivers, and, if so, to which respectively, or whether the writer means that each of the five rivers has a current constantly running out without impediment, at the rate of from six to eight knots an hour, according to the season. The latter meaning seems to be the most rational. Now, with all due deference, I would observe, that the rivers mentioned differ so essentially in their characters that their currents must be very dissimilar, as must also the quantity and the quality (as regards sedimentary matter) of their waters. As to the Neva in particular, I know not whence Mr. Barrett has gleaned the incorrect information as to the rapidity of its current: but I beg leave to assure him, on the best authority, that its ordinary velocity, so far from being from six to eight knots per hour, is 27 inches per second, or $2\frac{2}{57}$ knots an hour. I cannot state with equal confidence the velocities of the other rivers at their embouchures, neither could I point out, without taking up much more room than you have to spare, the several particulars in which the rivers mentioned differ from one another; nor is it essential to my present purpose. The point to which I would specially draw attention is this.

According to Mr. Barrett, it is the deposit, by the outflowing waters of rivers, of the debris with which they are charged, that forms bars, whether there be tide or not, and in proof of this assertion, he gives as an instance among other rivers, the Neva. Now admitting the general correctness of his views on the formation of bars, it must be confessed he has been most unhappy in mentioning the bar at the mouth of the Neva as a case in point. The fact is, the Neva, of all rivers in the world, is the least obnoxious to the reproach of forming a bar to prevent ingress; on the contrary, she does all she can to open her mouth and invite entrance. True, there is a bar, but the materials of that bar are brought *not by the river* but by the sea.

The Neva at St. Petersburg is 50 feet deep, and, having deposited all impurities in the immense Ladoga, its waters are at all times, except when a strong wind blows in from the seaward for any continuance, as clear as crystal.

The head of the Gulf of Finland narrows gradually to the very mouth, or rather mouths of the river: accordingly when a strong wind blows in from the Gulf, a sea is soon raised whose waves, being pent in, cross and break, and, with the sand stirred up from the bottom rush for escape to the open mouths of the Neva, where being met by the obstacle of the descending current of the stream (bearing along in its main stream a mass of 115,000 cubic feet of water in a second) there naturally results an annihilation of force and a deposit or bar of sand. This being the fact, I am sure Mr. Barrett will see the impropriety of bringing in the Neva in support of an argument to which it does not apply.

The truth is, a bar or deposit will ever be formed where two bodies of water meet, and one or both is charged with detrital matter; but in many cases it is the *sea*, and *not the river* which furnishes the whole of the material of the bar, and in almost every case, I believe, it brings its quota to the mass.

In conclusion, Sir, for I have already trespassed too far, I would say, the subject of bars is a most interesting and a most important one; but those who discuss it cannot be too careful in the choice of facts in support of their arguments if they would not furnish weapons against themselves.

I am, Sir, your most obedient servant,
J. R. JACKSON.

P.S. As connected with the subject of bars and sand-banks, I cannot refrain from adverting to a common error which is being continually repeated by persons writing on these matters, viz., that the sand of rivers and that on the sea beach, results from the trituration of the stones rolled by the stream or agitated by the waves. Now Mr. Editor, it is physically impossible that sand can be formed in this way. Sand is an original formation, and all that running water and waves do or can effect is, to wash away the lighter matter, and leave, or carry away, and deposit the sand in particular places. Trituration in the beds of rivers and on the beach, will wear away stones and rocks and polish them, and the result will be a fine impalpable powder, but not one particle of sand will be formed in the process, were it to continue till doomsday. It is high time this egregious error was exploded; an error which could never have gained credit but for that unaccountable indolence of mind which leads so many to take every thing for granted without a moment's reflection.

J. R. J.

ON CANDIDUS'S REMARKS ON THE LECTURES OF THE PROFESSOR OF ARCHITECTURE.

PROFESSORS, whether of architecture or any other art or science, are undoubtedly public men, and as such are open to the most unlimited criticism; but, by the same rule, the critics must submit to be attacked in their turn, if any one of the public should think proper. But it should be remembered that abuse is not criticism, and that more effect will be produced by clearly pointing out errors than by the use of "damnable" expressions, which is the style I alluded to, and which will be found scattered occasionally through the fasciculi. I should not, however, have noticed it, had not Candidus been so much in the habit of boasting of his freedom of speech, which, however, by his own confession, avails but little, as it is evident he might as well "try to tickle a rhinoceros with a rose leaf" as attempt, with a one Candidus power, what it would require sixty to effect.

The possibility of treating Gothic architecture properly so as to conduce to comfort, is still unproved. I find repeated the bare assertion of the necessity for treating it with intelligence and ability, but no evidence produced to show that the greatest ability can lead to satisfactory results.

If no more was to be expected from Grecian and Roman than is to be found at the British Museum and other works by the same architect or others of his school, I should then call for Gothic or any other style to save us from such insipid abortions, which are, at any rate, as bad as facsimilies of Gothic, and much worse, inasmuch as they have been so much more often repeated; but I have a higher opinion of the resources of those styles than to believe such to be the case, and from some former remarks of Candidus, I think he will agree with me in that point at least. I shall make no comment on the preference apparently given to the spire of St. George's, Bloomsbury, over that of Bow Church; such an assertion would require more boldness than even Candidus is gifted with—it can therefore be only a mischievous insertion of the printer's devil.

Barry has taken up Gothic architecture with an originality of conception to be found in no other architect—but even his success will not warrant the assumption that we shall ever be able to incorporate the principles of the style with the habits of the present day. At the period at which this style flourished, it followed a regularly progressing course, commencing with the Norman. This was gradually improved upon till it resulted in the early English, which, by further modifications, became that of the decorated period, the most perfect of all. From that time it increased in richness and exuberance, but declined in purity till it was worn out in the reign of Henry VIII. Now I cannot see how we can, with advantage, dip down into any one of these styles at pleasure, and follow it out in the spirit in which it was then followed, and in which is the only hope of success. It is like transporting the trees of the tropics into this country, where only the most assiduous attention can keep them alive—nothing can ever make them equal in beauty the natural growth of the trees of our own forests, though in their native climate they may as much surpass them as they now fall short.

S. L.

THE ROYAL ACADEMY.

SIR—I am very glad to perceive that painters as well as architects, are at length beginning to remonstrate against the truly preposterous system of hanging pictures and drawings at the Royal Academy. Let us hope that what has lately been said on the subject both in your own Journal, and the Art-Union, will now shame the Academy into common sense, and deter them in future from taking in more works than can be properly seen when hung up.

Of course this would contract their catalogue to about one-half its present extent—in which case it might be sold to the public at half its present price,—but both the public and artists would be benefitted by the reduction—I do not mean of the price of the catalogue, but of the dense throng of pictures and drawings, the majority of which are annually put out of sight, by being *exalted* to disgrace—to their own disgrace and to that both of the Hanging Committee in particular, and of the Academy generally.

Still it is very doubtful whether the expostulations and remonstrances that have been made will produce any effect, unless repeated from time to time, and dinned in the ears of the Academicians, until they can no longer affect to be ignorant of them. Did the matter rest entirely with the President, the evil complained of would no doubt be remedied at once, but I suspect that like some other great personages, he is no more than "the puppet in the chair," and permitted to fill it on the condition of his napping in it, and not interfering with those around him. Though those composing them may be well-intentioned and reasonable people, corporate and public bodies are almost invariably shameless, and do not scruple to do in their united capacity, what hardly one among them would dare to sanction, defend, or justify individually and personally.

In the course of his remarks, the writer in the Art-Union attributes some portion of the present absurd system of hanging pictures in our public exhibitions, to the want of better contrivance and arrangement on the part of architects who build the rooms. Herein he is partly right, but he is assuredly mistaken if he supposes that, as far as architectural appearances is concerned, any thing would be lost were the rooms to be designed in such a manner as to render it impossible to put any pictures at more than a moderate height above the eye. On the contrary, as much might be gained in point of architectural effect as of positive convenience; since it would not be at all requisite that the proportions of the rooms, as to height, should be altered, or their ceilings an inch lower than at present. All that would be necessary is that no more than a proper altitude should be allowed as the available space for hanging pictures on the walls, (which might vary in the different rooms accordingly as they are intended for small or large paintings); and from that height the architectural decoration of the upper part of the walls and ceiling should commence. By this means the general appearance would be very greatly improved; and instead of the broker's-shop and picture-dealer's-warehouse look, which now so disagreeably characterises all our exhibition rooms, there would be an air of elegance and spaciousness,—of there being room enough and to spare without *stowing away* a number of pictures, piling them up to the very ceiling, when they might just as well be poked into a lumber garret at once.

In short, let the Academy and other exhibiting Societies break up their *Lumber Troop* corps, dismiss their host of supernumeraries, and instead of surfeiting their visitors with an annual cram—consisting of a good deal of trash, give us much less as to quantity, and much more as to quality.

I remain, &c.,

COMMON SENSE.

PILBROW'S CONDENSING CYLINDER STEAM ENGINE.

THIS is a contrivance intended, according to a pamphlet written by Mr. Boyman Boyman, to save the loss of power occasioned by the imperfect exhaustion of the cylinder in steam engines of the ordinary construction, and by which Mr. Pilbrow considers that he will save *more than half* the fuel of Mr. Watt's Rotative engines. The author of the pamphlet in question, however, dispels at the very outset the illusion as to the extent of saving by stating that Mr. Watt estimated the mean resistance of the unexhausted steam at 4 lb. per square inch, in an engine loaded so as to exert its intended power, the steam being 2½ lb. less than the atmosphere. In this case the pressure of the steam is 2¼ lb., from which deducting 4 lb. for imperfect exhaustion, and 1¾ lb. for friction (as at page 28) there remains an effective pressure of 6·46 lb. The pressure in the condenser at a temperature of 100 is 1 lb., therefore the limit of what may be saved by Mr. Pilbrow's arrangement is 3 lb. per square inch, which is the entire loss resulting from the exhaustion in the cylinder being less perfect than in the condenser; but if the whole of this were saved, the load of the engine being increased, the friction would be so likewise, and the effective pressure would become, say 9·09 lb., and the saving of fuel would be less than 29, instead of more than 50 per cent., as anticipated by Mr. Pilbrow. It is evident that the loss in question would not rise in the same proportion as the pressure of the steam employed, particularly when it is expanded in the cylinder, which is now pretty generally done to a greater or less extent, and we are persuaded that Mr. Farey must have overrated the resistance of the unexhausted steam, where it is used at 3½ lb. above the atmosphere, when he estimated it at 5·71 lb.; but even with this allowance the consequent loss of duty amounts to no more than 29 per cent. It should be observed that this is the *whole* loss due to imperfect exhaustion in the cylinder, which can certainly not be saved by Mr. Pilbrow's arrangement, though he considers that it is.

Little need be said of the theory of condensation, as it is called, laid down at pages 19 and 20, which is very little of a theory, and nothing at all to the purpose; but since it is dragged in, as it were, in confirmation of the advantages of the Condensing Cylinder Engine, we shall merely show that the inferences intended to be drawn from it are erroneous.

The theory of condensation is that "steam can only be condensed as fast as it rushes from the cylinder to the condenser, as far as the injection can enter, and as fast as the water, or cold surface, can absorb all the caloric of the steam." Mr. Boyman concludes that "if the vacuum gauge shows, whilst the steam is being condensed, a less mean vacuum in the condenser than what is due to a temperature of 100°," (considered by Mr. Watt as a fair average), "it shows that the steam has flowed quick enough to the condenser, and is there waiting to be condensed," and that "no increase of eduction valve would, therefore, cause a quicker annihilation of the steam, to give a better mean exhaustion of the cylinder, for it is already large enough to permit its escape as fast as a certain quantity of water can take up its caloric." But what is the just conclusion to be drawn from the above circumstance?—Simply that there is not sufficient injection water to reduce the condensement to the required temperature; a knowledge of the actual state of exhaustion in the cylinder would alone show whether the steam flowed fast enough into the condenser. Mr. Boyman harps continually on one string—the impropriety of reducing the condensement to a lower temperature than 96° or 100°, and pretends to conclude therefrom that no better cylinder exhaustion than was obtained by Watt can be achieved with the ordinary air pump, separate from the condenser.

The long discussion of the comparative performance of Mr. Watt's rotative engines and the present is irrelevant, and we shall therefore discuss it with one or two remarks.

After extracting Mr. J. S. Russell's proof of the fallacy of the opinion that the better the vacuum the greater is the duty, the author informs his readers that "the above formula is given because it confirms the general principle, that more is lost than gained by a vacuum *beyond certain limits*. It does not embrace," he says, "the principles of condensation, but has reference simply to temperature; not," he continues, "that this theory is supported by the practice of Cornish engines, where the greatest duty is performed with the greatest vacuum."

If, then, this theory is not supported by facts, how can it be said to confirm the general principle?

In speaking of the *extraordinary* Indicator diagrams of the present day, (which seem to puzzle Mr. Boyman exceedingly, because they show that Mr. Farey's observation, made 14 years ago, is not applicable to engines of the present day, namely, that "the modern engines are, by their construction, less capable of speedy exhaustion of the cylinder than the original construction"), he mentions that in the diagrams of the *British Queen*, where a mean cylinder exhaustion of 12·3 lb. is shown, the condensement is reduced to the temperature of the external water, but he does not seem to be aware that *the condensing water left the condenser at a much higher temperature*, which it must have done, or it could not have condensed the steam. It is however certain that, whatever may have been the state of the vacuum in the upper part of the condenser, where the steam from the cylinder entered it the mean difference between it and the mean cylinder exhaustion *cannot possibly* have amounted to 2.41 lb., the external barometer standing at 30 inches, as that would indicate a perfect vacuum, which is obviously impossible.*

In Mr. Pilbrow's engine the ordinary condenser and air pump are replaced by a double-acting air-pump of the same size as the steam cylinder, called the condensing cylinder, in the interior of which the condensation is effected by injection alternately above and below the piston, which is of course solid, like the steam piston. The two cylinders are connected at top and bottom by passages, with valves to open and close the communication alternately. The action will be as follows: while the steam piston is ascending, the air-pump piston is descending, and the two cylinders communicating at top, the steam which performed the previous down stroke will flow into the condensing cylinder, and be condensed by the jet, by which, as we know from the experience of ordinary condensing engines, the vacuum above the air-pump piston will be maintained at nearly its maximum, while the exhaustion of the cylinder will be nearly the same as in ordinary condensing engines. Mr. Boyman however supposes that, "during its condensation, the uncondensed steam will keep giving to the condenser piston, until completely annihilated, just as much power as it offers resistance to the effective action of the steam piston." The exhaustion on the under side of the condenser piston will be the maximum throughout the stroke, so that the resistance to the motion of the steam piston (exclusive of friction and the resistance to the discharge of the condensement in the latter part of the stroke) will be equal to the mean pressure of the used steam remaining in the steam cylinder *minus* the difference between the maximum and mean exhaustion in the condenser, and this difference, which is quite insignificant, is, after deducting the surplus power required to work his large air-pump, the true gain of power obtained by Mr. Pilbrow's contrivance, and we think it probable that after the deduction the gain will be found to be negative, or a loss.

* It may be as well to observe here that the difference between the exhaustion in the cylinder, and in the condenser is independent of the mode of condensation: and that consequently, if by any improved process the vacuum in the condenser be increased, the cylinder exhaustion must be so too.

CARBONIC ACID GAS VERSUS STEAM.

(From "Buckingham's America.)

Towards the close of our stay in Philadelphia, I had an opportunity of attending one of the chemical classes of my friend Dr. Mitchell, and witnessing there a most interesting experiment for the rendering carbonic acid gas solid, and for producing by it a degree of cold, extending to 102 degrees below zero, on the scale of Fahrenheit's thermometer. The materials, first confined in a strong iron receiver, were, super-carbonate of soda and sulphuric acid, in separate divisions; the whole was then powerfully shaken, so as to be well mixed or incorporated, and this operation continually evolved the gas, till the whole vessel was filled with it in a highly condensed state.

An instrument not unlike a common tinder-box, as it is used in England, but about twice the size, and with a small tube of inlet passing through its sides, was then fixed by this tube to a pipe from the receiver. The inside of this box was so constructed as to make the gas injected into it fly round in a series of constantly contracting circles, which was effected by projecting pieces of tin at different angles, fastened around the sides of the interior. The gas being then let out by a valve, entered this box from the receiver, making as loud a hissing noise as the escape of steam by the safety-valve of a large boiler, and in about three or four seconds the emission of the gas was stopped.

The box was then taken off from the receiver and its cover opened, when it was found to be filled with a milk-white substance, in appearance like snow, but in consistence like a highly-wrought froth, approaching to a light paste. It was surrounded with a thin blue vapour like smoke, and was so intensely cold, that the sensation of touch to the fingers was like that of burning; and the feeling was more like that of heat than cold. The slightest particles of it dropped on the back of the hand, and suffered to remain there, occasioned a blistering of the skin, just like a scald; and some of the students of the class who attempted to hold it in their fingers, were obliged to let it drop as if it were red-hot iron.

Some liquid mercury, or quicksilver, was then dropped into a mass of this "carbonic acid snow," as it was called, mixed with ether, upon which it instantly froze, and being taken out in a solid mass, it was found to be malleable into thin sheets under the hammer, and capable of being cut up like lead, with a knife or large scissors. As it became less cold it grew more brittle, and then, when pressed strongly by the thumb or finger against a solid substance, it was found to burst under the pressure, with a report or explosion like the percussion powder.

A small piece of this carbonic acid snow was placed on the surface of water, where it ran round by an apparently spontaneous motion, and gave out a thin blue vapour like smoke. Another piece was placed under the water, and kept beneath it, when it emitted gas in an immense stream of air-bubbles, rushing from the bottom to the top; thus returning, in short, from its solid to its original gaseous condition. Some of the snow was then mingled with the well-known "freezing mixture," and by stirring these both together, a degree of intense cold was produced, extending to 102 degrees below zero, and there remaining for a period of ten or fifteen minutes; though the weather was extremely hot, the thermometer standing at 94 degrees in the shade, in the coolest parts of Philadelphia, and being at least 90 degrees in the lecture-room itself.

The practical application of this discovery to the propelling of engines in lieu of steam, was then exhibited to us. A model of an engine of the ordinary kind now in use for mines, manufactories, and steam-ships, was placed on the table before the lecturer. A metal tube was then screwed on to the pipe and valve of the receiver, in which the condensed carbonic acid gas was contained, and the other end of the tube through which the gas was to escape, when let into it from the receiver, was applied to the wheel of the model engine; the gas was then let out, and the rushing torrent of it was such as that it propelled the engine wheel with a velocity which rendered its revolutions invisible, from their speed, making the wheel appear stationary, though in a trembling or vibratory condition, and rendering all perception of the parts of the wheel quite impossible till the gaseous stream which gave the impetus was withdrawn.

Dr. Mitchell expressed his belief that this power might be made to supersede entirely the use of steam and fuel in navigation, and thus overcome the greatest difficulty which has yet impeded long voyages; he thought it might effect the same salutary change in manufactories where engines are used, so as to remove the greatest nuisance, perhaps, of all manufacturing towns, the immense quantities of smoke which darken the atmosphere, and destroy the cleanliness of places, persons, raiment, and dwellings. He founded his belief on the expansive power of this gas when brought into a highly condensed state, such as we saw it, and the practicability of bringing this power to act upon engines of any size by land or by sea. For the latter purpose he suggests the use of iron tanks, made with the requisite degree of strength, to act as receivers; these being fitted to a ship's bottom, along the keelson and the inner floor of the hold, as the iron water-tanks of ships of war are at present, it may be placed on board vessels intended to be propelled by engines, in such quantities as the length of the voyage may require; communications from these tanks, by tubes of adequate size and strength, would then have to be made to the engines, and placed under the complete control of the engineer, as the steam-power is at present. The expansive power of the condensed gas, and its pressure outward, or tendency to escape, being the same in its nature with steam, but greater in degree, the application and direction of this power would effect all that steam now does, and thus supersede the use of fuel, with its inconveniences and accidents, entirely.

In reference to the expense, Dr. Mitchell had made such calculations as to satisfy him that it would be cheaper than the present materials of steam navigation. The Great Western steamer, in coming from London to New York, actually consumed 600 tons of coal, which, at the lowest possible estimate, could not cost less than £1000 sterling, or 5000 dollars. But as it was necessary to provide for a longer voyage than that actually performed, in case of accident or delay, no less a quantity than 800 tons were taken on board, and consequently 800 tons of space were wholly lost, or rendered unproductive, by its appropriation to fuel. The expense of the requisite quantity of gas for such a voyage, including all the fittings, would not, he thought, exceed that of the coals and requisite machinery; and the saving of the space, for freight, would be a source of considerable profit; while the avoidance of the heat and smoke, inseparable from fuel and steam, the absence of boilers and chimneys, and the safety from accidents of bursting and taking fire, would be all such high recommendations to passengers, that none would venture to embark in steam-ships while those propelled by carbonic acid gas were available.

PROCEEDINGS OF SCIENTIFIC SOCIETIES.

INSTITUTION OF CIVIL ENGINEERS.

March 16.—The President in the Chair.

"*Description of two Wrought-Iron Roofs over the buildings at Mr. Thomas Cubitt's Works, Thames Bank.*" By Mr. Adams.

This communication describes in detail the construction, and gives the dimensions of the several parts of two fire-proof roofs of 29 feet span, one of which bears, in addition to the covering, a ceiling of tile arches upon iron girders, the weight of which is equal to 5 tons 4 cwt. upon each truss.

The paper is accompanied by two drawings of the roofs.

"*Description of a Double Telescope Theodolite.*" Arranged by Nathaniel Beardmore, Grad. Inst. C.E.

The improvement in this theodolite consists in its having a second telescope fixed over the ordinary one, in a reverse position, so that the line of collimation of the two telescopes when properly adjusted should be the same. The principal advantage gained is, that a straight line may be carried out with perfect accuracy, without the tedious and uncertain process of adding 180 degrees to the observed angle and reversing the instrument. A drawing of the instrument accompanied the communication.

"*On setting out Curves for Railways.*" By R. C. May, Assoc. Inst. C.E.

The method of setting out curves proposed in this communication is founded upon the 32nd Prop. of the 3rd book of Euclid. It consists in cutting off by a chord a segment of the circle to be described, and then finding any number of points in the curve by means of a reflecting instrument, which is set so as to reflect the angle in that segment.

The instrument which has been adapted by the author for this operation, consists of two plane mirrors, the upper one being fixed vertically upon a disc of brass, and the lower one fastened to an arm which turns upon its centre, and permits the two mirrors to be set at any angle with each other: the arm can be fixed by a clamp screw. In the case surrounding the mirrors are two holes, for admitting light, and between them is the sight hole, placed so as to bisect the angle formed by the mirrors. From the underside at the centre of the instrument is suspended a slender wooden rod, with a pointed end, weighted with lead.

Angles are taken with the instrument in the same manner as with the box sextant. To determine any point in the curve, the instrument when set fast is placed in such a position that the two given objects coincide in the mirrors, and the weighted rod being released by withdrawing a bolt, falls directly beneath the centre of the instrument, marking the required point in the curve.

The author presented with this paper a Reflecting Instrument, and field tables of chords and segments to be used in setting out curves by this method.*

March 23.—The PRESIDENT in the Chair.

"*An improved Plank Frame, for sawing Deals and Planks of various thickness into any number of boards.*" By Benjamin Hick, M. Inst. C.E.

The principal improvement in this machine is a novel kind of gearing for producing what is usually termed the "taking-up" or "traversing motion" of the plank during the operation of sawing.

A revolving motion is given to two pair of coupled vertical fluted rollers, by means of worms and wheels, which are worked by a ratchet wheel and catch, from the crank shaft of the machine. When a plank is introduced between the moving rollers and the fixed guides in the centre of the machine, the tendency of the motion is to draw the plank forward at each stroke, with a force exactly corresponding to the degree of resistance opposed by the teeth of the saw. By this means, the necessity of any other support or side roller to the plank, during its progress through the machine, is avoided, and any number of planks of different length, depth, and thickness, can be put through the machine after each other, without any alteration or stoppage of the work.

Several minor improvements are introduced in the general arrangement of the machine, particularly in the position of the crank shaft and connecting rod, which latter is placed in the centre of the moveable frame, occupying a space which has not hitherto been made use of in machines for cutting two planks simultaneously; and by carrying the crank shaft upon the framing, instead of having it fixed upon a separate foundation, the construction is simplified as well as rendered less expensive.

The communication was accompanied by a working model of the machine.

"*An historical Account of Wood Sheathing for Ships.*" By J. J. Wilkinson.

This communication commences with the earliest history of naval architecture, the different modes of construction, and the precautions taken for the preservation of the vessels from the attacks of marine animals.

A very early instance of extraordinary attention to the preservation of the bottom of a vessel appeared in a galley supposed to have belonged to the Emperor Trajan, A. D. 98 to A. D. 117, which was found in the fifteenth century in the lake Hemorese (or Lago Riccio), in the kingdom of Naples, and was weighed after it had probably remained more than 1300 years under water; it was doubly planked with pine and cypress, coated with pitch, upon which there was a covering of linen, and, over all, a sheathing of lead fastened with nails of brass or copper; the timber was in a perfectly sound state.

In the reign of Henry VIII. large vessels had a coating of loose animal hair attached with pitch, over which a sheathing board of about an inch in thickness was fastened "to keep the hair in its place."

It is believed that the art of sheathing vessels was early practised in China: a mixture of fish oil and lime was applied; it was very adhesive, and became so hard that the worm could not penetrate it.

The opinions of Sir Richard Hawkins, of François Cauche, and of Dampier, on the practice of wood furring, are then given at length, with extracts from their journals.

The sheathing the bottoms of ships with timber, appears to have been disapproved by these early navigators. In 1668, the officers of the fleet, then preparing under Sir Thomas Allen for an expedition against the Algerines, petitioned that their vessels might not be thus encumbered, as they were in consequence always unable to overtake the light-sailing unsheathed vessels of the enemy; the petition was granted, upon the condition that precautions should be taken by cleaning the ships' bottoms very frequently.

In 1670 a patent was granted to Sir Philip Howard and to Major Watson, for the use of milled lead sheathing; it was not, however, introduced without difficulty; nor until an order was issued that "no other than milled lead sheathing should be used on his Majesty's ships." About the year 1700 the lead was acknowledged to have failed, and wood sheathing was again introduced.

Numerous instances are given of the employment of wood as sheathing for ships in celebrated expeditions: the ravages of the worm, the accumulation of barnacles and weeds, are then described; the qualities of the wood employed for sheathing in different countries, both formerly and up to the present time, are examined, and the author, who undertook the investigation of this subject in consequence of finding how little good information existed in an accessible form, promises the history of metal sheathing in a future communication.

"*A Machine for bending and setting the Tire of Railway Carriage Wheels.*" By Joseph Woods, Grad. Inst. C. E.

The usual mode of bending tire bars was by means of swages and hammers round a fixed mandril; after being welded, they were stretched on a cast-iron block formed of two semicircular pieces hinged at one point, and wedged apart at the opposite side; the hoops being heated were placed on this block, and by repeated blows driven into close contact with the mould.

Much difficulty was experienced in thus making up tires for large railway wheels, and the present machine was constructed for facilitating the process.

One end of the tire bar when heated is wedged into contact with one of four segments of a circle, of the required diameter, upon a cast-iron table, which is caused to revolve slowly; the pressure of a guide wheel at one side forces the tire bar to warp round the segments, and to form the circular hoop required; its ends having been previously scarfed, are then welded together.

The tire is again thoroughly heated and placed around the four segments, which slide radially on the table, and are then simultaneously forced outwards by a motion of the centre shaft.

The tire being slightly chilled, and assisted by the swage and hammer, soon adapts itself to the segments, and forms a circular hoop instead of two semi-circles irregularly joined at their points of contact, as by the old system; it is then ready for being chucked on the lathe, and bored out before shrinking on the wheel.

It is apparent that a machine of this description becomes applicable to tires of any diameter, by having three or four sizes of segments adapted to the table. It is found to diminish the manual labour, and to prepare the tire more accurately than by the usual process.

A model of the machine, and a detailed drawing of the several parts, accompanied the communication.

"*On the improvement of the Roads, Rivers, and Drainage, of the Counties of Great Britain.*" By Robert Sibley, M. Inst. C. E.

The author had on a former occasion drawn the attention of the Institution to the subject of a Bill before Parliament, "for the better regulation and general improvement of the Drainage of the Country;" and at the same time pointed out the course pursued by the magistrates of the County of Middlesex, in procuring with his professional assistance an accurate account of the Rivers, Bridges, &c., hoping that it might lead to similar surveys in other counties.

In the present communication he investigates the nature of the works which each county may be expected to undertake, and the means of accomplishing them economically, so that real public benefit may accrue.

The objects principally requiring the attention of the county magistrates, he considers to be, First—Facility of intercourse by the improvement of the roads, bridges, rivers, and canals. Secondly—Protection from injury by the passage of the waters from or through the county; and Thirdly—The removal of causes tending to vitiate the atmosphere, or to render unwholesome the water used for the support of human life.

All these points, which do not appear to have been fully comprehended in the Sewage Acts, are examined at length, and suggestions are offered for their regulation, with examples of the effects resulting from their neglect.

The advantage of placing the water-courses of the country generally under a well regulated system of management, is insisted upon as the most effectual mode of guarding against the destruction of property, and not unfrequently of human life, which ensues from the effects of sudden inundations, such as have recently occurred in the county of Middlesex.

March 30.—The PRESIDENT in the Chair.

"*Description of a new Universal Photometer.*" By Dr. Charles Schafhaeutl of Munich, Assoc. Inst. C. E.

The inadequacy of the photometric instruments invented by Pictet, Rumford, and others, is universally acknowledged. The bromide of silver, as used by Sir John Herschell, although extremely sensitive, is only slightly affected by artificial light.

These circumstances induced the author to complete the present instrument,* which he contemplated about twelve years since.

* This paper, with enlarged field tables, has been published by the Author, with the permission of the Council of the Institution, to accompany the instrument.

* The instrument was constructed by Mr. E. M. Clarke, 428, Strand.

The intensity of the undulations of gaseous fluids, as well as that of the air, is proportional to the amplitude of the oscillations, or more properly to the square of the amplitude.

A wave of light striking the retina must create a similar vibratory motion in the nerves of the retina, because the velocity of the molecular movement of the nerves depends upon the force with which they have been struck by the original wave, and if this velocity could be measured, it would show at the same time the intensity of light.

It is scarcely possible to obtain a direct accurate measurement of this velocity, but if the time during which the vibratory motion of the nerves ceases, be ascertained, the velocity of the vibrating molecules, and therefore the intensity of light, may be determined; because the duration of an impression on the retina is dependent on the resistance which the molecules of the nerves oppose to every force striking them; but as this resistance of the nerves increases as the square of the velocity, four times the momentum or intensity is necessary to double the time of duration; or, in other words, the intensity of the pencil of rays is as the square of the time of the duration of that impression made on the nerves of the retina.

The new photometer consists of a brass bar fixed vertically in a stand, carrying at its upper end a small tube in two parts, which may be lengthened from 5 to 10 inches if requisite. This eye tube has at each end a sliding plate pierced with holes of corresponding diameters. From the bottom of the bar a projecting arm sustains the lower end of a strip of rolled steel 18 inches long, $\frac{5}{16}$ths inch broad, and $\frac{1}{32}$nd inch thick; this has at the upper end a thin plate pierced with a small hole, corresponding with the holes in the sliders, and standing $\frac{1}{8}$th of an inch from one of them: upon the main bar is a prism with a slit in it, through which the strip of steel passes; this prism can be moved up or down by a rack and pinion, so as to lengthen or shorten the vibrations of the strip.

The method of using the instrument is to adjust the two holes at the opposite ends of the horizontal eye tube, so that they perfectly correspond, and do not permit any rays of light to enter, unless the plate at the extremity of the spring be pushed aside. The light to be compared is then placed at a certain given distance behind the plate, so that by bringing the axis of the hole which is pierced in it into the axis of the tube, a small pencil of light may enter the pupil of the eye. The prism is then placed at 100 of the scale on the side of the brass bar, and the steel strip caused to vibrate gently. A luminous disc immediately appears, accompanied by scintillations, which are caused by the impressions on the retina being interrupted by dark intervals: the prism is then gradually raised until the length of the vibrations of the strip being diminished, and the velocity increased, the luminous disc appears perfectly steady and clear. The length of the vibrating portion of the strip is then read off by the verniers marked on the brass rod, and compared with the whole length of the spring, measured from 100, which is considered as unity. The number of the vibrations to be computed from the found length of the spring, are inversely to the numbers of vibrations of the whole length, as the squares of their relative lengths. Hence are constructed the formulæ for calculation, which are given at length in the communication.

A fresh luminous impression is made on the retina as often as the circular aperture in the screen on the top of the spring cuts the axis of the tube. If the duration of the small vibration of the nerves of the retina is shorter than the time of a vibration of the spring, a dark interval appears between the two luminous impressions. In this case the vibration of the spring is shortened until the next impression returns just as the first ceases, and therefore the dark interval disappears; then by measuring the length of the shortened spring, the number of vibrations can be computed, and from them the intensity of the light.

This communication was illustrated by a series of experiments upon different lights, with the Photometer which was presented by the author to the Institution.

"*On the circumstances under which the Explosions of Steam Boilers generally occur, and on the means of preventing them.*" By Dr. Schafhaeutl, of Munich, Assoc. Inst. C. E.

Explosions of Steam Boilers.—In this communication it is assumed, that perhaps not one-tenth of the recorded explosions of steam boilers can be correctly attributed to the overloading of the safety valve, or to the accumulation of too great a quantity of steam in the boiler. The author alludes to the degree of pressure which hollow vessels, even of glass, are capable of sustaining, if the pressure be applied gradually. He found, in repeating the experiments of Cagniard de la Tour, subjecting glass tubes of one or two inches in length, one-fourth part filled with water, hermetically sealed, and immersed in a bath of melted zinc, that they apparently sustained the immense pressure of 400 atmospheres without bursting; but if the end of an iron rod was slightly pressed against the extremity of the tube, and the rod caused to vibrate longitudinally by rubbing it with a leather glove covered with resin, the tube was invariably shattered to pieces.

Hence he concludes, that something more than the simple excess of pressure of steam in the boiler is necessary to cause an explosion, and that a slight vibratory motion alone, communicated suddenly, or at intervals, to the boiler itself, might cause an explosion. From the circumstance of safety valves having been generally found inefficient, he concludes that a force has operated at the instant it was generated in tearing the bottom or sides of the boiler, before it could act upon the safety valve.

From the sudden effect of this force, explosions have been ascribed to the presence of hydrogen, generated by the decomposition of water; but independently of the difficulty of generating a large quantity of hydrogen in such a manner, it could neither burn nor explode without the presence of a certain quantity of free oxygen or atmospheric air; and such an explosive mixture would not take fire, even if mixed with 0·7 of its own volume of steam.*

Sudden conversion of Water into Steam.—The ordinary mode of converting water into steam is by successively adding small portions of calorie to a relatively large body of liquid; but if the operation was reversed, and all the heat imparted to a given quantity of water in one unit of time, an explosive force would be developed at the same moment. For example, if a bar of iron be heated until it is coated with liquid slag, and is then laid upon a globule of water upon an anvil, and struck with a hammer, the liquid slag communicates its caloric instantly to the water, becoming solid at the same time that the water is converted into vapour with a loud report. A similar occurrence may take place in a steam boiler when a quantity of water is thrown into contact with an overheated plate, either by a motion of the vessel or from a portion of the incrustation formed on the bottom or sides becoming loosened. A sudden opening of the safety valve may, under certain circumstances, prove dangerous, or even any rapid increase of heat which would cause a violent excess of ebullition in the water.

An examination is then entered into of the respective powers of water and of steam, to transmit undulatory motion, and of their compressibility. According to Laplace, the conducting power of steam at our atmosphere and 294·1° Far. is 1041·34511 feet per second, and that of water 6036·88 feet. The ratio of these different velocities is therefore as 1 : 4·5.

In cases of a sudden explosive development of steam, the principal action is directed against the bottom or the sides of the boiler, whence, spreading itself through the water, it is finally transmitted through the steam to the safety valve; a wave created by an explosion, even at the surface of the water, would reach the bottom or the sides of the boiler, $1\frac{1}{2}$ times sooner than it would affect the top of the steam chamber; but if it took place at the bottom, the time for the explosive wave to reach the safety valve would be the sum instead of the difference of both velocities. Although these relative periods of time may be considered as infinitely small, it is contended that there is sufficient delay (counting from the moment at which the plates begin to yield) to cause the rupture of the material which would otherwise have yielded by its own elasticity had the time been greater, as all communication of motion is dependant only on time.

Experiments upon Wires.—To illustrate the effect of the sudden development of an explosive force upon the plates of a boiler, the author gives the results of a series of experiments made by him upon iron wires, for the purpose of ascertaining the amount of elongation which took place before yielding under the sudden application of a given weight. The result was, that a wire which had resisted a tension of 22 cwt. when gradually applied, broke invariably, without any elongation, when the same force was suddenly applied by a falling body.

Upon Railway Bars of different qualities.—Similar experiments with railway bars showed that fibrous iron, which supported a gradual tension, broke by the sudden application of the same force; while close-grained iron, which was incapable of resisting the gradual strain, bore perfectly well that of sudden impact. These facts are worthy of consideration in the selection of iron for boiler plates, where the sudden action of the rending force is to be guarded against.

The details are then given of a series of experiments, illustrating in an ingenious model, by means of an explosive mixture of chlorate of potassa, the effects of explosions at different heights within a boiler.

Proposed Safety-valve.—A careful examination of the circumstances, and the results of his experiments, convinced the author that a simple mechanical arrangement, applicable to all boilers, might be introduced, so as to diminish the danger arising from the sudden development of an explosive force. He proposes to connect with the bottom of the boiler, by means of a pipe, an extra safety valve of a given area, loaded to five-sixths of the absolute cohesive force of the boiler plate. In the event of a sudden development of steam, the first shock would act upon the valve and open it, which would have the effect of depriving the wave generated of its destructive force, and at the same time diminish the violence of the second shock from the top of the boiler, having permitted the escape of a portion of the water from the boiler.

The apparatus for conducting the experiments was presented with the communication.

Steam Boiler explosions.—Mr. Parkes stated, that he had been occupied for several years in collecting facts illustrative of the phenomena of steam boiler explosions. These disasters could not all be referred to one cause. A boiler might be too weak to sustain the pressure within it, and a rupture would be the necessary consequence. But though the simple elastic force of the steam might thus occasionally account for the rending of a boiler, that cause was insufficient to explain many well-known phenomena, such as the projection of an entire boiler from its seat, the separation of a boiler into two parts, the one remaining quiescent, the other being driven to a great distance, &c. He was of opinion that a very sudden development of force could alone have produced such effects.

Dr. Schafhaeutl had ingeniously shown that an explosive force generated under water would act upon the bottom of the boiler and burst it, before the

* See the author's experiments, Mechanics' Mag., Vol. XXX. p. 144.

safety valve could relieve the pressure. The Doctor deduced from Mr. Parkes's theory of "the percussive action of steam," and his own experiments, that if, from any cause, such as the breaking up of a portion of crust adhering to the bottom of the boiler, a volume of steam of high elastic force was suddenly evolved, a rupture of the bottom would be the consequence, or, the boiler might be separated into two parts. Mr. Parkes coincided in this opinion, and cited several examples in support of it.

It appeared to him that a force different from, and greater than, the simple pressure of the steam, was the principal agent. The Committee of the Franklin Institute, and others, who in their experiments had endeavoured to produce explosions of boilers, had very rarely succeeded, and the effects obtained fell far short of those which continually occurred by accident. It might be safely inferred from this fact, that the experimenters had not arrived at the true cause of the ruptures and projections of boilers, otherwise the production of similar effects would not have been difficult.

Salt Pans.—Describing the sudden development of a volume of steam, from highly heated plates, which no practicable number of safety valves could discharge quickly enough to save a boiler from destruction, he instanced the effects produced by the breaking up of the scale in salt pans. Carbonate and sulphate of lime were separated from brine by evaporation, and adhered very firmly to heated surfaces. A crust of salt frequently formed upon this deposit; the cessation of ebullition (if the deposit occurred over the furnace) was the consequence, and the bottom of the pan became red hot. The manner in which the pan scale was disengaged, was to strike it with the edge of a heavy iron pricker, which allowed the brine to reach the plate; it was also frequently broken through by the expansion and bagging down of the plates, leaving the crust above like an arch. In such cases the plate was seen for an instant to be red hot, and immediately afterwards an immense column of brine was projected from the pan, the steam evidently being of high momentary elasticity. Mr. Parkes had seen a yard square of scale thus burst, the whole surface of the plate being at a glowing red heat. Had the pan been closed, like a steam boiler, he conceived that the blow of the steam on the roof, bottom, or sides, would have destroyed the vessel.

A thin copper salt pan at Mr. Parkes's works, had a hole burst through its bottom by the sudden action of steam thus generated. The spot had no doubt been previously injured by heat. He conceived that similar phenomena might, and frequently did, occur in steam boilers.

Heated Plates.—A theory has been adopted by many writers on the explosion of steam boilers, that red-hot iron plates would generate less steam than plates at a less heat. This was founded on the experiments of Leidenfrost, Klaproth, and others, on the length of time requisite to evaporate a small globule of water in a red-hot spoon. But there was no analogy between the condition of a hot spoon containing a drop of water, and that of a body of water and heated plates in boilers.

Steam of great force would instantly be produced from a thin sheet or wave of water, passing over hot plates, the molecular attraction of a drop falling a short distance upon a plate would be destroyed, and the whole be instantly converted into steam of a high momentary elasticity. The theory of the hot spoon experiment, as applied to boilers, had been demonstrated to be fallacious by Dr. Schafhaeutl in a paper published in the *Mech. Mag.* vol. xxx. No. 799.

"Union" Steamer at Hull.—The explosion of several boilers had been attributed, and Mr. Parkes thought justly, to a wave of water washing over highly heated plates. He believed that the fatal accident to the "Union" steamer at Hull was so produced. The boilers of steam vessels were not at that period so well arranged as at present, for preventing the water from flowing to one side, and leaving a portion of the top of the flues dry with the fire beneath. Under such circumstances, the disaster which occurred would be inevitable, on the vessel's coming on an even keel. Mr. Parkes was not of opinion that it required the exposure of a large area of heated metal to effect the separation of a boiler and the projection of the upper half of it; as, in this case, it was the suddenness of the action, no number of safety valves could have deprived the steam of its instantaneous force, so as to have saved the boiler. The entire circumference of large boilers had been frequently divided as clean as a pair of shears would have accomplished the work. These phenomena were evidences of a force very suddenly exerted.

Sudden actions on the surfaces of boilers arose also from other causes than the heating of plates. During the inquiry into the causes of steam vessel accidents, he ascertained that of twenty-three explosions, nineteen occurred on the instant of starting the engines, or whilst the vessels were stationary; three only whilst the engines were at work: the greatest number took place at the moment of admitting the steam upon the piston. He attributed this effect to the steam's percussive force, which would be as much felt by the boiler as by the piston: if the boiler was weak, and, distended by steam to nearly the bursting point, the shock would be sufficient to cause its rupture. Mr. Parkes then gave several instances of such occurrences.

Steam Vessel explosion at Norwich.—In 1817, the boiler of a steam vessel at Norwich burst, and killed many persons. Previous to the accident, the boiler leaked in several places; the steam issued copiously from the safety valve, which was evidently very heavily loaded. The engine had scarcely made a revolution before the explosion occurred. By applying the present state of our knowledge to these facts, he felt assured that the steam's impact on the piston had been the immediate cause of that accident.

Explosion at Passy.—In 1826 or 1827, Mr. Parkes witnessed the effects of an explosion, a few minutes after its occurrence, in the neighbourhood of his works, near Paris. The boiler was of wrought iron, 6 feet long by about 2 feet 6 inches or 3 feet diameter. By his advice the owner had previously put in a new end, formed of one piece of hammered iron, and he was strongly dissuaded from overloading his engine, or using habitually such enormous pressures. The cylinder of the engine was horizontal, and was connected with the boiler by a short pipe and cock. The proprietor informed him, that finding his machinery working too slowly, he went into the engine-house and stopped the engine. He held down the lever of the safety valve, and on turning the cock to start the engine, the explosion instantly occurred. The new end of the boiler, which was opposite to the engine, was found separated from the body, and lying in the flue. The line of rivets and a complete ring of the new end remained upon the body, apparently little forced, and the faces of the fractured ends were as sharp and clean as if cut by a chisel or shears. The boiler, engine, and masonry, were driven into the yard in the opposite direction to the escape of the water and steam; thus, though the entire end of the boiler was removed, and the whole contents evacuated, it acted too late as a safety valve.

Explosion at Camden Town.—He observed similar effects last year in an explosion at Camden Town, being fortunately on the ground to investigate it before much change had been made. Two boilers were set end to end with a chimney between them. The end of one was blown out, and was lying close to its original seat. It was forced backwards into the chimney, which it partly supported on a pipe flange, and pushed the other boiler and entire masonry in a horizontal direction fully two feet. He considered that the percussion of the steam from its re-action against the opposite ends of the boiler in the act of tearing it off (which was the effect in this case) produced the recoil. In this case there were upon the boilers (which were connected together) two safety valves in good order, and not heavily loaded. The accident occurred during the breakfast hour, whilst the engines were not at work. One of the two stays which originally held the fractured end of the boiler, was found to have been previously broken, as its separated ends were covered with old lime scale—the other had evidently been long cracked, and was only held by a fragment. The fractured end of the boiler was not exposed to the fire, nor did the shell or the flue within it exhibit any marks of injury from fire or from dislodgment of scale. The steam, in its effort to escape, acting first against one end, not only raised the boiler from its horizontal position to an angle of about 15°, but gave it a twist obliquely from the line of its bed.

High and low pressure.—Mr. Parkes could not agree in the often expressed opinion, that what are called high-pressure steam boilers were more dangerous or more liable to explode than others. Much depended on care and management. He believed that he was in possession of accounts of nearly all the explosions which had occurred in Cornwall since the expiration of Mr. Watt's patent, when higher pressures began to be used, and they amounted only to five or six instances, exclusive of some cases of collapsed flues. More explosions had occurred in a small district round Wednesbury during the present year with low pressure boilers, than in Cornwall in forty years, where the highest pressures were employed. He believed also that the coal districts of Northumberland, Durham, and Staffordshire, would furnish more cases of these disasters from boilers both of high and low pressure, than all the rest of England put together.

The coal districts.—When the practice in the coal districts was contrasted with that of Cornwall, the explanation was simple. Where coal was so cheap, the quantity used was unlimited, the negligence was great, and the allowance of boiler was small for any given sized engine, as enough steam could be raised by fires of greater intensity—the rule there being, to save in the first cost of the boiler; in Cornwall, on the contrary, the object was to insure economy in the consumption of fuel; consequently, all that class of accidents arising from injury to plates by fire and deposit, would be in about the ratio of the intensity of the combustion.

Notwithstanding the bad practice generally prevailing in the coal districts, there were some exceptions. At an iron work near Dudley, there were boilers now in good order after nearly thirty years' use, having required but trifling repairs during that period. In those boilers the plates of the bottoms which were exposed to the fire were all made of hammered, not of rolled iron—the boilers were large for their work, and were cleaned thoroughly every week.

Hammered plates.—Tilted plates were alone used for salt pans in those parts where the heat was most intense. Though continually heated to redness, and distorted by the action of the fire, the quality of the iron in plates thus formed did not appear to be deteriorated, for when taken out the smiths used them for making rivets, nails, &c. Rolled iron plates would do for making coarse salt, which required a heat below ebullition, but they were quickly injured when used for fine salt, and were useless when taken out.

Explosion at Essonne.—Mr. Parkes then adverted to several other remarkable cases of explosion. It was a well authenticated fact, that a boiler belonging to Messrs. Ferey, at Essonne in France, exploded on the instant of opening the safety valve.

Explosion at Lyons.—Three successive reports were heard when Steele's steam boat boilers exploded at Lyons, indicating that they did not burst at the same instant. Now, though Mr. Steele had fastened down the safety valve to increase the pressure of the steam, yet the explosion of the first boiler should, according to the received opinions, have acted as a safety valve to the second and third, and have saved them—for, by the destruction of the first boiler, the pipes would be broken, and a free exit be afforded for the steam in the others; nevertheless, they all three burst in succession. Several similar instances of successive explosions had occurred in England. He would not at present enter upon an explanation of what he considered might have occasioned these phenomena, but he would express his conviction that the practice of suddenly opening and closing the safety valves was extremely dangerous. To be useful as escape valves, they should be allowed to open and to close in obedience to the steam's pressure only, not to be handled more than was absolutely necessary.

None of the theories yet advanced appeared clearly explanatory of the cause of the projection of heavy boilers from their seats, when in many cases they contained abundance of water. He instanced a case in which a boiler exploded, and carried to some distance a boiler connected with it, and in which some men were at work. The boilers separated while in the air, and the one which exploded attained a very considerable height, although it was 28 feet long by 6 feet diameter. The particulars of this explosion were furnished to him by Mr. Clarke, engineer to the Earl of Durham, but they could not be properly appreciated or explained without the drawings and description.

Explosion at Durham.—A boiler weighing about 2½ tons was projected from its seat at Messrs. Henderson's Woollen Factory at Durham, in 1835; it ascended to a considerable height, and fell 300 yards from the place where it had been seated.

Crenver Mine.—A cylindrical boiler exploded at the Crenver Mine in Cornwall in 1812. It passed through the boiler house, and opened itself in the yard outside, where it was described to have fallen "as flat as a piece of paper."

Facts of this nature were replete with interest, and should lead engineers to the consideration of causes and remedies.

Boilers red hot.—Mr. Parkes then instanced several cases of boilers which had become red hot, and had not exploded; one example was a set of three boilers, the tops as well as the bottoms of which were red hot, in consequence of the house in which they were fixed being on fire; yet they did not explode. No water had, however, been pumped into the boilers whilst so heated.

Explosions of hydrogen gas.—He was in possession also of several curious examples of ruptures and projections of vessels arising from causes very different to the foregoing. One case occurred in February 1837, at the Works of Messrs. Samuel Stocks and Son, in the Township of Heaton Norris, near Manchester. The boiler was 20 feet long, 9 feet wide, and 10 feet deep, and weighed about 8 tons. On a Saturday night the water was blown out of it through the plug-hole at the bottom, by the pressure of the steam, the man-lid not being removed. On Sunday evening the fireman proceeded to take off the man-hole cover to clean the boiler; on entering it with a candle and lanthorn, a violent explosion occurred; and the man was projected to some distance and killed. On examining the boiler it was found quite dry, no fire being alight, no traces of water near it, and it was quite cold: it had been lifted from its seat up to the roof, which it destroyed, and the walls of the building were thrown down. There was no difficulty in accounting for the presence of a combustible gas, as hydrogen might be evolved from the decomposition of the steam (which would remain in the boiler after the expulsion of the water) by the heated sides and bed of the boiler, and the atmospheric air which entered through the plug-hole or through the man-hole, when the lid was removed, was sufficient to form an explosive mixture. The projection of the man was the simple effect of firing the gas; but to account for the entire boiler being carried from its seat, was more difficult. The figure of the boiler after explosion exhibited two distinct actions; the ends and sides had evidently been bulged outwards by the force of the explosion within it, and the bottom had been crushed upwards by the force which raised it from its seat.

Mr. Parkes thought the circumstances admitted of a satisfactory explanation, but would not then enter upon it, as it involved the history and phenomena of projections of vessels from their beds with a vacuum within them, which he thought would be better understood after the reading of his paper on the "Percussive Force of Steam and other Aeriform Fluids," then in preparation for the Institution.

The foregoing case of the formation of hydrogen gas in a boiler, after all the water had been evacuated, was confirmed by one which took place in a similar manner at the Sugar-house of Messrs. Rhodes and Son, in London, of which all the particulars had been furnished to him by Mr. Henrickson, the manager. A man entering the boiler with a candle and lanthorn to clean it, was projected to a great height. No rupture of the boiler took place, as the quantity of hydrogen seemed to be comparatively small, and to be confined to the upper portion of the boiler, but a series of detonations occurred, like successive discharges of cannon.

These two remarkable instances showed the importance of attending to minute circumstances in the management of boilers. The practice of completely blowing out boilers whilst the flues were intensely heated, was evidently dangerous, nor should it be done without removing the man-hole cover.

Mr. Parkes felt that these notices of explosions were very imperfect without drawings, and reference to documentary evidence, but, as the subject had been brought before the Institution by Dr. Schafhaeutl, he hoped that they would be received as contributions to the stock of knowledge, and as illustrative of the precautions to be observed by attendants on steam engines.

Mr. Seaward was glad to find the idea of the explosions of boilers arising from the formation of hydrogen gas, so successfully combated by Dr. Schafhaeutl and Mr. Parkes. He perfectly agreed with the former in his opinion of the causes of the majority of explosions. In all that he had witnessed the effects of the lower parts of the boiler appeared to have suffered most.

He was at the Polgooth Mine immediately after the explosion there, when seventeen persons were killed. In that case, he was told that the boilers were moved a distance of 7 or 8 feet from their seats, before any detonation was heard.

At the Hurlam Mine (which Trevithick had undertaken to drain for a certain sum) an engine with a cylinder of 10 inches diameter was erected immediately over the shaft. Its power was not sufficient for the work required; the pressure of steam was therefore gradually increased as the depth became greater. At length the boiler, which was of an immense length, was observed to have a constant tremulous or sinuous motion at each stroke of the engine, and eventually it exploded.

Boilers in London.—It appeared that there were fewer explosions of boilers in London, in proportion to the number employed, than in any other district. One reason for this might be, that fuel being expensive, it was used economically, by maintaining a slow rate of combustion, and a regular supply of steam, avoiding the intense action of the fire, which, in the event of the engine standing still for a time, had a tendency to produce an explosion.

Mr. Parkes attributed the small number of explosions of boilers in the vessels on the Thames to the practice of allowing the steam to act upon the safety valve, instead of the engineer lifting it when the engine was stopped, as on board vessels in the north. The sudden closing of the valve had in many cases produced an explosion.

While on this subject, he felt it necessary to comment upon what he considered fallacious reasoning of Tredgold on the formation of hydrogen gas in boilers.* The passage he alluded to was couched thus:—"Hydrogen gas may be, and frequently is, formed in steam boilers through the water being in contact with a part of the boiler which is red hot; and it seems to be regularly produced during the formation of steam at very high temperatures." Dr. Schafhaeutl had shown, that the effect of water coming suddenly in contact with a part of the boiler which was red hot, was only to disengage instantaneously a large volume of steam of very high elasticity. Mr. Parkes contended, that an instance of the sudden production of hydrogen gas in a boiler under such circumstances was unknown, and he much doubted the possibility of such an occurrence. Again, allowing such an event to be possible, an explosive mixture of gases must be formed before the boiler could be destroyed; and this could not take place so long as a sufficiency of water was present, from which any considerable quantity of steam could be generated.

Mr. Donkin did not entirely agree as to the non-formation of hydrogen in boilers under peculiar circumstances. He conceived the explosions which occurred in iron founderies, on the contact of the melted metal with wet sand, to be analogous. He believed, that when water was thrown suddenly upon red-hot plates, decomposition did occur.

He had once examined a wagon-shaped boiler which had exploded; the top was thrown to some distance, and the bottom was depressed throughout its entire length. He believed, that by intense firing the water had been nearly all evaporated; the bottom had then become red hot, the pressure of the steam had forced the bottom downwards when weakened by the heat; the water on each side then suddenly flowed on to the heated part, and an explosion instantly occurred.

Mr. Seaward had known instances of the internal tube of a boiler being collapsed without any injury to the external part or body of the boiler. He had always ascribed such occurrences to a deficiency of water; but Dr. Schafhaeutl's explanation of the rapid transmission of force through the wave to the bottom would sufficiently account for the effects which had been observed.

Mr. Donkin believed, that in almost every case the unequal pressure upon the exterior of the tube, arising from its not being perfectly cylindrical, was the cause of its collapsing.

Mr. Field was inclined to attribute all the explosions which he had witnessed to simple pressure.

When steam, or a small quantity of water, was suddenly admitted into a dry heated vessel, hydrogen gas was readily formed. He had made several sets of apparatus for the purpose. A strong wrought-iron tube was heated, and, being filled loosely with fragments of iron-turnings, steam was introduced and the gas was rapidly evolved.

He agreed with Mr. Parkes in condemning, generally, the fallacy of the opinion of Tredgold, previously mentioned, as to the formation of hydrogen gas. Still, in a large boiler, almost dry, and of which a portion was red hot, he conceived, that on the admission of a small quantity of water, hydrogen gas might be evolved.

Elevation of boilers from their seats.—The President was unwilling that this conversation should terminate without endeavouring to explain the cause of the elevation of the boilers from their seats. In his opinion, this might be satisfactorily accounted for by the action of atmospheric pressure.

When an explosion took place in a boiler, a considerable body of highly elastic fluid was disengaged; a partial vacuum was thus created above the boiler, whilst the full pressure of the atmosphere was exerted beneath it. This would cause the boiler to rise from its seat, provided the atmospheric air did not at the same instant rush into it, in which case the bottom would be pressed downwards, and the upper part being torn asunder, as had been described, would then rise into the air with the elastic fluid.

* Tredgold on the Steam Engine, vol. i. p. 251. Edition by Woolhouse.

When it was considered that the superficial area of these boilers was about 60 square feet; that the pressure of the atmosphere was nearly 1 ton per square foot, and that the weight of the boilers was only 8 or 10 tons, it would be apparent that the cause was quite adequate to the effect, with a very partial vacuum or inequality of atmospheric pressure. The case was analogous to those in which light bodies were raised into the air by whirlwinds.

He referred also to two cases of an equally uncommon nature, which had lately come under his notice professionally, and which he considered to arise chiefly from inequality of atmospheric pressure.

The first occurred at the Plymouth Breakwater during the great storm in the month of February, 1838, when several of the largest granite blocks, weighing from 3 to 8 tons each, composing the surface or pavement of the breakwater, which, although squared and dove-tailed into the structure, and embedded in excellent cement to the extent of their whole depth, and thus forming a solid mass, were torn from their positions, and projected over the breakwater into the Sound. He attributed this to the hydrostatic pressure exerted beneath the stones, at the moment when the atmospheric pressure above had been disturbed by the masses of water suddenly and rapidly thrown upon the surface of the breakwater. Blocks of stone were thus often carried to a great distance, not so much by the waves lifting them, as by the vacuum created above them by the motion of the water, which exerted at the same time its full pressure from below.

The other case occurred during a storm in the year 1840, when the sea door of the Eddystone Lighthouse was forced outwards, and it strong iron bolts and hinges broken by the atmospheric pressure from within. In this instance he conceived that the sweep of the vast body of water in motion round the lighthouse had created a partial and momentary, though effectual, vacuum, and thus enabled the atmospheric pressure within the building to act upon the only yielding part of the structure.

Signals for Railways.

A letter was read from Mr. Edward Alfred Cowper, describing some experiments on the use of maroons as signals on railways.

The maroons are either small tin cases, or cartridges of brown paper, charged with from ½ oz. to 2 oz. of gunpowder, mingled with which are 4 of "Jones's Prometheans," which are small glass tubes, each containing a drop of sulphuric acid; the tubes are surrounded with chlorate (hyper-oxy-muriate) of potassa, and are each enveloped in a strip of paper.

In the event of an accident occurring, which renders it necessary to give notice that an approaching train should be stopped at a given point, two or more of these maroons are fastened upon the upper surface of the rail by the strips of lead attached to them. The wheels of the engine, in passing over them, crush the glass tubes of the "Prometheans," the sulphuric acid inflames the chlorate of potassa, and causes an explosion of the gunpowder, which is distinctly heard by the engine driver, who immediately shuts off the steam, and puts down the break.

Mr. C. H. Gregory had permitted several trials to be made with these maroons on the Croydon Railway.

An engine was driven at full speed with a number of empty wagons attached to it, and with the steam blowing off to create as much noise as possible, yet the explosion of even half a drachm of gunpowder was distinctly perceived: he considered the invention to be practically useful.

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

ELEVENTH MEETING, 1841.

Description of the existing and contemplated Railways and Machinery connected with the Granite Quarry on Dartmoor, and of the mode of working them. By William Johnson, Grosvenor Wharf, Westminster.

Dartmoor is an extensive granitic table-land occupying the heart of the county of Devon, and in which many of the rivers of this county originate. It is in length from north to south 22 miles, and in breadth from east to west 14 miles. The height of the table-land above the level of the sea is from 1000 to 1200 feet; but the surface is broken by numerous masses of rock, which run up to three, four, and five hundred feet above the ordinary level of the moor; these are ranged in short chains, or they rise in rifted blocks, or in insulated hillocks, which are distinguished as Tors, or provincially *Tors*.

The surface granite of Dartmoor, which is in detached blocks, in infinite quantity, had been employed in the neighbourhood for the ordinary purposes of building from time immemorial. Quarried granite from Dartmoor was first brought into the market about 1820 by the Haytor Granite Company. A stone tramway was constructed from the Haytor quarries on the south-eastern face of the moor to the Stover Canal, near Newton Bushel, a few miles above Teignmouth, the nearest available port at which stone could be shipped, and by this means Dartmoor granite came into the market at considerable advantage, especially as the quality of the stone is such as to enable it to compete with the best Aberdeenshire, and, for many purposes, the lightness of its tint aided by the fineness of its texture, and the almost unlimited size of the blocks in which it could be procured without defect secured it a preference. The western face of London bridge is mainly composed of granite from Dartmoor. Dartmoor granite has also been introduced into many of the public buildings in the metropolis; amongst others the New Post Office, the Goldsmith's Hall, Fishmonger's Hall and Buckingham Palace.

The establishment of the Plymouth and Dartmoor Railway, which was completed in the year 1825, directed attention to the fine granite on the western face of the moor, by affording ready means of transport to the port of Plymouth for stone from Foggintor and other points adjacent.

The length of the Plymouth and Darmoor Railway, from Prince-town to the Tide Docks, known as Sutton Pool, at Plymouth, is about 25 miles; though the distance from one terminus to the other, by the carriage road, is not more than 16 miles; whilst a right line, from point to point, does not exceed 13 miles in length, the greater length of the railway being occasioned by windings to save expensive works, and to obtain tolerably equable inclinations upon which the trains might run down freely and allow the empty or slightly laden waggons to be drawn back without much waste of power.

The whole rise of the railway from its toll-house in Plymouth to the Prince-town terminus, by the Prisons of War, is 1350 feet; which, upon the net distance of 24 miles between those points, gives a rise of 56·25 feet per mile, or a ratio of nearly 1 in 94. The road is almost entirely upon the surface, with occasional slight cutting and filling, and a short tunnel (30 chains in length) occurs within the fourth mile from Plymouth. The wagons or trucks used upon the line consist of a platform or bed, set upon two centres, on two under carriages, to adapt them to their work and to the excessively sharp curves and irregular surfaces that frequently occur upon the line. The power used in working the line is the gravitation of the load, assisted by horses, the return being by horses entirely. Three horses draw eight single wagons, or four double ones, with from 30 to 40 tons of granite down, and take the wagons back when empty. There are at present no planes upon the line having gear worked by fixed power, or as self-acting planes.

The quarry which affords this railway its principal occupation, is worked by the Haytor Granite Company. It is situated within a quarter of a mile of the main line of the railway, from which a branch is laid into the quarry, at two miles from Prince-town, the floor of the quarry being at a level of 48 feet above the turn-out, and 1260 feet above the level of the quay at Plymouth, from which the stone is shipped.

The quarry is on the side of the Mount known as Foggintor, at from 350 to 400 feet below the summit. A gullet was first driven in horizontally, until a face of rock 50 feet high was obtained, presenting a most beautiful section of stone, in beds or layers of from eight to ten feet thick. The gullet has since been carried forward from 110 to 120 yards, and extended laterally until the bed of the quarry presents a cleared horizontal surface of nearly 4000 square yards. The benching onwards and outwards of the upper layers exceeds 2600 square yards, and the highest bench is 80 feet above the rails on the floor of the quarry. A considerable further extent of surface, beyond and above this, is uncovered of earth, and, the crust being removed, a vertical section of the granite tor is exposed, of nearly 100 feet in height.

A single blast in this quarry has been known to separate and remove 3000 tons of stone, and single blocks have been sent out weighing 20 tons, computed to contain about 250 cubic feet.

From the lower benches, in the face of the quarry, the stone has been taken up by derricks, or moveable cranes, and placed by them in the usual manner upon trucks on the railways, laid on the floor of the quarry; whilst, from the topmost benches, the stone is delivered over the side of the hill, and skidded down an inclined plane to the masons' sheds, where the operations of converting and dressing are performed, and from whence the blocks are conveyed upon railway trucks to the place of shipment.

The existing facilities for working the quarries, are now in course of further extension, by the construction of strong timber stages or scaffolds, with travelling frames, and upon the frames powerful traversing crabs, avoiding thereby the excessive labour and delay of lifting by the ordinary means of derricks and cranes. These stages rest upon the floor of the quarry in front, and run in parallel lines of 36 feet in width onwards upon the benches according to their heights, and give the means of taking up the stone wherever the blocks may be thrown out in blasting upon the different benches, and placing them at once upon the trucks on the floor of the quarry, by which they are taken to the mason's sheds, so that the quarry is kept constantly clear, and the largest blocks of stone are moved out with the greatest possible ease. An arrangement is in progress for transferring the travelling frames, with the crabs upon them, from one line of scaffold to another, by which means power may be accumulated to almost any extent upon any one stage, to operate upon blocks of extraordinary size.

Foggintor granite is at present extensively used for all the purposes to which granite has been hitherto applied. It is superior to any other in this country for steps, plinths, string and blocking courses, ashlars, pedestals, obelisks, columns, cornices, and indeed for all the purposes of architecture, because of the freedom and comparative ease with which it can be worked, being alike capable of the finest arris and of the fairest face, whether moulded or plain: whilst the purity and evenness of its colour, and the fineness of its texture in the deep beds, give it advantages not possessed in an equal degree by the produce of any other quarry in Great Britain. Foggintor granite is moreover peculiarly fitted for the more massive works of the hydraulic architect or engineer, on account of the magnitude of the blocks in which it procurable. It is in great demand for the quoin, hinge, and heel stones dock and other lock gates, for altars in graving docks, as well as for floors and curbs of such massive constructions, and for bridge constructions in all their varieties. Indeed, notwithstanding the facilities with which the work in the quarry is performed, the extent and depth of face exposed, and the ease with which the blocks are got out of the quarry, and upon the railway, it has hitherto been found difficult to supply, with sufficient rapidity, the existing demand.

The works at the Government Yard at Devonport—those of the magnificent new graving dock now in course of construction at Woolwich—Tenby Beacon in Pembrokeshire—the Neale Memorial in the New Forest, Hants—and the Nelson Testimonial—the retaining walls of Trafalgar Square—and the new buildings of the Sun and Alliance Fire Offices, in London, are all supplied with granite from the Foggintor Quarry. Many private works in various parts of England are also supplied with granite from this quarry, and the terrace walls and their approaches in the great quadrangle of Christ Church, Oxford, are about to be restored with Foggintor granite. Indeed, the fine texture and tint of Dartmoor granite adapt it peculiarly for terraces and for the basements of buildings whose superstructure and other collateral works are of Portland stone, Bath stone, or any of the best English freestones.

An important feature in the quarry now under consideration is the great depth at which the beds already accessible lie below the surface, yielding therefrom stone of the greatest degree of compactness and strength with perfect equality of colour; whilst the horizontal disposition of the rock allows of the removal of stone of fair forms, and in blocks of the largest size. Blocks have been sent from the quarries on Dartmoor even to Scotland to supply works there with sizes which could not be procured in that country. Sir Francis Chantrey's bronze statue of King George the 4th, in Edinburgh, stands on a block of Haytor granite, and the statue of Watt, at Glasgow, by the same distinguished sculptor, is also placed on a block of granite from Dartmoor.

Mr. Rendel bore testimony to the excellence of the quality of the Dartmoor granite, and to its peculiar fitness for any kind of work. The material was extremely good, and of sufficient fineness to admit of the most delicate moulds being made for it. It cleaves freely; there is little waste, and pieces of stone of all sizes, from the smallest to the largest, can be readily obtained. He had, some time ago, taken the dimensions of a block, and found it to be 67 feet in length, 5 feet by 8 feet at one end, and 3 feet by 5 feet at the other end. If a great outlay were justified, this granite would be the cheapest stone that could be used. The President stated, that he had attempted, some years ago, to introduce this granite into the market by means of the canal, near Tavistock, and now that such facilities existed for its transport, he would direct public attention to the beautiful slabs, columns, vases, and forms into which the Aberdeen granite was worked, and express his hopes that before the British Association next met at Plymouth, there would be a large manufactory of these articles in Dartmoor granite. The beautiful porphyry of Cornwall might also be employed in a similar manner. He could mention a remarkable instance of the durability of the Dartmoor granite. A slab which had been used as a foot bridge from time immemorial had recently been removed, and on the face, which had been turned downwards, was a Roman inscription, showing it to be at least 2000 years old.—Mr. Eaton Hodgkinson, in reference to some questions which had been asked, respecting the strength of stone according to the position in which it was placed, stated that in all bodies of uniform texture the strength would be the same in whatever position they are placed, but in bodies that are laminated the case is very different. He observed a very pernicious practice to have prevailed in the construction of many of our buildings, namely, the placing the stone without any regard to the direction of its lamination. He had extended his experiments to a great variety of stone, and he found that cubes of granite when broken with the greatest care, break up at once into wedges. Some valuable experiments on the strength of granite were published in the Transactions of the Institution of Civil Engineers, but the mode in which the experiments had been conducted was not stated, and a distinction is drawn between the crushing and the breaking force; but he thought that if the experiments had been made by pressing the stone between two perfectly smooth plates a somewhat different result would have been found; the granite would have broken up at once without crushing, as was uniformly the case in his experiments. He thought it important to interpose a thin substance, as a sheet of paper, between the plate and the stone; the pressure by this means becomes more perfectly distributed. A remarkable connexion existed between the ratio of the forces of extension and compression, and the angles at which the wedges or masses would slide off when broken by pressure. If these forces were equal, the wedges would slide at an angle of 45°.—Prof. Moseley remarked that the experiments of Mr. E. Hodgkinson were peculiarly valuable, because he had not confined himself to cubes, but extended his experiments to other forms. A singular prejudice had existed in favour of cubes. The commissioners appointed to report on the stone for building the House of Commons, experimented simply on cubes, whereas rectangles would have been much better.

Dr. Lardner's *Report on Railway Constants* was read. Details of this paper were presented to the Association in the year 1839, and reported very fully in the *Journal*, vol. 2, page 383, but as the communication was then merely verbal, and the rules of the Association require a written report, the report was formally presented, and the reading led to a good deal of discussion, but no new facts were elicited.

"*Report of the Committee on Railway Constants.*" By Edward Woods.

In a preceding Report of the Committee (published in the 8th volume of the Transactions of the British Association), five various modes of ascertaining the resistance to the tractive power on railways were described, and their relative merits discussed, and a variety of experiments on one of these methods, viz., by observing the motion of a load down an incline, sufficiently steep to give accelerated motion, having been made, it appeared, that the resistance increased in a degree previously unsuspected in proportion as the speed of the train increased,—but in what ratio, was not then determined, owing to certain discrepancies due, principally, to the varying effect of the wind at the time of the experiments. The Committee have continued to conduct their experiments in a similar manner, repeating them with various sizes of trains, at various velocities, on the Sutton incline, of 1 in 89 on the Liverpool and Manchester Railway, and on the inclines of 1 in 177, 1 in 265, and 1 in 330 on the Grand Junction Railway.* The data ascertained and given in the Report are,—1, The co-efficient of gravity on the inclination of the plane. 2, The initial velocity of train at some determinate point on that plane. 3, The terminal velocity at some other determinate point on the same plane. 4, The time elapsed in traversing the space intervening between these two points. 5, The space intervening. 6, The force of gravitation. 7, The weight or mass of the train, exclusive of the wheels and axles. 8, The weight or mass of the train subject to the rolling motion, viz., the wheels and axles. 9, The radius of the wheels. 10, The distance from the centre of the wheel, to the centre of oscillation. If a body move down an inclined plane without resistance, its velocity at any given depth below the level of the point where its motion first commences, will be equal to the velocity it would have acquired by a free vertical descent through the same height. This standard velocity being compared with the observed velocity of a body moving down an incline, and meeting with resistance, the amount of that resistance can be assigned. This mode has been objected to, from the apparent inconsistencies in the results; but these may be readily explained; and the Report shows a remarkable correspondence in the motions of the same train, when permitted to descend the same plane from the same point, provided the atmosphere be perfectly calm. The usual formula is applicable to three cases of accelerated, uniform, and retarded motion; the co-efficient of gravity is greater than, equal to, and less than the co-efficient of resistance accordingly; and the requisite correction will be negative, zero, and positive, so that the co-efficient of resistance may be found in all cases. The method of determining this correction was set forth in the former Report. When the motion is uniform, the mean resistance for any particular velocity may be assigned; but when the motion is accelerated or retarded between the two points of observation, although the mean resistance may be known, it cannot be stated with accuracy, whether that mean resistance is due to the mean velocity, or to some other velocity intermediate between the limits of the initial and terminal velocities, because experience has not yet assigned the law of the corresponding increments of resistance and speed. The results which the tables of this Report present, are considered under the following heads: the determination of the friction; the additional resistance produced by increase of speed in trains of different sizes; the effect of modifying the form of the front or end of carriages, and of other changes in the external surface of the train. Three first-class carriages were allowed to descend the Sutton incline from rest four times in succession, a length of 2420 yards. It appears that the resistance diminishes until the train attains the speed of 7·58 miles per hour, after which it increases; at 4·32 miles per hour, the resistance was 6·07 lb. per ton; at 7·58 miles per hour, 5·6 lb. per ton. This remarkable and hitherto unobserved result is owing, probably, to the more perfect lubrication of the axles at the higher speed; a certain thickness or film of grease is formed between the brass step and the upper surface of the journal, and keeps the two surfaces more effectually apart; at the lower velocities, the pressure of the step upon the journal has a longer time to act in effecting the displacement of the fresh grease which has been supplied from the box, and the result is, a greater amount of friction. Eight second-class carriages were allowed to descend the Sutton incline; the friction was a minimum at 5·84 miles per hour. The following results may be deduced from the above-mentioned series of experiments. 1, The friction was least when the train was moving at the rate of about 6 miles per hour. 2, The total resistance was also least at the rate of about 6 miles per hour, notwithstanding the effect of the atmosphere at that speed. 3, The mean resistance of first-class carriages was never less than 5·6 lb. per ton; and of the second-class never less than 7·75 lb. per ton; 6 and 8 lb. per ton will represent very nearly the mean of the resistances; and these values are used in the subsequent part of the Report. The motion of these trains being observed at lower parts of the incline, where the velocities were greater than the preceding, the resistance to the train of three carriages was 8, 12, and 16 lb. per ton, at velocities of 22, 26, and 29, miles per hour respectively, and the resistance to the train of eight carriages was 11, 12, and 14½ lb. per ton, at the velocities of 20, 25, and 29 miles per hour. Trains of 4 and of 6 carriages were impelled to the summit of the incline, and, the engine being detached, commenced their descent at the rate of 33 and 26 miles per hour. They descended through the first half of the incline with a mean velocity of 34 and 29 miles per hour, and through the latter half, with a mean velocity of 37 and 33 miles per hour. Other series of ex-

* As Dr. Lardner's paper on "the Resistance of Air to Railway Trains," (read at Newcastle, and reported fully, with diagrams, Journal, vol. 2, p. 383, was founded on these experiments, the reader had better refer to it.

2 U 2

pe[illegible] made on the Grand Junction inclines; and the result of the whole shows the existence of an opposing power, created at it were by the speed itself, far exceeding that hitherto suspected.

A train of eight carriages weighing 40½ tons was started down the Madely incline 1 in 177, at speeds varying from 23 to 26 miles per hour; the mean speed attained was 25½ miles per hour. The motion of the train became uniform, so that the coefficients of gravity and resistance were equal. The mean resistance of the train was 12½ lb. per ton. A train of four carriages was started down the incline at 40 miles per hour, half way down the plane the velocity was reduced to 30 miles per hour, and at the foot, it was only 25 miles per hour. Four other carriages were started at a velocity of 32·7 miles per hour, they were retarded to 22·7 miles per hour, and proceeded with this uniform velocity to the foot of the incline. The results obtained in these experiments with the trains of eight carriages are of great practical importance, this being the nearest approach to the average passenger trains. 30 miles per hour is a fair average speed, and the resistance at the speed is about 15 lb. per ton, or almost double the value of the friction only. The friction may be diminished by proper attention to the fittings and the perfect lubrication of the axles, but its reduction is of secondary importance in the economic working of passenger trains, which, from their high velocity, must necessarily bring into play large and independent sources of resistance. The resistance to trains at different speeds being ascertained, the Committee directed their attention to the effect of external configuration on the resistance. A pointed body, as a prow, was fixed successively to the front and end of a train, but the differences observed were extremely slight, and such only as would have occurred with the same experiment repeated twice over; the pointed figure, whether before or behind, exercised no appreciable influence on the rate of the train's motion, or on the resistance of which that motion is the index. Experiments were also instituted, to ascertain whether the carriages being sent with their square ends forward, instead of being preceded by an engine and tender, would affect the results, but here also there were no greater differences than might be expected in an experiment repeated twice over; and it may be fairly concluded, that the form of the front has no observable effect, and that whether the engine and tender be in front, or two carriages of equal weight, the resistance will be the same. The intermediate spaces between the carriages were closed in, by stretching strong canvas from carriage to carriage, thus converting the whole train into one unbroken mass. The results were in favour of the train without canvas, but the differences are extremely slight; it is certain that no additional resistance is occasioned by leaving open spaces between the carriages, confining the intervals to the dimensions allowed in practice.

The Committee having ascertained that the excess of resistance, after deducting friction, required for its estimation something besides the elements of the dimensions and form of frontage, and of continuity of surface, it becomes important to inquire, what is the element exerting so powerful an influence? Their former Report contains the results of experiments with wagons on the Madely incline loaded to six tons each, and furnished with boarded fronts and sides moveable at pleasure; the differences in the results attained, were then referred to the increased frontage alone. But the experiments detailed in the present Report having been made, it became probable that the increased resistance was in a great measure dependent on the general volume of air displaced; and the Committee recommend experiments to be directed, to ascertain the effect on the resistance of diminishing and increasing the bulk of trains, the weight remaining the same.

Experiments were also made with the view of determining the amount of moving power expended in working a line, and for this purpose, the character of the line, in respect of its inclines, the weight and bulk of the train, and the speed at which the load is required to be conveyed, must be considered. The first of these alone is constant, depending on the nature of the acclivities and declivities. As an abstract question of dynamics, the power expended (the resistances being supposed constant, whatever the speed) is the same for a train travelling between two points on the same level, whether the road be be level or undulating, a due allowance being made for the difference of distance traversed. On the level line of railway, the speed of travelling would be uniform, but on the undulating line it would vary. And the real question is, will the increased velocity on the declivities compensate for time lost on the acclivities? Will the average rate of speed over the whole line be different? In order to obtain some definite result on the point, it was determined to send a train from Liverpool to Birmingham and back, a distance of 190 miles. Great care was taken in conducting this experiment, and the results are tabulated in great detail; and the following remarkable inference may be drawn, that a train of 12 carriages drawn by the same engine can be conveyed over a railway whose gradients range within the specified limits, in the same time as it could over a perfectly level railway of the same length. In ordinary practice, an engine of the dimensions tried (the Hecla) would receive assistance up the Sutton, Whiston, and Warrington inclines (1 in 89, 96, and 89), but this was not the case in the experimental trip, and the train encountered acclivities and declivities not contemplated in the application of this theory. It may therefore be inferred that the opinion entertained was correct, or that trains whose weights bear an ascertainable relation to the nature of the inclines they have to traverse, may be made to traverse those inclines at an average speed equal to what the power of the engine can effect on a level, and that an ordinary train would travel over the Grand Junction Railway (the steeper inclines of 1 in 96 being excepted) in as short a time as if the line had been absolutely level.

Mr. Brunel remarked on the inapplicability of results obtained from trains running down inclines to the ordinary working of trains on railways. Many of the results given in the Report differ exceedingly from the results of his experience in the working of the Great Western Railway. The cause of this discrepancy arose from the manner in which the resistances were obtained. In the train of carriages running down an incline, each carriage is slightly pressed upon by the next behind, so that the whole train is in the condition of a train that is pushed; and it is well known that the resistance of a train pushed from behind is much greater than of the same train pulled from before, as the carriages are thrown out of square.—*Atheneum.*

"Remarks on the Connexion which exists between Improvements in Pitwork and the Duty of Steam-engines in Cornwall." By Mr. Enys.

After adverting to the admission of the truth of progressive increase of duty, it was shown that considerable changes have been made in the course of seventy years, in the methods by which water is lifted out of the mines in Cornwall; and that in comparing the duty of earlier periods, an allowance of the difference of the Imperial and Winchester bushel of coal ought to be made. The distinction between horse-power and duty, pointed out by Mr. Parkes, was alluded to; one excludes, the other includes, the friction of the pitwork; and the remarks attached to each in Lean's report, show the necessity of adverting to the different conditions of the pitwork, in an attempt to estimate with accuracy the relative merit of different engines separate from the pitwork. In an endeavour, some time ago, to trace the causes of the great variation of the duty, a small amount of expansion was observed in engines remarkable for a low duty, and the reasons assigned were, either weak pitwork—flat rods—heavy load per square inch on the piston, and old boilers—and often the joint action of the above causes. The strength of the pitwork, or of the boilers, in different cases, seems to become the limit of expansion in the engines. In reference to deficiency of water from pumps, in proportion to the calculated quantities, on which duty is founded, two causes have operated in inducing a strong belief that it is less than at any former period: 1. Greater attention to the pitwork by the managers of the mines, under whose care it is placed, to the exclusion of the engineers of the steam-engine by which it is worked; 2. The extended use of the plunger pump—the latter instantly showing the slightest defect of the packing, and allowing of an easy remedy: while the bucket pump, on the contrary, does not show the defects in the packing; and the operation of tightening it is attended with great difficulty, so much so, as often to cause the repairing to be delayed to the last moment that the pump will lift water. The first cause, though it has a tendency to decrease duty in proportion to improved water delivery, has in a still greater degree the tendency to reduce the friction of the pitwork on a given load: yet it is not easy to assign the exact values. On the whole, a reduction of total resistances probably occurs in shafts of equal depth. On the other hand, the great increased depth of many shafts obviously produces a greater proportional friction on a given load. Under these circumstances, it becomes the fairer method to select the duty of engines working the deepest shafts, for a comparison with the duty of the earlier periods, when engines were worked so differently as regards the steam. Mr. J. W. Henwood (Wheal Towan) estimates the deficiency of water delivery at 7 or 8 per cent.; Mr. T. Wicksteed (E. Holmbush) 10 per cent. water from three lifts measured and weighed: Mr. Enys (Eldon's engine, United Mines), 4 per cent., measured four strokes of the engine from one plunger lift. The absence of attention in earlier times can only be assumed from the known habits of the miner, and the absurd stories prevalent of particular instances of neglect. Another great, but almost inappreciable change, has occurred within the last ten or fifteen years, in the increase of weight in the rods for a given load; but the circumstance of the greater weight of such rods again allowed of the reciprocal action of a still greater amount of expansion in Watt's engines; and in the heavy pitwork, the accumulated force stored up at the commencement was restored at the end of the stroke; the only loss in duty arises from an increase of the friction of the necessary balance weight; because, while a direct gain is obvious, the same mean power, by a greater amount of expansion, is obtained from a smaller quantity of water expended as steam. The present form of rod, with lifts alternately, where the shaft admits of this method, was probably due to Wat, or Murdoch. Smeaton, at the Chacewater Atmospheric Engine, in 1775t seems to have effected the introduction of one rod for a portion of the shaft, and dispensed with the older practice of tying up to the arch of the beam a separate rod for each lift. The plunger pump seems to have effected another change of some importance, in the velocity with which the larger portion of water is raised. The engines are usually made to go, out of doors, at rather more than half the velocity of the in-door stroke, the piston moving in-door, from 240 to 260 feet, and out of doors from 14t to 156 feet per minute; the velocity of the plunger, or bucket, is usually four-fifths of these amounts, or 110 to 120 feet per minute. Still a portion of the water, from one-third to one-sixth, is raised at three-fourths of the higher velocity; and recently larger valves have been placed below the plunger than above, with a view of equalizing the resistance of the water on passing the valves. A few experiments of trying an engine in-doors at a very low velocity have been made, which may perhaps be extended, to determine the increase of pressure due to different velocities of water in the pumps. The column of mercury, however, only becomes the measure of the total resistances of all kinds, which are subsequently, as far as practicable, to be separated, and values assigned to each as nearly as our means of observation admit. In commencing motion, after the state of rest to which pumping engines are brought, it is possible a greater power may be employed than is required to continue it. Still the term variable load, formerly adopted by the writer of this paper, may be too strong, and the rapid action of the mercury may render it inappreciable. In an attempt to value friction by the area of the rubbing surfaces of the packing of the plungers, it appeared the unanimous opinion of many of the best pitmen, that water could be kept from escaping with less friction by means of twelve-inch packing than with nine inch packing, in a twelve inch plunger-lift—a circumstance that requires attention, not only in this, but probably under numerous other conditions. In regard to the effect of expansion on the pitwork, in producing a variable strain during the load, it was observed, that with twelve times expansion on an engine recently erected, of Watt's construction, including clearance steam, the variation was as 8 to 1 at the end of the stroke; but that in a new engine of combined cylinder, by Sims, in which the expansion after three times in a smaller cylinder indoors, was increased about four times out of doors into a larger cylinder, and which power was converted in-doors into a constant quantity by means of a balance, the variation would be about as 2 to 1; and in Hornblower's or Woolf's, if worked with high steam, that under the condition of twelve times expansion, including clearance steam, the variation might be roughly taken as 3 to 1—that the commercial part of the question of more or less expense in engines or pitwork, would determine the relative advantages, on the whole, of each engine for lifting water from deep mines. It seems that expansion has not been carried out to so great an extent when the load is near the end of the beam, and when the enormous balance weights, usual in Cornish pitwork, are not required to be applied, though it is obvious that this condition causes less pitwork friction.—*Ibid.*

KING'S COLLEGE.

By a prospectus that has reached us of the business of the ensuing session, we perceive that, in accordance with the intimation given in our last number, the department hitherto known at this college as that of "Civil Engineering, and of Science applied to the Arts and Manufacture," is now designated the department of "Engineering, Architecture, Arts and Manufactures."

The course of instruction proposed for students in architecture is as full and satisfactory as that for engineers has been found to be. It extends over three years, and is as follows: "Mathematics; the principles of Mechanics, Hydrostatics and Acoustics: the theory of Construction; the elements of Chemistry; Mineralogy; Geology; the principles of Experimental Philosophy; Geometrical and Perspective, Ornament and Landscape Drawing; Land Surveying; Machinery; the principles and practice of Architecture, including Design and Composition, Construction and Architectural or Building Surveying."

Mr. Hosking has been appointed to the Professorship of the Principles and Practice of Architecture, in addition to his former duties, and he is to be assisted by Mr. Andrew Moseley, a younger brother of the County Surveyor of Middlesex, and of the eminent Professor of Natural Philosophy in the same College. The drawing of enrichments will be taught under the direction of Professor Dyce, of the Government School of Design, and Landscape Drawing by Mr. Cotman, who is well known as an artist, and for his work on the Picturesque Architecture of Normandy.

BITUMEN.

A new application of this material which promises to be of very great service in engineering works, has lately been successfully practised by the Parisian Bitumen Company. The new application consists in cementing large masses of rubble stone with the bitumen in a liquid state, and this has been successfully practised on a very extensive scale on the works of the Upper Medway Navigation Company in the following manner.

The river is divided into levels by weirs and locks in the usual manner. Some of those wiers are constructed at great expense of squared masonry; others are less expensively constructed, by throwing in the rubble stone of the country to the desired shape and height of the weir; it may be remarked that no care is taken in bedding the stones, or in laying them, which is performed by the ordinary labourers of the country. The bitumen is then melted and run in between the stones, and the whole forms a mass of such solidity as to resist the heaviest floods, and is perfectly impervious to water in every part, and it is supposed that it will not require one tenth of the repairs usually bestowed on weirs of the ordinary construction.

It may be noticed that previous to this material being used, the repairs after the winter floods, which are very heavy, were very great, and caused considerable interruption to the traffic.

The great advantages arising from using the bitumen in the manner described are cheapness and facility of construction—a very considerable reduction in the expence of repairs. It is evident that this may be used to very great advantage in foundations of bridges or large buildings, as forming a compact body capable of resisting any pressure, bearing any weight that may be imposed on it, and becoming perfectly solid in five minutes after being laid; it will effectually prevent vermin from getting into houses or burrowing near the foundations.

The manufacture of bitumen is now brought to great perfection by the same Company. Some beautiful specimens of tesselated pavement are being laid of different coloured bitumen, and floors of stations, churches, halls, &c., may be made very ornamental, and equally durable with Yorkshire stone, whilst it is much warmer to the feet and not more than half the price.

Presentation of a Piece of Plate to Mr. Storey, C.E.—A piece of plate value 350 guineas was lately presented to Thomas Storey, Esq., civil engineer, purchased by subscription and presented as a token of the respect entertained for that gentleman by the different parties connected with the great public works which have been completed under his superintendence. The plate was presented at the Fleece Inn, Darlington, after a sumptuous dinner to which 62 persons sat down. The service consisted of an epergne, elegantly and elaborately chased; a full-sized tureen; two do. sauce-do; four double vegetable dishes, with handles to remove, and to form eight dishes; two 12-inch salvers; four salt-cellars, gilt inside; four spoons do. to match; two gravy spoons; one fish slice; one soup ladle; two do. sauce. On the epergne, the tureen, and six other pieces, the following inscription, surmounted by Mr. Storey's crest, was beautifully engraved:—"This service of plate was presented to Thomas Storey, Esq. C.E., by a number of his friends, as a sincere though inadequate tribute of the esteem and regard they entertain for his professional talents, and private worth." Nicholas Wood, Esq., of Killingworth, C. E., presided, and John Harris, Esq. of Darlington, filled the vice-chair. In proposing Mr. Storey's health, the Chairman said—

"It has, however, been Mr. Storey's lot to extend his services beyond the immediate district. Of the great line of communication between England and Scotland—the great chain of communication—he has had the good fortune to execute a link; and I may add that it is a pretty long link. Now when I call to remembrance that it is 45 miles, I venture to say that this link will bear a comparison with any other link in the chain between London and Darlington (immense cheering). Gentlemen, I have heard only one opinion of that link; which is, that it is the smoothest and best piece of road between London and here (cheers). When I mention a "chain," I speak of the great lines of communication—the great public railways, and when I allude to the railway from Darlington, I do not refer to the various local lines which are more immediately connected with the transmission of coals; but I allude to the line between York and Darlington, which I think will bear comparison with any of the great lines that lie between this place and London (applause)."

Removal of the North Pier Light-house.—We have this week to record one of the most ingenious efforts of mechanical skill, which has ever been exhibited in the town of Sunderland. The enterprising engineer to the Commissioners of the River Wear, John Murray, Esq., who has already manifested so much ability in improving our harbour, and our noble piers, has long been engaged in erecting a new pier on the north side of the river, for the purpose of widening the entrance to the port, and this being now nearly completed, it has become necessary to remove the lighthouse from the old pier to the present splendid erection. To give our distant readers an idea of the difficulty, we may state that the height of the lighthouse is 68 feet, and its weight 280 tons. It was on Monday last, the 2nd inst., every thing having been prepared for the attempt, that Mr. Murray carried the first part of his design into execution, and actually succeeded in moving the ponderous mass 20 feet 5 inches to the northwards. The means by which this was accomplished will seem very simple when explained to our readers; but in reality great ingenuity was requisite in overcoming difficulties, which, to many persons, seemed to present obstacles altogether insuperable. Five principal pulling screws were strongly fixed to the glacis in front of the building, and were attached to chains fastened to the cradle upon which the lighthouse stands. These screws were worked by 24 men. In addition to these, there were four screws behind the cradle to assist in propelling it, which were worked by three men each; the total number of men employed on the occasion was forty. The cradle was supported on a great number of wheels, which travelled on eight parallel lines of rails, and the entrance end of the bracing was supported on slide balks. Operations were commenced at half-past three P.M., and at a few minutes after eight it was safely landed on the new pier, where it now stands, without the slightest accident having taken place. The building is now intended to be carried 150 yards to the eastward, or very nearly to the end of the New Pier, and for that purpose it will be blocked up in its present situation, until the railways and wheel timbers are reversed, which part of the work will occupy about a fortnight, when it is intended to resume the operations for its removal.—*Sunderland Advertiser, Aug. 6.*

LEGAL CONSTRUCTION OF RAILWAY ACTS AS TO BRIDGE BUILDING.

The Queen v. Walker and Another, and the Birmingham and Gloucester Railway Company.—(De Montpelier Street.)—This was an indictment against the Birmingham and Gloucester Railway Company for a nuisance. The bill was found at the January sessions, and having been removed into the Court of

Queen's Bench, by writ of *certiorari* obtained by the defendants, it came down to be tried on the civil side.

Mr. Serjeant Goulburn, Mr. Humfrey, and Mr. Daniel appeared for the prosecution; and Mr. Hill, Q.C., Mr. Clarke, and Mr. Spooner for the defendants.

It appeared that the company had erected a bridge for the purpose of carrying their railway over Montpelier Street, at Highgate, near Birmingham, which street it crossed nearly at right angles. The 16th section of the Company's Act of Parliament provides, "that where any bridge shall be erected by the said company for the purpose of carrying the said railway over or across any public carriage road the span of the arch of such bridge shall be formed, and shall at all times be, and be continued, of such width as to leave a clear and open space under every such arch of not less than 15 feet, and a height from the surface of the road to the centre of such arch of not less than 16 feet, and the descent under any such bridge shall not exceed one foot in 13 feet."

By the 48th section of the same act it is provided, that "whenever the said railway shall cross any public footpath not on a level, the said company shall raise or lower the said footpath so as to preserve an ascent or descent, as the case may require, of not more than one foot in 13 feet."

The span of the bridge in question over the carriage way was 16 feet, being one foot more than the span mentioned in the act, but about four feet less than the original width of the road. The company had at first intended to obtain the required height of 16 feet under the arch by lowering the surface of the road, but at the request (as was stated) of some of the neighbouring inhabitants, who apprehended inconvenience from such a declivity, they had only lowered the road about seven feet, leaving a headway of ten feet eight inches.

When, however, the bill of indictment had been found against them, they excavated the road about five feet more, but not, it appeared, sufficiently by about six inches to give the full height of 16 feet. This excavation rendered it necessary to build retaining walls of 96 yards in length to support the footpaths on each side of the carriage way, the thickness of these retaining walls being an encroachment on the original width of the carriage way till they reached the bridge. At first no provision had been made for the footpaths, but subsequently the piers of the bridge had been cut through, and the footways had been carried through them, descending under the railway by steps, and ascending in the same manner on the other side.

Mr. Serjeant Goulburn opened the case on behalf of Mr. Unett, the prosecutor, the proprietor of an estate in the neighbourhood, and contended that the company were bound to preserve the road of its original width, and had no right to contract it by means of their bridge: that the width of 15 feet mentioned in the act was a provision only applicable to cases where the road had been originally of no greater width, or of less width than 15 feet, and was the minimum, not the maximum width which the company were bound to leave; that the company were not justified in lowering the surface of the road, but ought to have obtained their height of 16 feet from the surface of the road to the centre of the arch, by taking the railway across the road at a higher level; that with respect to the retaining walls they were an encroachment upon the approach to the bridge, and were not justified by the act; and with respect to the footpaths the company had no right to contract their width where they were carried through the piers of the bridge, nor to carry them underneath the railway by means of steps.

Mr. Justice Parke, on the counsel for the prosecution calling Mr. Hornblower, architect and surveyor, of Birmingham, as the first witness, suggested that the case appeared to be a question of law upon the construction of the act of parliament, more than a question of fact, and enquired if the facts could not be agreed upon. It was ultimately arranged that Mr. Hornblower's examination should be proceeded with, as the shortest way of eliciting the facts, which were proved by him to the effect above stated.

Mr. Justice Parke then ruled:—1st. That the company were not bound to preserve the road of its former width, but had a right to contract it by means of the bridge, provided they left a width of not less than 15 feet.—2nd. That the company had a right to lower the surface of the road in order to obtain a height of 16 feet under the arch, and that they might lower the road either before or after they had built the bridge.—3rd. That the company had no right to contract the carriage way in its approach to the bridge by the retaining walls.—4th. That the company had not complied with their act by carrying the footpaths under the railway by means of steps; but as this plan appeared the most convenient to the public, and as the sloping of the footpath, in lieu of steps, would render it necessary to underbuild the houses, the court would not compel the company to alter the footpaths.

At the suggestion of the judge, and by the consent of the parties, a verdict was entered for the crown, the company entering into a rule to widen the carriage way by pulling down the retaining walls, and throwing them back into the footpath, and undertaking to lower the road still further, so as to leave a height of 16 feet clear from the surface of the road to the girders of the bridge.

The costs to be taxed by Mr. Hilditch.

The Queen v. Same.—This was an indictment for a similar nuisance in Highgate Place.—A like verdict was taken.—*Midland Counties Herald.*

ST. GEORGE'S CHAPEL, WINDSOR.

August 2.

For some years past the grand western window of this edifice has been considered to be in an extremely dangerous position, and very far from secure, in consequence of its bulging considerably inwards in many of its parts to the extent of several inches.

About 10 or 12 years since, the late Sir Jeffry Wyatville minutely examined the stone work of the window, and in consequence of his report it was determined it should undergo the necessary repairs under Sir Jeffry's superintendence: but, in consequence of the architect's then engagements, the repairs were not proceeded with.

The Dean and Canons, however, have just decided that the massive stone work shall be taken down, and the whole window entirely rebuilt, preserving the valuable stained glass it contains for replacement. The execution of this work, which will require the greatest care, so as not to injure some of the finest specimens of painted glass in the kingdom, has been intrusted to Mr. Blore, the architect, by the Dean and Canons.

The great painted window, over the altar, representing the Resurrection of our Saviour, divided into three compartments, designed by the late Benjamin West, and executed by Messrs. Jarvis and Forest, in 1788, has hitherto been seen to great advantage, in consequence of the three windows on the north and south sides of the west-end of the choir having been darkened (to give greater effect to the design), and painted over with the arms of the Sovereign and Knights Companions of the Order of the Garter in 1782, 1799, 1805, and 1812. The arms of each knight are encompassed with the Star and Garter, and surmounted with his crest and coronet. The George is beneath, affixed to a blue riband, on which the Christian name and title are inscribed. These six windows are to be immediately taken out, and for the darkened glass there is to be substituted transparent painted glass (containing the arms of the Sovereign and the Knights, and other heraldic devices), thus giving an air of great lightness and elegance to this part of the chapel, although, at the same time, very materially diminishing the grandeur and effect of the large painted window over the altar.

One of the windows was completed on Saturday July 31, and judging of the effect which will be produced from this one only, the alteration decided upon by the Dean and Canons will greatly improve the general appearance of the interior of the chapel. It will only require the remainder of the windows of the choir, which are now plain, to be of stained glass, to render St. George's Chapel one of the most imposing and magnificent sacred edifices in the kingdom.

The painted glass for the six windows referred to has been executed by and under the superintendence of Willement.

Except on Sundays the chapel has been closed for several weeks past, in order that no delay may take place in the completion of the work.

The splendid organ, which is considered to be one of the finest instruments in England, has just undergone a thorough repair by Gray. The old keys, which were upwards of 50 years old, and completely worn through, have been replaced by new ones, and several additions have been made to the pipes.

As soon as the improvements now in progress are completed, it is the intention of the Dean and Canons that the whole of the interior of the chapel shall undergo a complete and thorough cleansing and repair. Nothing has been done to the chapel in these respects during the last half century.

THE RIVER CLYDE.

At a meeting of the River Trust held on Tuesday, 27th July last, Mr. James Hutchison called the attention of the Trust to a matter of the last importance, viz. the extent to which the river should be widened. In the Bill which had lately passed Parliament powers had been taken to widen the river vastly beyond its present breadth, but if these powers were acted upon to their full extent, the time occupied in the operations, and the vast increase which it would cause in the expense of dredging and maintaining the extended river at the proper depth would be such as to place the Trust in a most dangerous position; and Mr. Bald had given it as his opinion that it might be productive of ultimate ruin. Mr. Bald had, however, prepared a plan of the contemplated improvements, similar to those which had been approved of in 1836, and though this plan did not widen the river to the extent which they had power to widen it by the Act of Parliament, still it must be admitted by all that it would improve the river sufficiently to accommodate the most extensive trade which could be reasonably expected to belong in after years to the harbour of Glasgow.

Mr. Bald briefly addressed the Trust, in explanation of his plans. From his remarks we learn that the width of the river from the bottom of harbour (at which it is intended to commence operations,) down to Renfrew, varies at present from 165 to 190 feet. It was his intention, however, to increase this width to 300 feet at the bottom of the harbour; to 310 at the mouth of the Kelvin, and to 325 at Renfrew Ferry; and at the same time to "sweeten" the course, or, in other words, to remove angles and jutting points, and to make the line a straight one. If the Clyde were thus widened it would be sufficient for any increase of trade that would come to it. By not going beyond this proposed width, the channel would deepen itself, and of the progress of this deepening process, they had that day an example in the arrival in their harbour of a ship drawing 17 feet water; and he anticipated, that in a few years, if the large or extended plan were not adopted, that the depth would increase to from 18 to 20 feet. He considered the proposition to increase the width of the river to 400 feet, beginning immediately below the harbour, to be most unwise, and one which he would not advise, even though the Trust might possess the means to execute it. It would take 70 years to complete the operations according to this extended plan, and when once finished the expense of maintaining it would be absolutely ruinous.

To a question from Mr. Burns,

Mr. Bald replied, that it was a law recognised by all engineers that if the channel of a river were widened beyond the proportion of its depth, it became more shallow, from the slower motion of the current. If, on the other hand, it was narrowed beyond this proportion, it had a tendency to become deeper from the more rapid motion of the stream, particularly in land floods. He instanced three places in the river, the harbour being one of them, where deposits were continually taking place, from their being unusually wide.—Were it otherwise, this silt or deposit would be at once removed by the land flood to the sea.

Mr. James Hutchison explained, that at the time it was resolved to take powers to widen the river to a great extent by the last Bill, Mr. Walker, upon making out the plans, informed them that if the breadth of the river was at any time extended according to these plans, they must make up their minds to the maintaining of it by dredging being immense.

After a conversational discussion of some length, it was finally resolved that Mr. Bald's modified plans should be adopted, and, as we understood, that operations should be commenced immediately.—*Glasgow Argus.*

STEAM NAVIGATION.

The Iron War Steamer Phlegethon.—We perceive, by the Calcutta papers brought by the India mail, that this vessel, which was built by Mr. John Laird, of North Birkenhead, for the East India Company, has arrived at that port. She is about 500 tons measurement, armed with two 32-pounders and other small guns, and is exactly the same size and model as the former iron war steamer, the Nemesis. She was to sail for China about the middle of June, to join the expedition. It was reported in the Bombay papers, that two armed steamers, the Ariadne and Medusa, both built by Mr. Laird, carrying each two 26-pounders, would be ordered to China: they would make an effective flotilla of four powerful iron armed steamers attached to the expedition, and, from the services rendered by the Nemesis, are likely to prove a great acquisition. The following extract of a letter, dated Calcutta, June 5, gives an account of the Phlegethon:—"I am too full of business to write at length just now; but you will be delighted to hear we arrived at this place on the 22nd of last month, as sound in hull, boilers, and engines as when we left England. We have had some severe trials, and a large share of stormy bad weather. The Phlegethon, in bad weather, has surpassed my most sanguine expectations, and having gone over 17,157 miles without straining a rivet, will I consider quite carry out the principle that these sort of vessels can navigate in security between England and India."—*Liverpool Albion.*

The Steam Ship "Admiral."—In these days of steam triumphs, we have frequently had to record the achievements of mechanic art, as applied to steam-ships of leviathan dimensions, as well as of the consummate skill displayed in the performance and management, and we remember few that have possessed greater claim to public attention than the splendid steamer *Admiral* now running between Liverpool and Glasgow, the same line on which the *Achilles, Commodore, Actæon, City of Glasgow,* and *Princess Royal,* all splendid steamers, are employed. The *Admiral* is a vessel well worthy of her name and lineage, and, whether the size and beauty of the ship, her excellent accommodations, or the great power and perfection of her machinery be the object of admiration, it must be admitted, that in each of these departments, she has never been surpassed. The engines supplied to this vessel are of unusual power and beauty of construction, fitted up with expansion gear, and possessing all the latest improvements: they were produced at the Glasgow Vulcan Foundry, and are of 200 horse power. It is a matter of great interest to witness the cleanliness and order always observed in the engine-room, and the great care and attention of the engineers are particularly worthy of notice for skill and sobriety: neither is the grand desideratum to a landsman (roomy accommodation) to be forgotten. There are 107 sleeping berths, all of the most ample dimensions, a limited number of which are divided off into state apartments. The grand salo n, around which these state apartments are arranged, is a magnificent room, and unites extreme comfort with ornament; on either side of it tables are ranged with elegant seats of richly carved oak, uniform with the chase panelling and groined roof. The entire fittings are of the most costly description, and the cuisine is excellent and cheap. The range of the *Admiral's* deck is 220 feet, it is perfectly flush, and forms a beautiful and unbroken promenade. The *Admiral* is a vessel of the same class and under control of the same business management at Liverpool as the Halifax line of steamers, and the same system of speed, punctuality, and good order which has obtained an exalted reputation for the Atlantic steamers prevails here, and has met with equal success.—*Morning Herald.*

MISCELLANEA.

ELECTRO-MAGNETIC PRINTING

On Monday, 2nd ult., the first public exhibition of Mr. Bain's electro-magnetic printing-machine took place in the Lecture-room of the Royal Polytechnic Institution.

The apparatus consists of a dial-plate, inscribed with the alphabet and numerals, with a revolving hand, worked by ordinary clock-work. On the other side of the room stood the important portion of the invention—that which furnished in type the communication to be sent forth from the dial-plate already described. Between these two machines a connexion (capable of being extended in practice to any length) by means of wire conductors, communicating with two electro-magnets placed on a frame, and connected with a cylinder covered with paper, upon which the type was to leave its impression—an horizontal wheel, in which types to correspond with the letters and figures on the dial were fixed. This wheel was ingeniously brought in contact with an inking roller, and these three portions of the machine were all brought into motion horizontally.

The party directing the communication stands at the dial-plate first described, and fixes a peg under the letter desired to be communicated. The index or revolving hand performs its rotation until its progress is arrested by coming in contact with the peg. A small trigger is then pulled, the galvanic power is then brought to bear by the aid of the communicating wires upon the two electro-magnets, with their machinery on the second frame, and the letter thus communicated is printed upon the paper affixed to the cylinder.

The operations excited universal admiration, and the machine itself is well worthy the attention of the curious, for though at present it may fail as a speedy means of communicating information in print, still by the adoption of a code of signals (by which one letter or character might be construed to denote a sentence or describe a subject) the invention might be made extremely valuable in the times in which we live.

Electro-magnetic Exhibition.—A very interesting exhibition has been lately opened at No. 8, St. Andrew Square, Edinburgh. It consists of several working models of different machines, such as a turning-lathe, a printing-machine, a saw-mill, and a locomotive carriage, driven by the power of electro-magnetism. The inventor of these models is Mr. Robert Davidson, an ingenious mechanic from Aberdeen, who has been engaged upon them for the last four years, and who has succeeded in effecting several improvements in the application of electro-magnetism, which promise to be of great practical value. He is the first, we understand, who has employed the electro-magnetic power in producing motion, by simply suspending the magnetism without a change of poles. The mode employed by Jacobi, Davenport, and Storrar, consisted in keeping the repulsive power (which is equal to a third only of the attractive power) in operation during the one half of the time, and the attractive power during the other half. Mr. Davidson's discovery consists in a simple and extremely ingenious method of communicating and cutting off alternately the galvanic current to and from a pair of electro-magnets that always act attractively, so as to exert a constant moving force upon the machine which is put in action. It has received the approbation of numerous scientific gentlemen, who consider that Mr. Davidson has succeeded in showing the perfect applicability of magnetism as a motive power to engines of every description. It would no doubt be desirable, however, to see experiments tried on a larger scale; which Mr. Davidson, we understand, is anxious to do, but is deterred by the want of funds.—*Scotsman.*

Travelling by Electro-magnetic Power.—We are informed that a distance of 57 miles has been travelled on the common road, in a Bath chair, by electro-magnetic power, in one hour and a half; and further, that the applier comes over daily from St. Alban's to the Bank of England in the said chair in half an hour at an expense of sixpence. The model of an electro-magnetic engine, which has been exhibiting at the Adelaide Gallery for some time, is an instance of ingenious mechanic arrangement, whereby contact is broken and renewed, the poles reversed, &c.; and from its performances gave great promise of practical powers on a larger scale. The battery employed is the nitric acid, or Grove's battery. Of the invention that has done the great feat, and established the successful application of this wonderful agent, we know little more than its success. We hear that the increase of power is due to the discovery of a new combination of elements; that this is the secret of the moving power; and that the battery is to be the subject of a patent.—*Literary Gazette.*

Edinburgh and Glasgow Railway.—It is gratifying to observe the incessant exertions which are making everywhere on the line in the vicinity of this city to get this national undertaking completed. The magnificent entrance to our great tunnel is drawing to a conclusion, while the booking and other offices are all but finished. The landing and departing platforms are now getting very handsome sheds, with elegant cast iron supports set up; and the ground is clearing out for laying the permanent rails. Yesterday Mr. John Craig, the mineralogist, made a survey of the tunnel, in furtherance of the objects of the British Association, and proceeded right through it, in company with the very polite and spirited contractor, Mr. Marshall. Amongst many other geological specimens got in the journey, we saw perfect masses of the *Nucula Tumida, Producta Scotia, Producta Martinnii, Bellerophon Urii,* and *Apiocrinites,* imbedded in a shale, above a two feet limestone, with many other interesting remains of a period long before the creation of man.—*Glasgow Constitutional,* August 4.

London and Brighton Railway.—The Brighton terminus is now completed externally. All the works are on a magnificent scale: and the passengers' sheds and station vie with any works of a similar kind in the kingdom. The station is even larger than that at the London terminus of the Birmingham Railway in Euston-square; and the edifice forms a pleasing and prominent object from various parts of the town.—*Brighton Gazette.*

Bristol and Glocester Railway.—The works on this line are proceeding rapidly in the neighbourhood of Wickwar, where 600 additional labourers have been put on this week.—*Glocestershire Chronicle.*

Cheltenham and Great Western Union Railway.—Contracts have been taken, and in some instances the works have been commenced, for carrying on this line from its present terminus at Cirencester towards Stroud and Gloucester. —*Cheltenham Looker-on.*

Paris and Rouen Railway.—This great work is proceeding rapidly, under the superintendence of Mr. Locke; and we understand that thirty-five miles of the Paris end of the line will be opened early in the spring of next year.

Railroad from Berlin to Hamburgh on the right bank of the Elbe.—The *Hamburgh Gazette* under date Berlin, the 24th ult., announces that a commencement had been made in this affair. The provisional committee was appointed definitively, with power to adopt resolutions. This enterprise was calculated to consolidate the interests of so many people, that the most perfect accordance was necessary. The number of subscribers amounted to 5,000.

Railway Filters.—For some time a number of men have been employed in the erection of filters on the top of the terminus of the Greenwich Railway, for the purpose of supplying the engines with pure water, it having been discovered that the water that has been used has occasioned considerable injury and wear to the machinery. There are also similar filters erected at the New Cross station, on the Croydon line.

Iron Lighthouse.—The necessity for a lighthouse to facilitate the navigation of the windward passage by the Morant point, in the island of Jamaica, so as to enable vessels to avoid the Morant Cays, a dangerous reef of rocks, 25 miles south-east of that point, having been long felt by the authorities of the island, they have determined upon the erection of a tower and lights for that object, upon the recommendation and under the direction of their consulting engineer, Mr. Alexander Gordon; and it may now be seen in a very advanced state of forwardness, from the road at Pimlico, erecting on the works of Charles Robinson, proprietor of the long-known establishment of Bramah and Sons. It forms a most conspicuous and imposing object as it rears its head above the surrounding buildings; and when completed to its full height, 100 feet, will doubtless attract much notice from its novelty. The diameter of the base is 18½ feet, tapering gradually to 11 feet under the cap, which supports the lantern containing the lights and reflectors, which, with the actuating apparatus for revolving the lights, are constructing by Deville, of the Strand.

The Dry Rot.—Government have recently ordered the opening of the fungus pits in Woolwich dockyards, which had been closed in August, 1836, for the purpose of testing the virtues of Sir W. Barnett's process for rendering wood, cordage, and all descriptions of woollen free from the effects of dry rot. The result, it would appear from the reports of the officers deputed by the Admiralty to superintend the experiments, is in every way successful, the prepared wood being as clear and sound when it came out as when first deposited.—*Inventors' Advocate.*

Thames Tunnel.—The shaft of the Thames Tunnel on the Wapping side of the river, in which the circular staircase is to be formed for foot passengers, has now almost entirely disappeared, and not more than five feet of it appears above the ground. A month ago it was on a level with the tops of the adjoining houses, and its gradual sinking as the earth below is excavated has excited the surprise of the inhabitants. In depth it is 60 feet, and it will be raised 15 feet higher, and again sunk. Since the engineer of the Tunnel, Sir Isambard Brunel, and three other gentlemen, passed under the driftway connecting the shaft with the Tunnel, many others have passed from one shore to the other by the same means. The completion of this stupendous work is close at hand.

Asphalte.—For some time past the Seyssel Asphalte Company's men have been actively engaged on the New Junction line of the Greenwich Railway, in covering the arches, which when completed will extend over a space of 400,000 feet.

New Steamers.—On the 21st instant a fine steam vessel was launched from the building yard of W. Pitcher, at Northfleet. She is for the Sicilian Government, and named the "Maria Teresa," her tonnage is about 300, and the collective power of her engine will be 120 horses, manufactured by Messrs. Boulton, Watt & Co. of Soho. A second vessel for the same government is in considerable progress, of smaller dimension to carry two 50-horse engines, from the same establishment.

A Miniature Steamer called the "Fire Fly," has been astonishing the frequenters of the Thames by its rapid evolutions on the river, she is a moderate sized boat propelled by Ericsson's propeller fitted in the stern and driven by two oscillating engines, set *horizontally*, and at right angles the crank shaft. The diameter of the cylinder is only 3 inches, and 6-inch stroke, making 180 to 200 strokes per minute, worked with high pressure steam of 50 to 60 lb. on the square inch, generated by a very compact locomotive boiler. The engines and boiler were entirely constructed by Mr. Warriner, formerly a pupil of Messrs. Braithwaite, Milner and Co., the engines possess several improvements worth introducing in larger engines, particularly the method adopted of conveying the steam into the cylinders instead of through the gudgeons, upon which the cylinders oscillate. She steams about 8 to 9 miles per hour through the water, and has run with the tide from Blackwall to Westminster Bridge in 50 minutes.

Captain Ericsson is now in New York, and engaged by the American Government to construct two engines of 1,000 horse power collectively for a large sea-going vessel to be propelled by the Captain's propellers.

Galvano-plastic Casts.—A letter from Munich informs us that the celebrated Bavarian sculptor Stigelmayer has brought to such a pitch of perfection his galvano-plastic process, that its effects would be deemed fabulous were they not publicly exhibited in the Museum of the Society of Arts. In the space of two or three hours colossal statues in plaster are covered with a coat of copper, which takes with the greatest accuracy the most minute and delicate touches, giving the whole all the appearance and solidity of the finest casts in bronze. M. Stigelmayer has also applied his process to the smallest objects, as flowers, plants, and even insects, bringing them out with such accuracy, that they seem to have been executed by the hands of the most skilful artists.

Highest Chimney in the World.—The highest chimney in the world is at the soda ash manufactory of James Muspratt, Esq., near Liverpool. It is the enormous height of 406 feet above the ground, 45 feet diameter inside at the base, 9 feet ditto at the top, and contains nearly 4,000,000 of bricks.—*Daily paper.*

LIST OF NEW PATENTS.

GRANTED IN ENGLAND FROM 28TH JULY, TO 27TH AUGUST, 1841.

Six Months allowed for Enrolment.

JOSEPH RATCLIFFE, of Birmingham, manufacturer, for "*certain improvements in the construction and manufacture of hinges for hanging and closing doors.*" (A communication.)—Sealed August 4.

OWEN WILLIAMS, of Basing Lane, London, engineer, for "*improvements in propelling vessels.*"—August 4.

JOHN LEE, of Newcastle-upon-Tyne, manufacturing chemist, for "*improvements in the manufacture of chloride.*"—August 4.

JAMES WARREN, of Montague Terrace, Mile End Road, for "*an improved machine for making screws.*"—August 4.

STOFFORD THOMAS JONES, Tavistock-place, Russell Square, gentleman, for "*certain improvements in machinery for propelling by steam or other power.*"—August 4.

WILLIAM CRAIG, engineer, ROBERT JARVIE, rope-maker, and JAMES JARVIE, rope-maker, all of Glasgow, in the kingdom of Scotland, for "*certain improvements in machinery for preparing and spinning hemp, flax, wool, and other fibrous materials.*"—August 11.

SAMUEL BROWN, of Gravel-lane, Southwark, engineer, for "*improvements in the manufacture of metallic casks or vessels, and in tinning or zincing metal for such and other purposes.*"—August 11.

JOHN SEAWARD, and SAMUEL SEAWARD, of the Canal Iron Works, Poplar, engineers, for "*certain improvements in steam engines.*"—August 13.

WILLIAM HALE, engineer, and EDWARD DELL, merchant, both of Woolwich, for "*improvements in cases and Magazines for gun-powder.*"—August 13.

JOHN HARVIG, of the Strand, gentleman, and FELIX MOREAU, of Holywell-street, Millbank, sculptor, for "*a new and improved mode or process of cutting or working cork for various purposes.*"—August 21.

JOHN HARVIG, of the Strand, gentleman, and FELIX MOREAU of Holywell-street, Millbank, sculptor, for "*a new or improved process or processes for sculpturing, moulding, engraving, and polishing stone, metals, and other substances.*"—August 21.

JOHN THOMAS CARR, of the town and county of Newcastle-upon-Tyne, for "*improvements in steam engines.*" (A communication.)—August 21.

GEORGE HICKES, of Manchester, agent, for "*an improved machine for cleaning or freeing wool, and other fibrous materials, or furs and other extraneous substances.*"—August 21.

CHARLES DE BERGUE, of Broad-street, London, merchant, for "*improvements in axletrees and axletree boxes.*" (A communication.)—August 21.

FREDERICK DE MOLEYNS, of Cheltenham, gentleman, for "*certain improvements in the production or development of electricity, and the application of electricity for the obtainment of illumination and motion.*"—August 21.

WILLIAM WALKER JENKINS, of Gred, in the county of Worcester, manufacturer, for "*certain improvements in machines for the making of pins, and sticking the same into paper.*"—August 27.

EDMUND MOREWOOD, of Highgate, Middlesex, gentleman, for "*an improved mode of preserving iron and other metals from oxidation or rust.*" (A communication.)—August 27.

MILES BERRY, of Chancery-lane, civil engineer, for "*certain improvements in the means and apparatus for obtaining motive power, and rendering more effective the use of known agents of motion.*" (A communication.)—August 27.

SAMUEL HARDMAN, of Farnworth, near Lancaster, spindle and fly-maker, for "*certain improvements in machinery or apparatus for roving slubbing cotton and other fibrous substances.*"—August 27.

THOMAS CHAMBERS and FRANCIS MARK FRANKLIN, of Lawrence-lane, London, and CHARLES ROWLEY, of Birmingham, button manufacturer, for "*improvements in the manufacture of buttons and fastenings for wearing apparel.*"—August 27.

TO CORRESPONDENTS.

"G. Coe."—*On Reversing Engines; an accident occurred, as we were going to press, which damaged the engravings, we were therefore obliged to postpone the notice until next month.*

Severn Navigation.—*We have received a very valuable report by Mr. Fulljames, on the proposed improvements of the river, well deserving a perusal by all parties connected with this long contested "improvement."*

Mr. Brooks and Mr. Barrett.—*After a careful perusal of the communications from these two gentlemen, we have determined not to insert them, as we feel convinced that they will only lead to an endless altercation between both parties.*

We must request the favour of our correspondents, who may favour us with articles which require engravings to illustrate them, to let the drawings be separate from the manuscript, and drawn on thin paper—good tracing paper is the best, and if possible to draw them so that they shall come within the width of a column (3½ inches), or the width of a page (7 inches.)

Communications are requested to be addressed to "The Editor of the Civil Engineer, and Architect's Journal," *No. 11, Parliament Street, Westminster.*

Books for Review must be sent early in the month, communications on or before the 20th (if with drawings, earlier), and advertisements on or before the 25th instant.

Vols. I, II, and III, may be had, bound in cloth, price £1 each Volume

ERRATA.

Page 319, *col.* 1, 18 *lines from the bottom, for* "quantity," *read* "pressure."
Page 319, *col.* 2, 23 *lines from the top, for* "our atmosphere," *read* "four atmospheres."

HISTORY OF DECORATIVE SCULPTURE IN FRANCE.

(Concluded from page 259.)

When the kings of the first race founded the French kingdom, they built churches, some of which are mentioned by Gregory of Tours (B. 2 § 14, 15, &c.), but which have all unfortunately been destroyed. Some remains of these primitive edifices are still however to be seen in marble capitals used in the churches rebuilt after the Norman ravages. Thus at Montmartre there are capitals of white marble, the style of which calls to mind degenerate antique forms, and which can only be assigned to the first ages of Christianity; this is evident from the Greek cross still to be seen on the volutes of one of them, the irregular management of the foliage, the inferior execution, and the sharp forms which made their appearance with Christianity, and did not leave until the Revival. These are features belonging to a period of art very nearly approaching the Lower Empire, but Christian notwithstanding as the emblems plainly show. At Jouarre, a place famous for its abbey, is still to be seen a subterranean chapel at the end of the cemetery, having, like the church of Montmartre, several capitals of white marble, which in the singular form of their leaves, and in the variety of their composition, since there are no two alike, show more of the classic character of antiquity, and on the contrary present all those which are proper to the first centuries of Christianity. The church of St. Denis has on several capitals *fleurons*, like those of Jouarre, and which might have formed part of the church of Dagobert. To the same period a Greek cross, found some years ago behind the apsis of the present church, appears to belong. The ruins of the Abbey of St. Medard, at Soissons, have among them a marble capital, in which may be recognized the degenerated traces of ancient art, and seeming to belong to some of the edifices of the kings of Soissons, who were buried at St. Medard.

Between this first period of modern civilization and the eleventh century, monuments are wanting to enable us to follow up step by step the history of the subject before us, a deficiency which must no doubt be attributed to the numerous invasions, which took place during the Carlovingian reigns. When the reign of the Capets commenced Robert the Pious rebuilt the churches, and art took a new direction, of which there is now abundant evidence. The church of St. Germain des Prés, at Paris, for instance, notwithstanding many details attributable to the barbarism of the age, has some fine parts, particularly around the choir. There, the capitals, composed of large leaves, contain chimerical animals, contributing to the effect of the composition, and the great variety which prevails is good proof of the rich and fertile imaginations of the medieval artists. At this period the leaves of the acanthus and the volutes, with other elements of ancient ornament, still formed part of decoration, but their general forms were entirely modified. The historical capitals of the nave of St. Germain are also of the eleventh century, and are not less interesting than those of the choir. (See Figs. 1 and 2.)

During this period of art, the capitals form two very distinct classes, 1st, of those in which, in imitation of the Pagans, Christian artists only imitated foliage as the basis of decoration; 2nd, capitals enriched with human or animal figures, and of which the origin is also to be found among the ancients. The first are evidently a consequence of the capitals of the first period of our era, of which we have mentioned that there are examples at Montmartre, St. Denis and Jouarre. In the eleventh century they exhibit an imitation more or less exact of the Corinthian column. The ornaments of the astragal of the capital in the church of St. Spire at Corbeil, and of Esnay at Lyons, are composed of water leaves, imitated from the antique, and executed badly enough. In the cloister of Moissac they are replaced by Byzantine rosettes. The foliage of this period presents acute forms, removing the artist from the study of nature, a direction which was given to art by the Orientals in the time of Justinian, and afterwards adopted in the west. Above the astragal is the capital, differing from that of the ancients as it takes every imaginable geometric figure, the details of the Corinthian foliage gradually disappearing and giving place to original compositions, sometimes not without harmony and taste. The subjoined capital from the church of St. Germain des Prés is an instance of this.

During the whole period, included between the last Carlovingians and the 13th century, the principal elements of ornamental sculpture are an imitation, more or less good, of the acanthus, their leaves edged with pearls, palms, scrolls, and other exotic types.

The second class of medieval capitals is distinguished from the first by heads of men and animals, chimeras, and sea or land monsters, mixed up with acute foliage imitated from the oriental flora, and which are afterwards succeeded by religious, historical, or symbolical subjects covering the whole surface of the capital to the exclusion of other

Fig. 1.

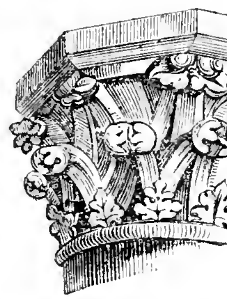
Fig. 2.

Capitals at the Church St. Germain des Pres.

ornament. This second system, like the first, owes its origin to antiquity. The Etruscans often mixed up the heads of men with foliage in their capitals;* the Romans introduced persons on foot, of which a fine example is to be found in St. Lawrence without the Walls. Without leaving France, ancient examples are to be found of this mode of decoration, as at Vienne in Dauphiny, where on a beautiful Corinthian marble capital of large proportion, are four heads of Pagan divinities. The Museum of the same city contains a fragment seemingly rather later, and in which are also figures and animals in the midst of foliage. A Medusa's head is in the middle, two serpents intertwined form the volutes, which rest on large acanthus leaves. The church of St. Germain des Prés shows the whole progress of the system, some of the capitals being covered with historical and religious subjects. (Vide Fig. 2.) The royal vault in the subterranean church of St. Denis, is decorated with purely historical capitals, representing kings of France, bishops removing relics, &c. (Vide Fig. 3.)

Fig. 3.

Fig. 4.



Capitals at the Church St. Denis.

In the 12th century national art acquired a less barbarous tendency, and in St. Denis, we see in the parts built by the Abbot Suger, capitals of good character and scrollwork still more remarkable, forming the decoration of the pilasters of the north side door to the cemetery of the Valesians. At this period, more than in the preceding, painting was applied in aid of sculpture, and in the next century, it attained its complete development. Even in the 12th century the Christian artists, deprived of ancient models, sought for the elements of ornament in the national flora; and in the succeeding period the acanthus and all the exotic plants were wholly excluded from sculpture, and gave way to French flowers and foliage. The execution of ornament in the end of the 12th and 13th centuries is very good, for the sculptor, being perfectly acquainted with the forms he was to imitate, produced broad and noble compositions, in a style which, although severe, was completely in harmony with the buildings. In the 13th century Peter of Montereau, architect to St. Louis, one of the most skilful artists of his time, gave new vigour to the art of decoration; he introduced in the chapel of Our Lady in the church of St. Germain des Prés, and the Sainte Chapelle of the Palais, ornaments of remarkable precision and taste. Notre Dame, which has some parts of the same date, shows in the great capitals, supporting the columns of the nave, and in the details of the doors, how much the art of the scultpor was advanced,

* See an example in the British Museum.—Edit.

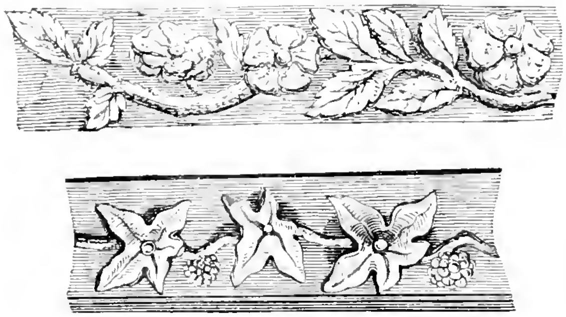
Capitals at the St. Chapelle, Paris.

Figs. 7 and 8.

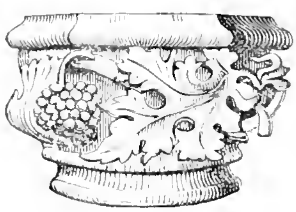


Ornaments from the Church Notre Dame, Paris.

The capitals of the Hotel de Dieu at Paris, of the Abbey of Poissy, of the front of St. Julian the Poor, &c., were so many masterpieces of the luxuriant imagination of the decorators of the 13th century. Among the examples of this period may also be classed the beautiful ironwork of the gates of Notre Dame; it is composed of scrollwork in the best taste and of the finest execution. The date of it is not decided; but it evidently belongs to the 13th century, agreeing in style with the ornament of the rest of the building. In the gate in the middle of the grand front the skilful artist has intermingled birds, winged dragons and foliage, with a statue of St. Marcel in the midst. This beautiful piece of ironwork is unique in Europe, and well deserving of the attention of artists on account of the elegant forms which have been given to the iron.

The ornament of the 14th century was of a character almost as high as that of the preceding, but the forms had already become less simple and less true, the capitals were divided into stages of foliage, the as-

Fig. 9.



tragals assumed the obtuse angles of the polygon, and the foliage rolled upon itself, gives an appearance of confusion which destroys the general effect. The fleurons which decorate the finials and crocketings are formed of sharp and divided leaves, as thistles and holly, from which there results less severity of appearance in buildings of this age than in those of the foregoing.

In the 15th century great license prevailed in national art; the sculptors gave themselves up to the most vagabond inventions, representing climbing plants of a light form and divided foliage. The vine, thistle, and endive were the most frequent models adopted in buildings of this period, and the use denoted the approach of a revolution. The execution is free, and shows great facility, which they abused, and often to such a degree that their productions are mere

sketches, touched up with taste. While however we refuse to the decorator of this period the gravity, which characterizes the labours of the two preceding periods, we are obliged to acknowledge that they produced works, remarkable for the luxuriance and variety of their composition, and the effect of the boldness of their undercutting. Towards the end of this century the Revival of ancient art began to take root in the midst of the productions of national medieval art, and again were oriental productions mixed with those of the indigenous Flora. The reign of Louis 12th has left us many monuments of this period of transition, among which the façade of the Chateau de Gaillon, at the Palace of the Fine Arts, deserves to be particularized, as showing the union of the two styles.

Under Francis the 1st, the revolution in art became complete, the ancient style imitated with more or less perfection, sometimes witnessed the introduction of Gothic forms, but always without any disturbing effect. The details of the tomb of Louis the 12th, and the capitals of the Chateau de Madrid, are well enough known to require only to be alluded to. It was under Henry the 2nd, that the Revival arrived at its height. The Louvre, the Chateaux of Anet and Ecouen

Bracket for a Lamp, from the Chateau de Gaillon.

and the Tomb of Francis the 1st are monuments perfect in the details of their ornamental sculpture, in which they may contend with classic antiquity, the Revival however was never a servile imitator of the Greek and the Romans. This epoch is particularly remarkable for the composition of capitals and arabesques.

From the reign of Henry the 4th, the Revival begins to lose part of its charm, ornaments became heavy, too numerous, and neglected in their execution, showing how much art had declined.

Under Louis the 13th and 14th, the direction given to ornamental sculpture was in some degree stationary, but at the end of that age, during the Regency and the whole reign of Louis 15th, the decline was rapidly going on. In fact, the corruption of form was such that no epoch in the history of the art has ever produced any thing similar. In the details of the architecture of this period, we witness the complete absence of the observation of nature, which hitherto had always been looked up to as a guide.

Under Louis 16th, it was seen how little this capricious style was adapted to the decoration of severe edifices, and a return to the antique was begun by the architects Soufflot and Servandoni. There were still to be seen however remains of the influence of that bad taste which gave way to the revolution of 1789, and the serious study of the antique which has been pursued in the 19th century.

THE ETCHING CLUB.

This association has been formed by twelve artists (eleven painters and one sculptor), composed of the following gentlemen, whose names will at once be recognized as amongst the most rising of the day:—Redgrave, A.R.A; Webster, A.R.A.; Knight, A.R.A.; Cope, Taylor, Creswick, Horsley, Townsend, Stonhouse, Bell, and F. Stone, with the view of reviving the older excellence of the art of etching, and of conferring upon the popular literature of the country, especially poetry, a more pleasing, original, and artist-like mode of illustration. The first work that they have sent forth, consists of a series of eighty-two illustrations of Goldsmith's exquisite poem, "The Deserted Village. These illustrations, in whatever way regarded, whether for originality of conception, beauty of composition, truth and delicacy of feeling, or correctness of delineation, are worthy of the highest praise. We regret, however, to perceive that the club have adopted the barbarous practice of destroying the plates after taking a certain number of impressions, which, in these days, is quite inexcusable.

FOOT BRIDGE OVER THE RIVER WHITADDER.

Sir—In the number of your Journal for July last, there is a description of a proposed new construction for railway viaducts on the tension bar principle, in which the writer refers to the foot bridge over the river Whitadder, in Berwickshire, on the property of George Turnbull, Esq., of Abbey St. Bathans, as an instance in which the principle he proposes has been applied to bridges. The principle however as adopted at Abbey St. Bathans foot bridge is not carried so far as in the proposed railway viaduct, and as it is simple in its construction, and is found to answer the purpose well, you may consider the accompanying sketch of its details not unworthy of a place in your Journal.

In 1821 Mr. Robert Stevenson of Edinburgh,* designed a bridge for the river Almond, in Edinburghshire, in which the principle of supporting the roadway by iron bars passing underneath was first adopted. This plan however differs from that now in use at Abbey St. Bathans' bridge and elsewhere, as the chains for supporting the roadway are fixed in the abutments, whereas at Abbey St. Bathans the roadway beams themselves are made to resist the strain. Mr. Smith of Deanston, has erected a foot bridge of this kind 103 feet span near Doune.

I am not aware where and by whom the plan of fixing the tension bars to the extremities of the roadway beams was first adopted, but the principle has now come into pretty general use. A beam may in this way be rendered perfectly rigid, and even forced into a slightly arched form, and from the lightness and compactness of the whole it possesses many advantages over the other methods in which the same thing is accomplished.

In 1833 a bridge was erected on the tension bar principle over an arm of the Lake of Geneva. It has 13 openings of 55 feet span, and is 25 feet broad. The same plan has been adopted for two foot bridges of 138 and 81 feet span respectively erected several years since over the river Ness, near Inverness, and also for a bridge over the river Whitadder, in Berwickshire, at Hutton Mill, designed by Mr. Jardine, of Edinburgh, which consists of three openings 50 feet span. Mr. Smith has also applied tension rods very successfully for supporting the floors of the Deanston cotton works, where they have been in use for many years. These, so far as I am aware, are the only instances in which this principle has been adopted.

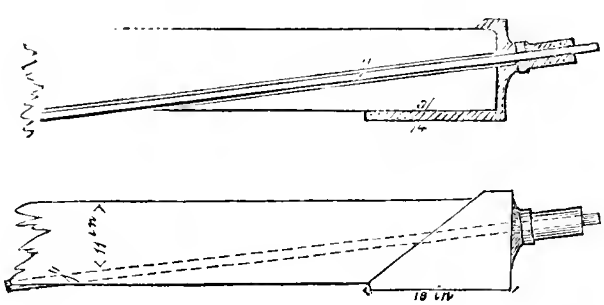
* See Edinburgh Philosophical Journal for October, 1821, and Drewry on Suspension Bridges, page 30.

The Whitadder is subject to heavy floods, especially in the winter season, which interrupts the intercourse between the opposite banks, and as there is no bridge within many miles of Abbey St. Bathans, the want of some means of communication was long felt to be a great inconvenience, and several attempts had been made to build a foot bridge by which the water might be crossed at all times, without having recourse to the inconvenient and often dangerous alternatives of a ferry-boat or a ford: but the heavy floods and ice during the winter destroyed the erections by carrying away the piers.

Messrs. R. Stevenson and Sons, of Edinburgh, being applied to for a design of a bridge, recommended one on the tension bar principle, from its simplicity of construction and the moderate cost at which it might be executed.

The bridge was commenced at the beginning of last summer, and finished in the course of six months. Its total length is 160 feet, and its breadth 4 feet. The planking is 16 feet above the water, which rises 11 feet on the piers during floods, and although the bridge was originally intended for foot passengers only, horses have been occasionally taken across it. It consists, as will be seen from the sketch fig. 1, of two main openings of 60 feet span, and a smaller one of 24 feet span. The beams are supported upon piers of coursed Graywacke rubble. The two in the centre measure 10 feet × 7 feet at the base, and batter to 6 ft. 6 in. × 4 feet at the top. The one which is most exposed to the water is founded upon rock, at the depth of 4 feet under the bed of the river, and the other is founded upon a platform of timber laid on gravel. A causeway of river stones is laid round the base of the piers to protect their foundations from the run of the water. The beams for supporting the roadway planking were made of four pieces of timber for the convenience of getting them readily conveyed across the hills; they measure 11 inches × 6 inches, and are formed of planks of red pine 11 inches × 3 inches. Two of them are 37 feet long, and two 27 feet, so that when put together the scarphs which are 2 ft. 6 in. long occur at different places and exactly over the uprights. The planks are firmly fixed together by means of oaken treenails 3 feet apart, driven right through and wedged at both ends. The ends of the main beams fit into cast iron shoes, as shown in figs. 5 and 6, and the tension rods which go under the beams, and support them by means of the uprights, pass through auger holes in the centre of the beams, and are secured by means of screw nuts 6 inches long to the back part of the iron shoes, as shown in figs. 5 and 6. The diameter of the tension rods is one inch. The screws are used in order to tighten up the rods, which is done until the beams are quite rigid.

Figs. 5 & 6.—Section and side view of the Ends of the Beams.



The main beams and iron work of the bridge were made by Messrs. J. B. Maxton and Co., of Leith Engine-works, and were proved in the work-yard with a weight of one and a half ton, before being sent to their destination. The remainder of the wood work was executed by Mr. Thomas Swan, of Cranshaw.

The entire cost of the bridge was as follows:

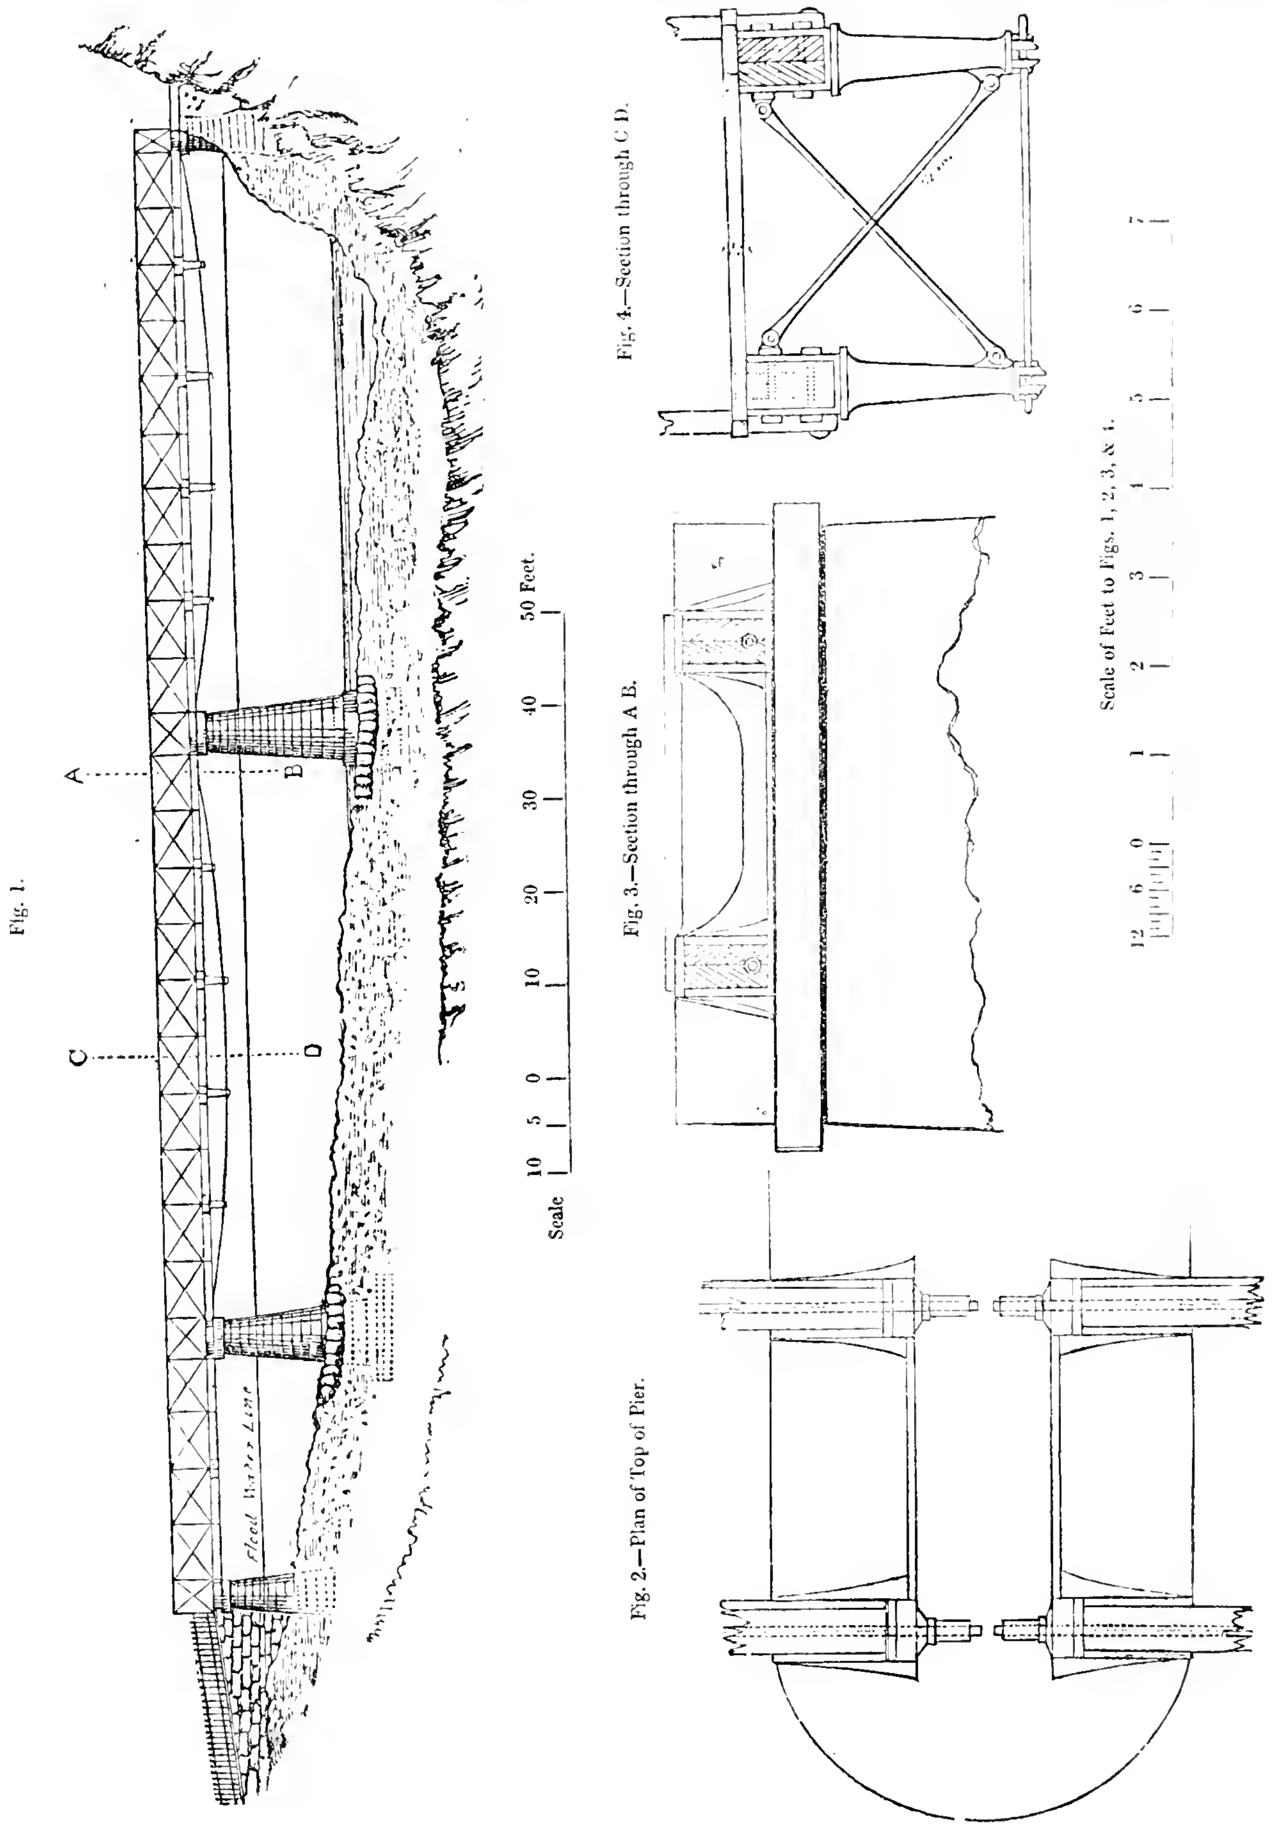
	£	s.	d.
Masonwork - - -	£101	7	5
Main beams and iron work - -	50	0	0
Planking and railing - -	78	6	0
Forming approaches, &c. - -	8	5	0
	£237	18	5

I remain, your obedient servant,

John R. Wilson.

47, *Melville Street, Edinburgh,*
27th August, 1841.

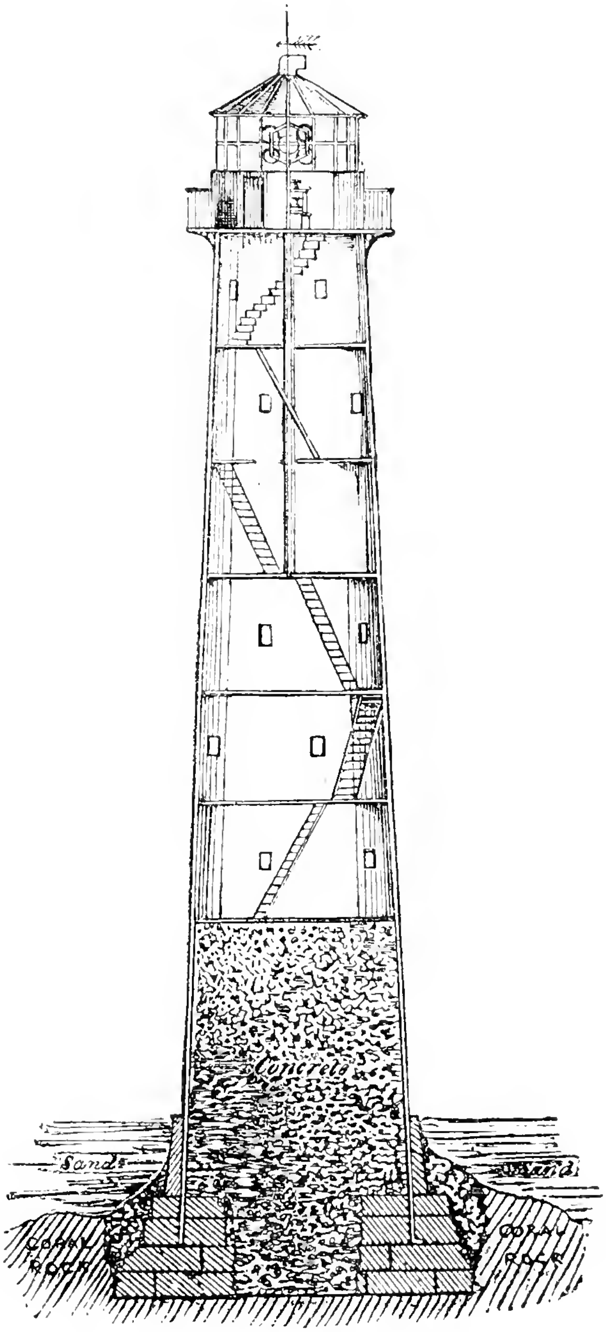
FOOT BRIDGE OVER THE RIVER WHITADDER AT ABBEY ST. BATHANS, BERWICKSHIRE.

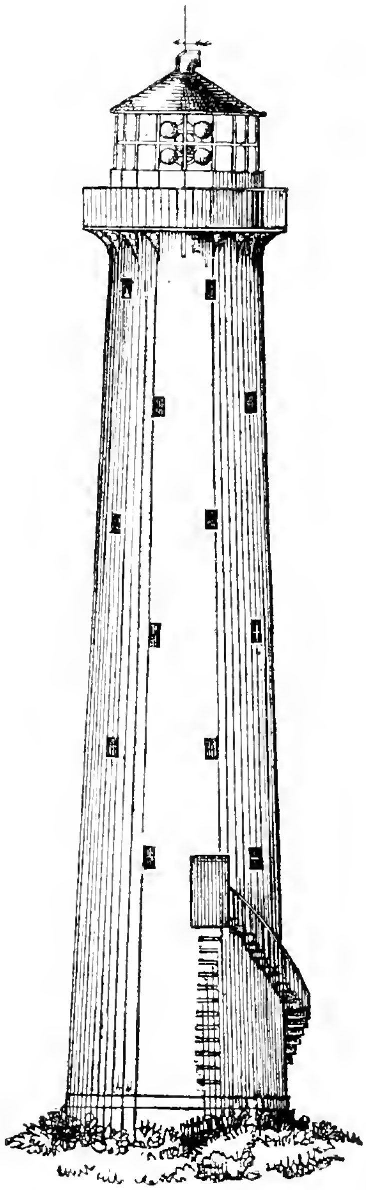


CAST IRON LIGHT-HOUSE,

In progress at Morant Point, Jamaica,

By Alexander Gordon, Engineer to the Commissioners.





In writing a description of a cast iron lighthouse tower just completed for the Island of Jamaica, an opportunity is afforded for a few words on the advantages offered by this peculiar mode of construction. Mariners have frequently been deprived of the security afforded by lighthouses on dangerous coasts, from the great costliness of such structures, as well as from the danger or difficulty attending their erection, in consequence of local peculiarities arising either from tidal restrictions, or from the difficulty of obtaining foundations of sufficient solidity to support the heavy mass of masonry of the tower. It is a fact of common occurrence that years are required to erect a lighthouse of very moderate dimensions where the rate of working is limited, both by the nature of the tides, and by the peculiarity of the season; and the authorities who preside over these matters are frequently deterred from entertaining the application, for such facilities to navigation, from the cost and trouble attending their execution.

The situation for which the lighthouse represented in the accompanying drawings is intended, has long required this protection, but the great expence of stone or brick erection, and the time required to complete them have interfered with their earlier execution to com plete the plan.

Mr. Alexander Gordon, the engineer to the Commissioners appointed to carry the plan into effect, is the designer of this building, and who recommended the adoption of cast iron, in consequence of the suggestions some years ago of Captain Sir Samuel Browne, and the subsequent erection of a small light tower on Gravesend Pier, by Mr. Clarke.

The advantages which iron, when not in contact with sea water, possesses over stone or other materials, is, that upon a given base a much larger internal capacity for dwellings and stories can be obtained with equal stability. The nature of the material admitting of the plates being cast in large surfaces, there are fewer joints, and consequently greater solidity. A system of bonding the plates may also be adopted, which will insure the perfect combination of every part, so as to form one entire mass, and by the facility which such a plan offers for uniting the parts, the best form for strength and stability can be obtained. The time required for the construction of such a building in iron being less than that required for the preparation of one of stone, would in many instances influence its adoption, and from the comparatively small bulk and weight of the component parts of the structure, much greater facilities are afforded for transporting and erecting it at its destination. It is a fact worthy of remark that in less than three months from the date of the contract, the lighthouse in question was cast and erected on the contractor's premises, and it is the intention of Mr. Gordon, the engineer, to have the light exhibited in Jamaica, on January 1st, 1842, being six months from the date of its commencement. This is a degree of expedition commensurate with the extraordinary despatch of the present day, when all operations however great and difficult, seem to advance with a celerity which a few years back would have been deemed chimerical.

The expences of the construction, the transmission to its destination, and its final erection, will not exceed one-third the cost of a stone building of equal dimensions and capabilities, and in localities where the materials are not naturally produced, but have to be transported from a distance in a fit state of immediate erection, the expence would considerably exceed this ratio. Another prominent feature in the construction of iron lighthouses, &c. is the security from electric influence, the material itself being one of the best conductors of the electric fluid, and if proper means be taken to transfer the electric fluid from the base of the tower to the sea by means of copper conductors, no danger need be apprehended from its effects.

The lighthouse in question is the first of its kind that has been practically carried out, and from its having to withstand the destructive hurricanes, which, as well as the frequent earthquakes that occur in the West Indies, it will afford a good example for future practice. The form has been selected as well for strength as for symmetry; and the arrangement of the lantern and light apparatus reflects the greatest credit on the manufacturer, Mr. Deville.

The tower is to be founded on a coral rock, a little above the level of the sea, the face of which rock is about 10 feet beneath the surface of the sand, and which will be excavated to receive the base of the tower, resting on and cased with granite, to prevent the natural filtration of the sea water from acting upon the iron. The course of granite upon which the base of the tower rests, is grooved to receive the flange of the lower plates, from which the lightning conductors are continued to the sea. The diameter of the tower shaft is 18 ft. 6 in. at its base, diminishing to 11 feet under the cap; it is formed of nine tiers of plates, each 10 feet in height, varying from 1 to ¾ inch thickness. The circumference is formed of 11 plates at the base, and nine at the top, they are cast with a flange all round the inner edges, and when put together these flanges form the joints which are fastened together with nut and screw bolts, and caulked with iron cement. The cap consists of 10 radiating plates which form the floor of the light room, and secured to the tower upon 20 pierced brackets, being finished by a light iron railing. The lower portion, namely 27 feet, is filled up with masonry and concrete, weighing about 300 tons, and so connected with the rock itself that it forms a solid core of resistance; the remaining portion of the building is divided into rooms which are to be appropriated as store rooms and berths for the attendants in the lighthouse.

The light room consists of cast iron plates 5 feet high, on which are fixed the metal sash bars for receiving the plate glass, these terminating in a point are covered with a copper roof, from which rises a short lightning rod, treble gilt at the point, to attract the electric current.

The light is of the revolving kind, consisting of 15 Argand lamps and reflectors, 5 in each side of an equilateral triangle, and so placed as to constitute a continuous light, but with periodical flashes.

In order to preserve as low a temperature as the nature of the circumstances and climate will permit, the iron shell is to be lined with a non-conducting material, such as slate or wood, leaving an annular interstice, through which a constant ventilation will be effected, and by which the excessive heat will be carried off, or which it will doubtless be assisted by the evaporation of the sea spray which may accidentally be cast upon it, as it will be placed within 60 yards of the ordinary water level.

In order to preserve the two lower tiers from oxydation, they have been coated with coal tar, and Mr. Gordon intends to set them in the granite with a bituminous cement. The only bracing which has been thought requisite is a few cross ties at each horizontal joint, over which the iron tongued wood floors are laid.

The several rooms are provided with five apertures fitted with oak sashes glazed with plate glass; the approach to the doorway which is about 10 feet above the level of the sand, will be by means of stone steps, ladder irons are also provided in the event of the stone steps being carried away by a hurricane.

Over the entrance is a large tablet of iron, supported by two small ones, and on them, in bas relief, are the following inscriptions:—

"Erected A. D. 1842,
"Under the act 3 Victoria, cap. 66.
"Commissioners.

"Vice-Admiral Sir Charles Adam, K.C.B.	"E. Jordan, Esq.
"Commodore Douglas, R.N.	"P. Lawrence, Esq.
"Hon. S. J. Dallas.	"Hon. T. M'Cormack.
"W. Hyslop, Esq.	"Hon. E. Panton, Speaker.
"J. Taylor, Esq.	"A. Barclay, Esq.
"Hon. H. Mitchell.	"H. Leslie, Esq.
	"G. Wright, Esq.

"On the designs and specification of Alexander Gordon, civil engineer. London."

And on the side supporters:—

"Captain St. John, R.A., Island Engineer."	"C. Robinson, Engineer, London, *fecit*."

The whole of the castings were executed by Mr. Robinson at his manufactory, (late Bramah and Robinson), at Pimlico, and put together in the yard of the manufactory prior to their removal for its intended destination.

The work will be re-erected in Jamaica by means of a derrick and crab from the inside, without the aid of any external scaffolding.

Arch. R. Renton.

September 22, 1841.

[We understand that the whole expence of the lighthouse, including the passage over the Atlantic, and the erecting it on the promontory in Jamaica, will not exceed £7000, and that the entire weight of iron of the whole fabric is about 100 tons. The masonry is being prepared in this country, as it will be more economical to send it from England than it will be to get the stone and work it in Jamaica. Three mechanics are also to be sent out with the work to put it together on its destined spot.—Editor.]

TURKEY.

The spirit of improvement which has been of late years exhibited by the Turkish government has not been confined to political and social reforms, but has also been directed to objects of a practical nature. In aid of these efforts frequent calls have been made on the talents of our engineers, and some very fine machinery indeed has been sent out to Constantinople. Much of this has been on a very large scale, and we may enumerate saw mills, musket machinery, and gun-boring machinery. The machinery supplied by Messrs. Maudslays for boring brass guns, said to be the finest and most extensive of any in the world, has given great satisfaction. The same firm have lately finished an order for mint machinery, also on a large scale, which has excited great commendation from the completeness of its design, and the beauty of its execution. It consists of two 16 horse power high pressure engines, two pair of large rollers, and two pair of smaller rollers, six cutting out presses, two double draw benches, four coining presses with pneumatic apparatus, and a die sinking press, with two double acting milling machines, ingot moulds, &c. To those who admire this class of machinery, as who does not, the examination of this minting apparatus was highly interesting, uniting as it did all the recent improvements which have been adopted in our mint. The Turkish dockyard it must be farther remembered, is directed by an Anglo-American, and is in a very efficient state, and the public at Constantinople have recently been turning their attention towards steam navigation, so that we may look forward for a new market for our machinery in the Turkish empire. To the engineering and mining interests the progress of this increasing branch of our commerce is of great importance.

IMPROVED CONSTRUCTION OF PISTONS AND VALVES, FOR RETAINING OR DISCHARGING LIQUIDS, &c.

Patented by Messrs. G. H. Palmer and Charles Perkins.

Fig. 1.

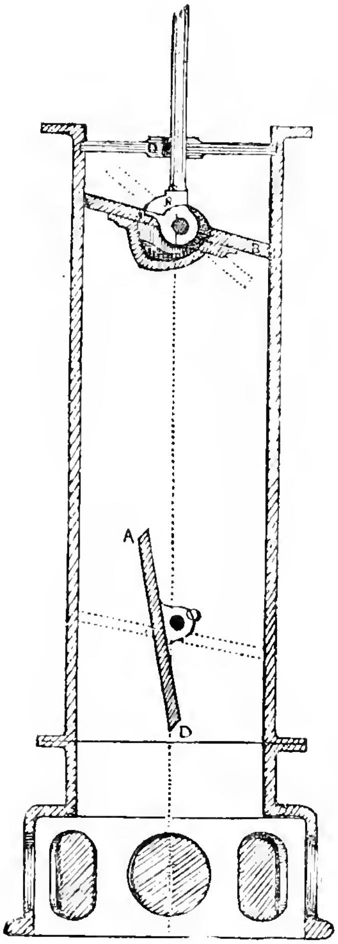


Fig. 2.

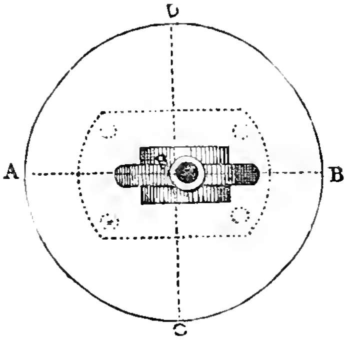

Fig. 3.

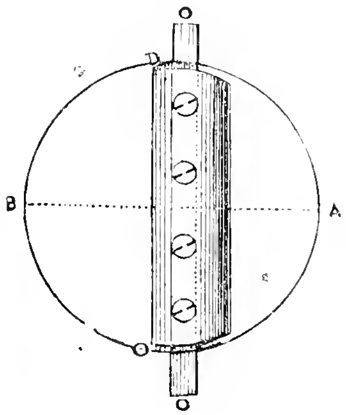

Fig. 5.

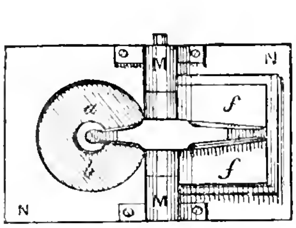

Fig. 4.

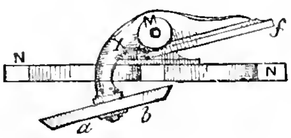

Fig. 1, is a plan of the piston, a section of which is shown by fig. 3. A B the major, C D the minor diameter; the joint (by which the pump rod is secured), is in the centre of the true line of the major diameter A B, but neither in the centre of the pump or piston, being removed therefrom more or less as the diameter of the pump, the altitude of the column of water lifted, and other circumstances may require. The whole area of the piston is therefore divided into two unequal areas.

Fig. 2, is a plan of the lower valve, which is fixed in the barrel by means of the axle O, the eccentricity of which is regulated upon the same principle as that of the joint in the upper valve or piston.

Fig. 3, shows the relative position of the piston and valve during the upward or effective stroke. The dotted lines show the position of the valves in the downward or return stroke.

Figs. 4 and 5, are a plan and section of a patent double balancing valve, an application of the same principle as adapted for safety, or any valves connected with steam engines or air pumps, also to lock gates or sluices, and generally as a simple and effective mode of retaining or discharging liquids, gases and steam. The two valves being of unequal, but the inner of the greater area, and the pressure upon both, being in the same line of direction, it is evident that the power to open or shut them may be determined at pleasure by regulating the difference between the two areas, *a b* is the larger, and *f f* the valve of smaller area, each of which are connected with, and works upon, the axle M M, supported by carriages on the valve bed N N. The valves *a b* and *f f*, receive simultaneous action by means of the curved lever or tail piece X.

The patentees recommend the adoption of the patent elliptic self adjusting balancing pistons in all pumps for whatever purposes intended, as the most simple, durable and effective of any arrangement now before the public. Simple, as is evident from the diagrams and description herewith. Durable, because the process of raising water from any depth is performed by two metallic discs, not liable to derangement, and free from most casualties of climate, circumstance, or wear. Effective, first, because a very superior water way is obtained, (there are no valves to clog or gag, no resting place for any extraneous matter to impede the duty of the pump, whether it be sand or rubbish). Secondly, it will remove the evil arising from concussion in pumps of large diameter; and thirdly, in consequence of the decreased amount of friction, the service of a man in pumping is increased in the ratio of nearly 3 to 1, as the following statement will demonstrate.

The patentees have two 10 inch pumps, the levers 6 to 1, the stroke 8 inches, the column of water 5 feet; both pumps were made by Messrs. Bramah and Robinson, in their best manner; alike in all respects, except that one is fitted with the usual packed bucket and butterfly valves, the other with the patent piston and valve. In an experiment recently made with weights over a pulley, it required the exertion of a force equivalent to 461 lb. to raise and deliver the water, (about 2 gallons), and return the bucket with the packed pump, and only 19.5 lb. to do the same work with the patent pump; making the labour to work the two pumps in the ratio of 461 to 196 = 23 to 10.

Another experiment was made for the patentees by Mr. Beale, of Greenwich, showing similar advantages in the diminution of friction, and consequently an increase power. The following is the result of this experiment.

A vessel of a capacity equal to 314·16 gallons = 3141 lb. was filled by pumping 140 strokes in $1\frac{1}{2}$ minutes, which was at the rate of 31 strokes per minute, and 2·244 gallons per stroke. The working barrel of the pump was intended to be 10″, but was said to have been turned to $10\frac{1}{4}$ inches nearly.

If the diameter was 10, then the delivery by computation in 140 strokes of 8″ = - - - - -	318 gallons.
If the diameter was $10\frac{1}{4}$, then the delivery = -	330
The actual delivery was by computation of the receiving vessel = - - - - - - -	314

The average lift during this time was about six feet.

In a second experiment the water in the well was kept at an average height which, with pipes added to the exit pipe, made the total lift 15 feet 4 inches.

Under these circumstances weights were applied to the end of the lever, and it took 98 lb. × 6 the leverage to raise the column of water.

Now 98 × 6 = - - - - - - - -	588 lb.
The actual weight of a column of water $10\frac{1}{4}$″ diameter and 15 feet 4 inches in height, is - - - - -	550 lb.
Leaving for friction in the up stroke only - - -	38 lb.

As there was no friction in the down stroke or return of the piston, it results that 38 lb. was the total amount of friction out of 588 lb. (exerted), being only 6·46 per cent. or $\frac{1}{16}$ part.

The velocity of the water may be taken at 20 feet per minute.

In a third experiment, to produce a *maximum* effect, two men made 41 strokes in one minute, lifting the water 15 feet 4 inches, and delivering as per first experiment 2·244 gallons, or 22·44 lb. per stroke = to 14107·28 lb. raised one foot high in one minute by two men, or 7053·64 lb. raised one foot high in one minute by *one* man.

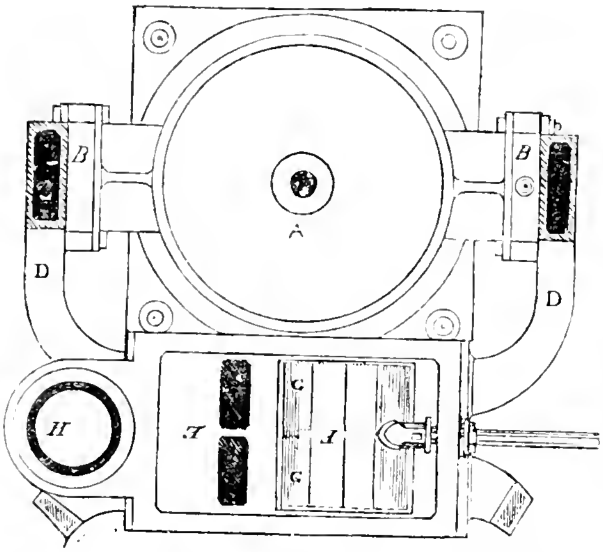
Artificial Ice.—The projectors of the artificial ice plan have found a site in the New Road, opposite Lord's cricket ground. We have seen the composition, which seems to succeed, and the plan is approved by the Skating Club.

ON REVERSING OF ENGINES.

Sir—When we look to the methods of reversing the motion of reciprocating steam engines which have hitherto been generally adopted, it becomes a matter of surprise that, whilst in almost all patents for rotary engines, where it has been considered the motion would want reversing, it has been done on the principle of changing the steam induction and eduction passages, (*i. e.* what is the induction for one way is made the eduction the other, and *vice versâ*), the same principle has not been adopted for them. The most general and simple way of changing the passages in rotary engines has been by means of the common slide valve, and my object in now addressing you is to propose the adoption of the same slide valve to the reciprocating engine.

The accompanying figures represent it as applied to a pair of marine engines, for which it seems particularly suited. Let A in the figures represent the cylinder; B B B B, valve boxes fitted with stop valves *v v v v*, almost similar to those of Messrs. Seaward's patent, except that both the valves and boxes are faced on both sides; C 1, C 2, communication pipes to each pair of boxes; D D, branch pipes from C 2, C 1, to the apertures in the slide valve box E; being alternately steam and exhaust as their respective apertures may be covered by the slide valve F; G is the exhaust or eduction to the condenser; H the induction or steam-pipe from the boiler. The valves strike simultaneously (as Seaward's), and are like them worked by one fast eccentric.

Fig. 1.—Plan of Cylinder.



It will be seen as the valves stand in the figures that the steam passing down H into the valve box E, and down the uncovered apertures to communicating pipe C 1, finds the upper aperture stopped up, it consequently makes its way through the lower one and forces up the piston, at the same time the upper valve on the other side of the cylinder is open, and a vacuum being formed in the condenser, it exhausts G, under F, the branch to and the communicating pipe C 2, and the portion of the cylinder above the piston.

If we wish now to reverse the motion, we have only to push the valve F to the other end of the box, as represented by dotted lines in fig. 3, the branch pipe, and C 1 is open to the condenser, and the steam passes down the branch into C 2, and presses down the piston.

The mode of operation will I think be now understood. Fig. 4 is a view of the valve F, as proposed for a pair of engines, showing the midfeather to separate the exhausts or eductions to the respective condensers. The branch pipes to the other cylinder are shown broken off. There is another use of the valve F, it is a perfect regulator or throttle valve, to stop or regulate the engine by; for it is so constructed that supposing the steam to be shut off by it when running either way, still the exhaust apertures remain entirely open. The simplicity of its action, and its doing away with a considerable number of small moving parts consequent on reversing and management in general, by the present methods are its recommendations, not to mention that one man could manage a pair of the largest engines which have yet navigated the ocean, better than 4 or 6, or even 10 men, to some of our

Fig. 2.—Section of Cylinder.

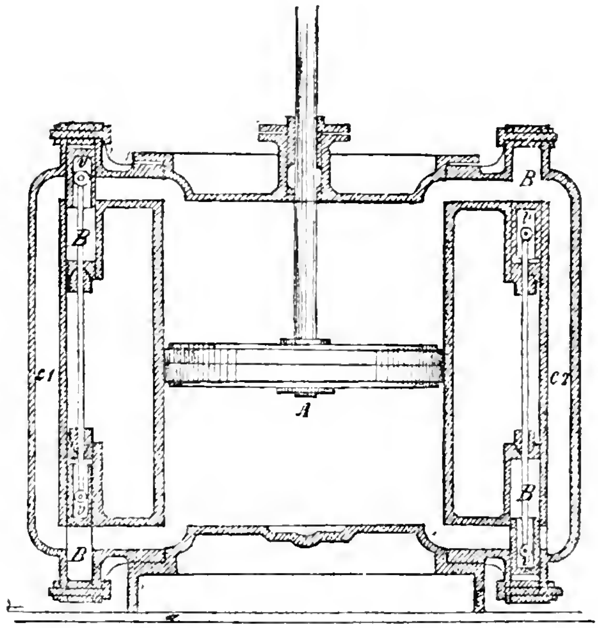


Fig. 3.—Elevation of Cylinder and Section of Valves.

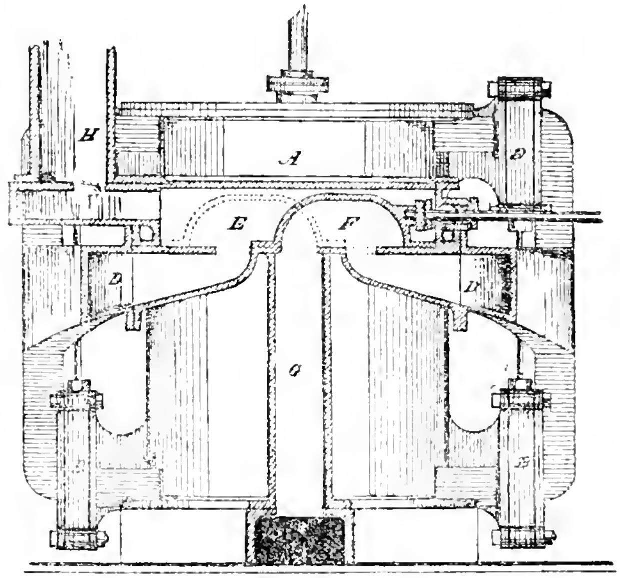

Fig. 4.

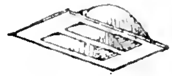

present large marine engines. I have a sketch by me, only in pencil as yet, for working locomotives by the same principle, but being so confined as to space, little difficulties present themselves in the arrangement, which a more practical man might soon set aside.

Your's,

G. Coe, Civil Engineer.

CANDIDUS'S NOTE-BOOK.

FASCICULUS XXXI.

"I must have liberty
Withal, as large a charter as the winds,
To blow on whom I please."

I. Those who rail against competition, not because competitions are for the most part vilely conducted—most bunglingly also, supposing there to be honesty of intention, or else most fraudulently, as there is frequently good reason to suspect, perhaps all but positive evidence to prove—the declaimers against competition, carefully keep out of sight the mischiefs that have been produced by non-competition. It is impossible to believe that Buckingham Palace would have been the miserable architectural abortion it now is, an object of shame to Englishmen, and of contempt to foreigners, had others been allowed to measure their talents with those of John Nash. In such case an open competition might not have been at all advisable, but a middle course might have been pursued, and a certain number of those of most likelihood in the profession should have been invited to send in designs, and every set of drawings should have been paid for except those by the successful architect, who would be amply remunerated otherwise. A thousand pounds a-piece would not, perhaps, have been at all too much: while it would have been sufficient to induce those selected as competitors to exert themselves heartily, it would not have been an extravagant reward, considering the study such a subject would have required, the expenses the competitors must have incurred, and the other engagements they must have neglected or postponed. Supposing the number of competitors had been ten—it might have been fewer, the £9,000 would not have been recklessly squandered. Even supposing the result had been precisely the same as at present, we should at least have had the satisfaction of knowing that the bauble we have now got was the very best thing of its kind that was to be had. As it is, there was the saving of a few thousands in the first instance, and we have got John Nash's chef-d'œuvre—no very great bargain after all, any way, when we take into account the tens of thousands expended in pulling down and re-building, while it was in progress, and afterwards in botching it up and licking it into shape.

II. The anti-competitionists would do well to consider what sort of design we should have had for the new Houses of Parliament, had there been no competition, but a Nash, a Soane, or a Smirke, been called in, and left to do his best or his worst, and to go on as he pleased without further inquiry. Without much fear of contradiction, it may be affirmed that had there been a competition for the National Gallery, we should have had something better rather than worse than the present structure; and the same may be said in regard to a great many other buildings. Of course it must be assumed that the competition is fairly managed, and that there be not only perfect fairness, but the requisite taste and judgment also. It is no satisfaction to be assured that the decision has been made to the best of their ability by those with whom it rested, if the choice itself convicts them of utter inability and incapacity for such office. If associated with bad taste, honesty may do more harm than good in such matters; yet as far as honesty is concerned, there is very little danger of any mischievous consequences from excess of it, at least not just now, for, if reports may be credited, some very ugly instances of thorough-paced roguery and rascality in the management of competitions, have recently taken place.

III. If no other, there is at least one remarkable peculiarity attending architectural criticism, viz. that so far from endeavouring to be *au courant du jour*, it generally lags most wofully behind-hand, as if it were almost a positive breach of decorum, to discuss the merits of productions belonging to our own times. Why it should be considered requisite to exercise such forbearance towards living architects and their works, more especially, the very reverse of it being frequently manifested in the case of literary men, actors, artists, &c., it is difficult to understand. Neither is such over-delicacy particularly complimentary, since it almost amounts to a confession that it is impossible to speak honestly of the living without also speaking harshly, therefore the critic who would neither give offence nor compromise his own judgment, has no other alternative than silence. On the other hand, however, Brummagem criticism and puffery are allowed to circulate freely enough; for though delicacy may withhold some from giving their opinion unreservedly in the case of architects either living or recently deceased, many there are who do not scruple to cry up almost every thing as a wonder of its kind. With them every goose is a swan, or rather a phœnix. Whatever they are speaking of is, for the time being, superlative of its kind. Their chief merit is their impartiality, since they treat all alike, making no distinction between a Charles Barry and a Richard Brown. Yes, incredible as it may seem, even Professor Brown has his admirers; not long ago a flaring-up puff appeared in a weekly paper on the Professor's "Domestic Architecture," bearing testimony to the value of the work, and the varied talent displayed in the designs, "which would afford to the student examples in every style of building"! Thus a publication which is absolutely pestiferous in taste, and as far as it circulates, is calculated to spread the most vulgar taste throughout the land, not only escapes reprobation, but is actually recommended as an authority and a trustworthy guide. Pity it is that Pugin did not show up some specimens of his brother Professor's designs along with "castellated" firegrates, and similar monstrosities. Should Welby not be yet aware of the existence of Brown's publication, we earnestly recommend it to *him*, for he will find in it some exceedingly piquant tid-bits, *inter alia*, a sample of Egyptian that might very well pass for one of the plagues of Egypt.

IV. Want of keeping is so exceedingly prevalent a fault in architectural design, that it would seem to be the most excusable of any, as being of all others, the one most difficult to be avoided, whereas I should decide precisely the reverse, it being, in my own opinion, one of the most offensive and the least venial, because that which argues the absence of artistical feeling. In every composition there ought to be some leading features, and some parts of a building will very properly bear to be more ornamented than the rest; yet this should be so managed that the *ensemble* shall appear consistent, and the whole design all of a piece as to taste. Look at the Post Office—there are Ionic columns, but the structure itself is absolutely dowdy in its style. Look at the Post Office, Dublin—there we have another large Grecian Ionic portico attached to a very plain and ordinary house-front. Look at Goldsmith's Hall—the lower half of the design is altogether different and distinct in character from the upper one. Look again at Lord Sefton's new mansion in Belgrave Square—within a carriage porch of the very plainest Italian Doric possible, is a doorway of unusually rich design, which, in such situation, looks as much overdressed in itself, as it causes the columns and their entablature to look plain, even to the appearance of being unfinished. In a new house near Park Lane, I observe there is some approach to the Italian style, the elevation being crowned by a cornice somewhat bolder and richer than usual; but the windows!—they are in the modern Pseudo-Grecian fashion, with no other dressings than architraves, and those of the very plainest description. In all such cases it looks as if the architect had been obliged to pare down his design in order to save expense, and that, instead of simplifying it consistently throughout, he had merely omitted in execution that decoration which was in the first instance proposed as essential to unity of expression.

V. Another great and pervading vice in modern design is that so little regard is had to the sound and legitimate principle of commencing decoration by first applying it to essential features—those arising out of construction, or required by utility and convenience, instead of introducing what is merely for embellishment, while other things that cannot possibly be omitted or got rid of, are left not only plain, but quite rude in appearance, so as to become, by contrast, positive eyesores. That such errors in taste—such violation of all artistic principles of composition, should ever be committed, is grievous enough, but that it should be committed so very frequently, and by those who are so fastidious and puritanically pedantic in regard to matters of infinitely less importance, is most grievous and most provoking. Utility and beauty ought to go hand in hand, but should be made to do so after a very different fashion from what is now generally the case, when one half of a design aims at nothing more than unadorned usefulness, and the other at ostentatious show. Their usefulness does not reconcile us to ugly chimneys and chimney-pots confusedly huddled together on the roof of a building—to bare openings for windows, or else having only some scanty common-place mouldings bestowed on them,—to insignificance and vulgarity as regards matters of that kind, while unnecessary and inconsistent, therefore absurd parade is indulged in as regards others. One ill consequence of such unfortunate system is that people are satisfied with mere shreds and patches of design, and think it quite enough if they are able to say such or such a part is very good, though the general effect may nevertheless be poor in the extreme, and the whole no better than a jumble of the most incoherent and contradictory members.

Progress of Steam.—We learn that in a short time the merchants of St Petersburgh will have a direct line of steam communication, *via* the North of Germany, Yarmouth, and this city, with New York.—*Bristol Standard.*

ARCHITECTURE AS A FINE ART: ITS STATE AND PROSPECTS IN ENGLAND.

By George Godwin, Jun., F.R.S.

"That art where most magnificent appears
The little builder, man."

"I shall not neede (like the most part of writers) to celebrate the subject which I deliver. In that point I am at ease. For architecture can want no commendation, where there are noble men and noble mindes." So wrote Sir Henry Wotton more than two hundred years ago, with reference merely to the Roman style, when classic architecture was but beginning to revive:—before Inigo Jones and Sir Christopher Wren had nationalized it amongst us, or Lord Burlington's example and endeavours, had made a smattering of its principles almost a necessity of fashion. Since then, the treasures of Greece have been ransacked and sent home to us to correct our taste and aid the study; the claims of middle-age architecture to be regarded as the work of supreme genius have been admitted universally, (its intrinsic beauty, the extraordinary skill displayed in its development, its power of inducing

"A stir of mind too natural to deceive;
Giving the memory help when she would weave
A crown for Hope!"

have all been felt,) and delineations of its choicest specimens in a thousand and one books have been dispersed amongst us to render its details more known, and its imitation less difficult.

The history of architecture has been written,—the beautiful relationship of the various styles has been shown, (each growing out of and in its turn producing,—) forming a narrative most interesting and striking to all who look not carelessly on the progress of the human family, and sufficient it might be thought, to arrest and retain the attention of all readers. The history of our ancient buildings is more fully felt to be inseparably connected with the history of our country,—every old stone in England is known to tell a story, and therefore should have now a firmer hold upon the people than then, and yet we doubt whether any might venture to repeat at this time Sir Henry Wotton's remark which we have quoted. Certain it is that many "noble men" care nothing about architecture, and that many more "noble mindes" seem to require it should have very much "commendation" before they will be induced to give attention to it.

The degree of ignorance on the subject of architecture to be found amongst persons in other respects not merely well informed, but even learned, is quite extraordinary. Grecian, Roman, Gothic, Elizabethan, as applied to architectural style, are to them but words without any corresponding ideas; they have never considered that architecture has a chronology, still less, a philosophy,—architectural integrity, harmony, proportion, fitness, are to them foreign things,—in fact, beyond a notion that architecture means piling one stone upon another, and forming places to live or meet in, they know nothing and care less.

Great part of this inattention on the part of the multitude to the interesting and noble study under notice, (and of which the results whether for good or ill, usually endure long, and are constantly before the eyes of all,) has been justly ascribed to the connection which exists in the public mind between architecture as a constructive *science*, and architecture as a *fine-art*, and every endeavour ought therefore to be made to enforce a knowledge of this difference on general readers, and to point out to them how large a source of fresh delight would be opened to them by its study in the latter point of view. The pleasure of travel is trebled by it. Proofs in aid of former studies, objects for investigation, incentives to inquiry, arise on all sides; tongues are literally, found in stones, and a habit is acquired of weighing causes, and testing by judgment whatever is brought before the mind, which is of the greatest value, not merely in this particular case but in all the affairs of life.

For the sake of example, but briefly, let a man possessed of its history, and imbued in some degree with its principles, visit, in company with one entirely ignorant of both, an old town, or be set down before a new building. In the first, he might perhaps find a massive piece of walling, formed of beach-stones imbedded solidly with mortar, and bound together at certain distances in its height, by layers of long thin bricks almost resembling tiles. This he would at once recognise as a remnant of the work of that period when the Romans brought, though as conquerors, the arts to England, and laid the foundation for after-elevation and prosperity. Britain and its skin-clad inhabitants, the invasion of Cæsar, the downfall of Rome, the invitation to the Saxons would be the concomitant remembrances.

One of the gateways leading into the cathedral-close—which we will suppose the town to possess, might present semi-circular arches springing from small columns, and ornamented on the face with a rude zig-zag moulding, or a series of bird's beaks, which he would know to be the design of some of those Norman architects who, after the conquest of England by Duke William, employed themselves actively for some time, in covering the land with donjons and churches. The abasement of the Saxons, the curfew, forest laws, the feudal system generally, would pass involuntarily through his mind, and afford matter for long and pleasant reflection.

The cathedral itself would perhaps display in part, the feathery lightness of the pointed style of architecture with lofty arches, pinnacles and buttresses, intermixed with work of later date, shewing arches almost flat, superfluity of adornment, and the decay of taste: all which would be sufficient not merely to recall to the initiated beholder the changes which took place in architecture during two or three hundred years, and ended in the importation of a style from Italy, in the reign of Charles I, or a little earlier, and a contemptuous disregard of the beautiful structures before spoken of, and then first termed *Gothic*, in derision,—but would bring before him the progress of Christianity, the power attained by the clergy, and the state of the country and the people, in a variety of fresh phases.

At the new structure again, he would perhaps see the clever adaptation of means to an end, and proportions well preserved; read in its architectural expression an accordance or otherwise, as the case might be, with its purpose; and study the causes which conduced to render the effect of the whole on the mind satisfactory and pleasing. Thus would the imagination of the one be gratified, his judgment strengthened, his sagacity increased, while the second, who had given no thought to the subject, and had gained no information upon it, would necessarily be blind to it all, or seeing, would understand not.

The analysis of the causes of beauty in works of architecture, is certainly far from an easy task: it yet remains for some powerful mind keenly perceptive and nicely discriminating to deduce a code of laws or principles to be universally applicable in this inquiry. Whether however, this is likely soon to be effected, or that these subtle properties will continue to evade reduction to general rules, it is difficult to say. At present we must be contented to apply in individual cases, a number of unconnected canons, and to investigate the particular results of certain arrangements of form, compliance with prejudices, or the production of novelty.

"The art which we profess," says Sir Joshua Reynolds, speaking of painting, "has beauty for its object: this it is our business to discover and to express; the beauty of which we are in quest is general and intellectual; it is an idea that subsists only in the mind; the sight never beheld it, nor has the hand expressed it: it is an idea residing in the breast of the artist, which he is always labouring to impart, and which he dies at last without imparting—but which he is yet so far able to communicate, as to raise the thoughts and extend the views of the spectator; and which by a succession of art, may be so far diffused that its effects may extend themselves imperceptibly into public benefits, and be among the means of bestowing on whole nations refinement of taste." Now in architecture, which is not an imitative art, but one of imagination and adaptation, if we may so speak, (born of necessity,) there are two other objects to be attained, namely, commodiousness, (or fitness for the purpose,) and stability: in reference to both of which, although perhaps it is not for these it is entitled to the appellation of a fine art, the claims of a building to perfect admiration must be tried. It seems clear that these qualities may exist without the production of beauty, even with *proportion* of the parts superadded,—(a word by the way the meaning of which is any thing but precise, as what is deemed proportion under some circumstances, or in one place, is not so in others:) but the production of beauty which will satisfy the mind can hardly be hoped for without minute attention to all these points. Variety and intricacy, with yet a prevailing uniformity, may be regarded as important in the production of pleasure in the spectator:—in so far as while the mind is able at once to comprehend and dwell upon the unity of the whole, it may be interested in the novelty or propriety of each detail, and find delight in this indication of the energy, ingenuity, and power displayed in its formation. We must not however here venture on an inquiry, which interesting as it may be, is beyond the intention of the present paper.

To return, then, to our former subject. The neglect which architecture has experienced at our universities (as, indeed, have all the arts), is another plainly apparent cause of the ignorance complained of, and it is gratifying to see indications, although but partial, of the presence of a different spirit amongst the members of the universities, if not in the universities themselves. Oxford and Cambridge both have now societies for the study of Gothic architecture, and for the purpose of aiding in the proper restoration of old buildings. Many papers of great merit have been read at both, and museums of casts have been commenced, classified in such a manner as to aid materially in impressing on those who will study them, the peculiarities and characteristics of the various æras in architectural history. In Bristol a similar society has been formed recently, and it is to be hoped that the example will be extensively followed throughout England.

Among the important advantages, not before alluded to, as certain to arise from the spread of architectural knowledge, would be an almost immediate improvement in the professors of the art themselves. Improve the capacity of the judges, raise the ordinary standard of taste, create a demand for superior skill, and the result inevitably must be that individuals will be found capable of supplying it, and that fine works will be produced.

The association of architects not merely for the study of their profession and the interchange of opinions and kindly feelings, but with a view to popularize their art, and by spreading abroad their Transactions, and inviting strangers to their meetings and *conversazioni* to render it matter of general interest, must be regarded as likely to assist greatly in removing the ignorance complained of. The Royal Institute of British Architects, a chartered body, including in its list of members the greater number of the heads of the profession, in correspondence with most of the continental states, and presided over by one of the most accomplished noblemen of the day, may be considered as the chief of these associations, and has it in its power to influence the age very materially—more so indeed than it has yet attempted to do. The publication of a volume of its transactions, at least annually, should be regarded by the members as most important, while, to make these transactions valuable and effective, should be the constant study of all who are connected with the Institute, or wish well to their art.* The London Architectural Society, the Institute of Irish Architects, and the Manchester Architectural Society, are all influential bodies of a like character, and are called on to exert efficiently the power which is in their hands.

At the Royal Academy, where of late years an inexcusable degree of inattention to architecture has been manifested, affairs are wearing a more promising aspect. The present accomplished professor, Mr. Cockerell, has entered on his duties with singular and praiseworthy zeal, and eminent as he is for a love of his art and desire to spread a knowledge of it, will not fail to pursue them energetically in a right course. The establishment of schools of design throughout the country (in the arrangement of which Mr. Cockerell has taken active part, as also did Mr. J. B. Papworth,) will be of great service to architecture, by increasing the number of those able to carry out effectively the designs of architects, while, by imbuing artizans with an artistical feeling, they will serve materially to raise their callings in the scale of society. How greatly the architects of the middle ages were indebted to the ability and feeling of their operatives is too well known to need notice here.

The want of information, and the low state of architectural taste, which have been complained of as still existing, have been strikingly exemplified in the results of many competitions for designs which have been brought before the public within the last ten years. The insufficient particulars and instructions given to architects, the want of courtesy displayed towards them, and the ultimate unjust decisions, have proceeded in as many cases from entire ignorance, with a wish to act rightly, as they have from underhand influences and bad motives. And until we can in some degree remove these first-mentioned evils, we can hardly hope, however much we may strive, to prevent this injurious result, injurious not less to the public than to the artists and art itself. That artistical competitions, by affording opportunities for the encouragement of unaided merit, by preventing professors of established practice from falling into a routine habit of composition, and by inducing young men to study subjects which otherwise might not come under their notice—are advantageous, is the opinion of the great majority of those who have thought upon the matter. We would go so far as to say that for *all* works entitled by their destination or importance to be called national, the nation should unquestionably be appealed to, and opportunity thus given for unknown talent to come forward.

Brunelleschi, Michael Angelo, Palladio, Fontana, Scamozzi, are all to be found in the list of those who competed for the honour of conducting important works in Italy. In England, however, until the decision in these matters can be more depended on than now, (when, in fact, the administration of every succeeding competition is worse than that which preceded it,) men of integrity and ability who have reputation to lose, will not enter the lists except in special cases, and the result must be that the field will be left chiefly to unemployed tyros or manœuvring traders.

If we be correct in our opinion, that until information be spread and the taste of the multitude be improved, we cannot expect to effect much alteration, it is to this end surely we should apply all our efforts, vigorously and unceasingly. Why should not architecture and the other fine arts be taught universally in our schools, and be made a necessary part of a liberal education? At all events, professorships should unquestionably be instituted at the universities, to spread a knowledge of the beautiful, and inculcate a love for it. Every day is science exerting its powerful influence to liberate men from the necessity of manual labour. Every day, therefore, does it become more and more necessary that unemployed minds should be put in the right track, that intellectual and moral wants should be created, and that all means be taken to elevate the taste of the multitude, and supply their cravings for excitement with proper *pabulum*.

To improve a love of the fine arts amongst a people, not irrespective of RELIGION, but in connexion with it, must be regarded by all wise and enlightened statesmen as an object of paramount importance, to be attained almost at any price.

* If a monthly *bulletin* were issued in a cheap form, containing an abstract of each night's proceedings, it would be of much service. Unconnected items of information elicited in conversation, and papers not sufficiently important to appear in the "Transactions," might therein be recorded. Information would thus be spread, and there would be an additional motive for members to communicate matters which, though trifling in themselves, might be important in the aggregate. Besides, the more the fine arts are talked about and written about—the oftener they are brought under public notice, the more likely it is they will receive general attention. The public require a thing to be said a great number of times, and in a great many ways, before they will hear it.

ENGINEERING WORKS OF THE ANCIENTS, No. 9.

In our present paper we conclude our extracts from Strabo.

THE GREEKS.

The silver mines of Attica (Book 9, chap. 1), were formerly very productive, they are now exhausted. When they still produced a slight return for the labour of the miners, they melted up the old rubbish and scoriæ, and a considerable quantity of very pure silver was obtained from them, seeing that the ancients were not very skilful in the art of extracting metal. A commentator remarks on this passage that it is a proof of the progress of mining in this age, but that even then the Romans had been by no means gone to the extent of modern art, as sufficient is still sometimes found in Romish scoriæ to pay for the expense of extraction. He farther observes that the mines of Laurium showed signs of exhaustion in the time of Socrates (Xenophon Memorabilia, book 3, chap. 6, § 12.)

In the next page Strabo notices a bridge over the Cephissus.

In book 9, chap. 2, our author gives a description of the works on the Euripus, but one which is very inaccurate.

Speaking of the plains of Beotia opposite to Eubea (book 9, chap. 2), an account is given of the works undertaken to drain them by a contractor for works of the name of Crates of Chalcis. He was obstructed by the factions among the Beotians, but in a report, addressed by him to Alexander, he relates that he had already drained several large tracts. This contractor is also mentioned by Diogenes Laertius, book 4, § 23, as being employed by Alexander.

In book 10, chap. 1, is an obscure passage relative to the mines of Chalcis.

In the same, chap. 3, Strabo refers to the labours of Hercules on the Achelous.

The Rhodians as well as the Cyzicans and Marseillese were famous as military engineers (book 14, chap. 2.)

CILICIA.

Book 12, chap. 1, contains an account of the mode in which King Ariarathes the 10th stopped up the Melas, a feeder of the Euphrates, and how the dike having burst and caused injury to the neighbouring lands, the king was fined 300 talents by the Romans.

PONTUS.

Chapter 2nd of the same book describes the mode of working the mines of Sandaracurgium.

EPHESUS.

The entrance of the port of Ephesus is too narrow, the fault of the architects and engineers, who were led into error by the king, who employed them on this work. This prince, who was Attalus 2nd, Philadelphus, King of Pergamus, seeing that the port was being silted up with banks from the deposits of the Cayster, and thinking that it could be made deep enough to receive large vessels, if a mole were thrown before the entrance which was too broad, ordered the construction of the mole. The contrary however happened, for the mud filled the port with shoals as far as the entrance, whereas before the deposit was sufficiently carried out by inundations, and by the reciprocal movement of the waters of the outer sea. Such are the defects of the port of Ephesus (book 14, chap. 1).

PERSIA, &c.

Alexander in his expedition to Gedrosia was preceded by miners to search for water (book 15, chap. 1).

In book 15, chap. 3, a bridge is mentioned as being thrown over the Choaspes at Susa.

In the next page sluices are mentioned on the Tigris.

In book 16, chap. 1, an enumeration is made of the works of Semiramis.

Alexander destroyed a number of sluices on the river Tigris. He also occupied himself with the canals, which are of the greatest importance to the agriculture of that country (B. 16, ch. 1), a theme upon which our author dwells at some length. He relates, on the authority of Aristobulus (see also Arrian, B. 7, § 22), that Alexander, seated in a boat steered by himself, attentively surveyed the canals, and caused them to be cleaned by employing a great multitude of men, whom he took with him, He also had certain outlets closed and new ones opened. He remarked a canal, principally leading to the lakes and marshes on the Arabian side, and the outlet of which, on account of the softness of the ground, could not easily be closed; he therefore opened a new canal or mouth about 30 stades off, in a rocky ground, through which he turned the waters.

EGYPT.

In his 17th Book, Strabo describes Egypt. He mentions the skill the Egyptians showed in hydraulic works, but the fact upon which he dwells is partly perhaps attributable to Roman science. He says that before the time of C. Petronius (ch. 1) Governor, A. D. 20, that the greatest inundation and most abundant harvest took place when the Nile reached fourteen cubits, but that under the administration of that governor an inundation of twelve cubits produced abundance.

In that book and chapter there is frequent mention of canals, and there is a description of the canal of the Red Sea. (See also Diodorus Siculus, B. 1, § 19 and 33.

Here also Strabo describes the Egyptian mortar as being made of pounded basalt, brought from the mountains of Ethiopia.

PAUSANIAS—ÆLIAN AND APPIAN.

In Pausanias the only notices in any way relating to our subject are an allusion to the silver mines of Laurium in the commencement of the Attics, and in the Laconics a statement that Eurotas diverted the river. In Ælian and Appian there is nothing except perhaps that the latter, in the account of the siege of Carthage, mentions a cut made through the harbour by the Carthaginians.

ARRIAN.

Arrian in his Life of Alexander, 7th book, chap. 21st, gives a better account than Strabo of Alexander's repair of the canal called Pallacopas, although this latter account differs, we shall content ourselves with a reference to it. We may observe that Gronovius has annexed to his edition of Arrian a small treatise on this canal, which embodies all the account and modern information respecting it.

In his second book Arrian devotes much space to the siege of Tyre, from which we shall extract some of his remarks on the mole. He says that the sea there has a clay bottom, and shallow towards the shore: but when you draw near the city, it is almost three fathoms deep. As there was abundance of stone not far off, and a sufficient quantity of timber and rubbish to fill up the vacant spaces, they found no great difficulty in laying the foundations of their own rampart; the stiff clay at the bottom, by its own nature, serving instead of mortar, to bind the stones together. The Macedonians showed a wonderful forwardness and alacrity to the work, and Alexander's presence contributed not a little thereto; for he designed every thing himself, and saw every thing done. In describing the subsequent operations Arrian says that many engineers, meaning military engineers, were brought from Cyprus and Phenicia.

In the fifth book a long account is given of the mode adopted by the Romans, and particularly by the old Romans, in forming temporary bridges for crossing large rivers.

The British Queen Steam-ship.—This splendid steamer sailed yesterday for Antwerp. A select party of gentlemen went in her on a visit to Belgium. The British and American Steam Company have, it is said, received for her the sum of £60,000 from the Belgian government. For the President the same company received above £70,000 from the underwriters. The losses sustained by the company since its establishment are supposed not to be less than £80,000 nor more than £100.000.—*Liverpool Albion, Sep. 6.*

ON THE MANUFACTURE OF BRICKS AND TILES.

[We are indebted for the following article to a very useful work by Mr. Aikin, just published; we have appended some additional notes, which we think will be found useful, and make the article more complete.—EDITOR.]

Till lately, bricks appear to have been made in this country in a very rude manner. The clay was dug in the autumn, and exposed to the winter frosts to mellow; it was then mixed, or not, with coal ashes, and tempered by being trodden by horses or men, and was afterwards moulded, without it being considered necessary to take out the stones. The bricks were burnt in kilns or in clamps; the former was the original mode, the latter having been resorted to from motives of economy. When clamps began to be employed I do not know: but they are mentioned in an act of parliament passed in 1726, and therefore were in use prior to that date. The following, in few words, is the present process of brick-making in the vicinity of London, for the practical particulars of which I am indebted to Mr. Deville and Mr. Gibbs.

It is chiefly, I believe entirely, from the alluvial deposits above the London clay, that bricks are made in the vicinity of the metropolis; and a section of these deposits generally presents the following series, such as would naturally result from a mixture of stones, and sand, and clay, and chalk, brought together by the force of water, and then allowed to subside. The lower part of the bed is gravel, mixed more or less with coarse sandy clay and pieces of chalk: this by degrees passes into what is technically called malm, which is a mixture of sand, comminuted chalk, and clay; and this graduates into the upper earth or strong clay, in which the clay is the prevailing or characterizing ingredient, the proportion of chalk being so small that the earth makes no sensible effervescence with acids. Bricks made of the upper earth, without any addition, are apt to crack in drying, and in burning they are very liable to warp, as well as to contract considerably in all their dimensions: on this account they cannot be used for the exterior of walls; and a greater number of such are required for any given quantity of work than of bricks, which, though made in the same mould, shrink less in the baking. The texture, however, of such bricks is compact, which makes them strong and durable. Bricks formed of this clay, whether mixed or unmixed, are called stocks; it was formerly used unwashed, and when the bricks were intended to be kiln-burnt, or *flame-burnt*, to use the technical word, no addition was made to the clay. If they were intended to be clamp-burnt, coal-ash was mixed during the tempering. Of these and all other clamp-burnt bricks the builders distinguish two kinds, namely, the well-burnt ones from the interior, and the half-burnt ones, or place bricks, from the outside of the kiln.

The calcareous clay or malm earth requires no addition of sand or chalk, but only of ashes. The bricks made of it differ from those made of the top earth, in being of a pale or liver brown colour, mixed more or less with yellow, which is an indication of magnesia. The hardest of the malm bricks are of a pale brown colour, and are known by the name of gray stocks; those next in hardness are called seconds, and are employed for fronts of the better kind of houses; the yellowest and softest are called cutters, from the facility with which they can be cut or rubbed down, and are used chiefly for turning the arches of windows. What I have said of top earth and malm earth must be understood, however, to refer to well-characterized samples of these varieties, but, as might be expected, there are several brick-fields that yield a material partaking more or less of the qualities of both, and therefore requiring corresponding modifications in its manufacture.

Brick earth is usually begun to be dug in September, and is heaped rough, to the height of from four to six feet, on a surface prepared to receive it, that it may have the benefit of the frost in mellowing it and breaking it down. It is then washed by grinding it in water and passing it through a grating, the bars of which are close enough to separate even small stones. The mud runs into shallow pits, and is here mixed with chalk ground with water to the consistence of cream, if any calcareous ingredient is required. When it has become tolerably stiff by drying, coal ashes (separated by sifting from the cinders and small pieces of coal) are added, in the proportion of from one to two and a half inches in depth of this latter to three feet of clay, the most tenacious clay requiring the greatest quantity of ashes. The ingredients are then to be well mixed; and, finally, the composition is to be passed through the pug-mill,* in order to complete the mixture

* The pug-mill is an iron cylinder set upright, in the axis of which an arbor or shaft revolves, having several knives, with their edges somewhat depressed, projecting from it and arranged in a spiral manner round the arbor. By the revolution of the arbor the clay is brought within the action of

and to temper it. The moulder stands at a table, and the tempered clay is brought to him in lumps of about 7 or 8 lb.: the mould is a box without top or bottom, $9\frac{3}{4}$ inches long, $4\frac{3}{4}$ wide, and $2\frac{3}{4}$ deep; † it lies on a table: a little sand is first sprinkled in, and then the lump of clay is forcibly dashed into the mould, the workman at the same time rapidly working it by his fingers, so as to make it completely close up to the corners; next he scrapes off with a wetted stick *(strike)* the superfluous clay, throws sand on the top, and shakes the brick dexterously out of the mould on to a flat piece of board, *(a pallet board)* on which it is carried to a place called the hacks formed of the new bricks, into open hollow walls, which (in wet weather) are covered with straw to keep off the rain; here they dry gradually, and harden till they are fit to be burnt. A raw brick weighs between 6 and 7 lb.; when ready for the clamp it has lost about 1 lb. of water by evaporation.* A first-rate moulder has been known to deliver from 10,000 to 11,000 bricks in the course of a long summer's day, but the average produce is not much more than half this number (1).

The price of bricks varies from forty to sixty shillings a thousand, of which not more than one shilling and three pence a thousand, at the utmost, can be the cost of moulding, assuming the average work of a moulder to be five thousand in a day; any improvement, therefore, calculated to save time in this department of brick-making by the introduction of machinery worked by steam, or by horse power, can only amount to a benefit equal to a fraction of one thirty-second or one forty-eighth of the entire price of the commodity. If we assume such machine to produce fifty-two million bricks in a year, this amounts to two millions a week (for the season for brick-making in this country continues no longer than from April to September inclusive) or three hundred and thirty thousand in a day, equal to the labour of sixty-six men or eleven horses, without making any allowance for friction, or any deduction on account of temporary repairs. The cost of hand-moulding fifty-two million bricks at one shilling and three pence per thousand is 3250*l.* from which, if we deduct the first cost and repair of machinery, the expense of fuel or of horses, of superintendence, &c. it would probably be found that nothing would remain for profit.

Bricks are burnt either in kilns or in clamps (2). In the former the burning is completed in twenty-four hours; in the latter it requires from twenty to thirty days, but is on the whole cheaper, notwithstanding that the loss from over-burning, from under-burning and other accidents amounts to one-tenth of the whole number of bricks (3).

The consumption of London is for the most part supplied from the brick-fields that surround it in all directions, the principal of which, however, are situated north of the Thames, at Stepney, Hackney, Tottenham, Enfield, Islington, Kingsland, Hammersmith, Cowley, Acton, and Brentford. Those made at Grays Thurrock, Purfleet, and

---

the knives, by which it is cut and kneaded, and finally is forced through a hole in the bottom of the cylinder.

* A malm brick of the above dimensions will shrink by burning to the length of 9 or $9\frac{1}{4}$ inches. A brick made of top clay without any mixture of chalk, will often shrink to $8\frac{1}{2}$ inches.

† From some experiments made in France we learn the following particulars:—A mould 8 inches 3 lines long, 4 inches, 3 lines broad, and 2 inches 2 lines thick, yielded bricks which on an average weighed, when first made, 5 lb. 14 oz. When dried and ready for the kiln they weighed 4 lb. 8 oz. having 22 oz. of water; 9 oz of this quantity evaporates in the first twenty-four hours, the other 13 oz. require five or six weeks to evaporate. By burning, 4 oz. more of volatile matter is driven off; a well-burnt brick of the above dimensions weighing 4 lb. 4 oz. A fresh-burnt brick when laid in water absorbs about 9 oz *i.e.* from one-seventh to one-eighth of its weight.

It appears, however, from experiments by M. Gallon, that the weight of bricks varies according to the care with which the clay is worked or tempered. Some clay was well worked, and then beaten for half an hour, on the morning of the next day it was again worked and beaten as before, and in the afternoon was again beaten for a quarter of an hour, and was then made into bricks. Another parcel of bricks was made of some of the same clay, treated in the usual manner. Both parcels were dried in the air for thirteen days, when it was found that those made by the former process weighed on an average 5 lb. 11 oz. each, while those made by the latter weighed 5 lb. 7 oz. Both kinds were burnt together for ten days; they underwent no relative change in bulk, but the weight of the former was 5 lb. 6 oz. and of the latter 5 lb. 2 oz.—*Arts et Metiers*, vol. iv.

(1) The operation of making the bricks is generally undertaken by one man called the moulder, who with his wife, children, and one or two men, form a gang. One of the gang, a man, wheels the soil to the pug-mill; after it is tempered it is removed by a boy or girl from the pug-mill to the *banker*, (the moulder's work-bench), it is then kneaded by a woman, who passes it to the moulder next to her, and as fast as the moulder turns the bricks out of the mould, they are removed by a boy on to the off-bearing barrow, which is wheeled to the drying-ground by 1 or 2 men, who set up the bricks in the hacks in a slanting direction, two in width, and about two inches apart, and 3 feet high: these hacks run the whole length of the drying ground and are placed in parallel lines 4 to 5 ft, apart. When the bricks have stood a few days they are reset with a greater space between them, which operation is called *scintling*, and in about a week after, they are removed to the clamp or kiln.—Ed. C. E. & A. Jour.

(2) A clamp is formed first by raising the earth a few inches above the natural surface of the ground to an uniform level; some of the hardest of the new made bricks, or, if there be any in the field, some old bricks previously burnt are set on edge over the whole site of the intended clamp, which are to prevent the moisture of the ground penetrating the new made bricks. Flues are then formed by the bricks being laid side by side, with a small space between to the height of 3 feet and about 9 inches wide: the top is covered by bricks being set off on each side, until they form an arch or covering; these flues run the whole length of the clamp, and generally about 6 feet apart; they are filled with furze or dry faggot wood, over which are laid small sea coal, or breeze (cinders), the intermediate spaces are filled in with bricks (this operation is termed *crowding*) laid a short distance apart, and between each course a layer of breeze is laid and repeated the whole height. The upper courses are laid a little closer than the lower ones, as they receive a greater proportion of heat, the outside of the clamp is generally closed in with place bricks (half burnt or soft bricks), and the top covered with breeze and sometimes earth; when the clamp is made up the fuel in the flues is ignited, which communicates with the breeze laid between each course, and shortly the whole of the clamp is in a state of combustion, and becomes one mass of fire, communicating with the ashes contained in the bricks; part of the exterior is sometimes coated with clay to prevent the cold winds penetrating. As soon as the whole of the clamp is properly ignited, the flues are closed, when particular attention is required to prevent the fuel burning too fiercely or too slowly. If it burn or draw too quickly on either side, screens are placed on the outside to check the draught. When the whole is properly burnt, which is in about 25 or 30 days, the clamp is partially opened and allowed to cool; the bricks are then sorted, those which are properly burned are called *stocks*—if they are not sufficiently burned they are of a pale red colour and soft, called *place bricks*—if the fire has acted too fiercely, several of the bricks will be vitrified into one solid mass, which are called *burs*. The whole operation of making bricks from the time the earth is turned into the pug-mill to the time the clamp is open, averages about 6 weeks.

The kiln is of an oblong form, brick built, with one opening in the end or side, and generally 13 feet long, 10 ft. 6 in. wide, and 12 feet high; and will contain about 20,000 bricks, the walls, on the top, are about two bricks thick, and at the bottom three bricks; they are built battering (inclining) inwards, the bottom is covered with narrow recesses arched over with openings left in the top, having the appearance of lattice work, in these recesses is deposited the fuel, on the top the bricks are laid with spaces between to allow the fire to pass up: the upper courses are laid a little closer than the lower ones, and the surface covered over with old brick or tile rubbish to keep in the heat and prevent the rain damaging the upper bricks; when the kiln is full, some wood is put in and ignited, to dry them thoroughly: when this is done, which is known by the smoke becoming transparent, the mouth of the kiln is closed with old bricks and covered with clay, leaving sufficient space for faggot; brushwood, furze, bavins or dry faggot wood to be put in and lighted. The fire being made up it is continued till the ashes assume a whitish appearance, and the flames appear through the top of the kiln, the fire is then slackened and the kiln cools by degrees. The process is continued, alternately heating and slackening till the bricks are thoroughly burned, which is generally in the space of 48 hours. The advantages of kiln burning is the greater certainty in the operation and shortness of time in burning, which is done in about two days, whilst the operation of clamp burning occupies frequently 30 days. The bricks are generally of a bright and sometimes dark red colour.—Editor C. E. and A. Journal.

(3.) The following are the prices for the several operations in brick making:—

DIGGING PER CUBIC YARD.	*s.*	*d.*
To digging the uncallow, including wheeling not exceeding *one run* (a run is three 20 feet planks placed in a continuous line, lengthways)	0	4
Digging and wheeling brick earth	0	4
Turning and soiling (mixing sand or ashes with the brick earth	0	$2\frac{1}{2}$

MAKING, PER THOUSAND.		
Making the bricks, including the tempering of the clay, molding, and hacking (stacking)	4	0
Scintling (removing and restacking the bricks in the hacks)	0	$2\frac{1}{2}$
Crowding (placing) the bricks in the clamps or kiln	1	$4\frac{1}{2}$
Two yards of clay or brick earth (which will make one thousand bricks) digging and soiling at $6\frac{1}{2}$*d.* per yard	1	1
Wear and tear of tools (found by the master) and keep of horse	2	0
One-fifth of a chaldron of ashes for soiling, at 5*s.* per chaldron	1	0
One-fifth ditto of breeze for fuel, 7*s.* 6*d.* ditto	1	6
Straw 6*d.*, sand 6*d.*	1	0
Kiln or clamp expenses for attending to open it, leading carts, &c.	1	0
Duty	5	10
Rent	2	0
£1	1	0

To the above must be added the expenses for removing the uncallow, risk, losses, interest on capital sunk, &c., and if washed the additional labour and cost of chalk, &c. Stock bricks average at this time about 30*s.* to 32*s.* per thousand, in the field, and place bricks 24*s.* The price to the latter is almost prime cost, consequently a greater profit must be allowed on the stocks to cover all losses, which in wet seasons are very serious. The duty is obliged to be paid on the quantity in the hack, notwithstanding any part or the whole may be damaged or destroyed by wet weather or in process of manufacture; for these risks government allow 10 per cent., reducing the duty to 5*s.* 3*d.* per thousand on the quantity made before burning.—Ed. C. E. & A. Jour.

Sittingbourne, are of a very good quality and a fine yellow colour; stone-coloured ones are made near Ipswich, and have been largely employed in the outside walls of some of the new churches of the metropolis. At Cheshunt, in Hertfordshire, is a bed of malm earth of the finest quality, no less than twenty-five feet in depth: from this are made the best small kiln-burnt bricks, called paviers. They are hard, absorb very little water, and are used for paving the floors of stables, wash-houses, &c. They have entirely superseded the use of Dutch clinkers, which formerly were imported from Holland in large quantities. The red sandy bricks called Windsors are made at Hedgerley. There is a considerable exportation of bricks from London; many being sent to the West Indies, to Quebec, and to other colonies.*

Tiles, from the purpose to which they are applied, namely, roofing houses in order to shoot off the rain, require a texture as compact as can be given to them, consistent with a due regard to economy. The fattest and most unctuous clays are, therefore, those which answer the best, especially if free from gravel and the coarsest sand. The price of tiles, compared with that of bricks, is such that the manufacturer can afford to dry them under cover; while, being not more than one quarter of the thickness of bricks, the drying is more speedily performed, and with far less hazard of warping or cracking: the same also is the case with the baking. Sand is added to the clay, but sparingly; for if, on the one hand, it prevents the ware from warping, yet, on the other hand, it increases the porosity, which is a fault especially to be avoided. The general manipulations of grinding the clay and tempering it are analogous to those already described for making bricks; but more pains are bestowed in getting it to the utmost degree of plasticity so as to allow of its being rolled, like dough, into cakes of a proper thickness, which are afterwards brought to the required shape by pressing them into a mould.

* The whole number of bricks made in Great Britain and Ireland in the year 1835, on which the excise duty was paid, was 1380 millions.

ON THE PERCUSSIVE ACTION OF STEAM.

Our correspondent C. S. in the last number of the Journal has taken an observation which we made in the first part of our article on this subject in the August number in a wrong light; nor should we have expected him to have attached so much importance to that observation after reading the rest of the article, from which he would have seen that, if we thought it unfair of Mr. Parkes to attribute all the advantage of percussive action to Cornish engines, and none to others, we also considered the amount of that advantage to be equal to nothing, which we think clearly demonstrated by our reasoning: so that we cannot exactly be of opinion that Mr. Parkes *favours* the Cornish engines, simply by considering that the percussive force of steam is only developed in them. The remark that this force should be developed in a greater degree in Locomotive engines does not necessarily imply that it should be developed favourably; for, by reason of the lead given to the slide valve in those engines, the steam is first let on to the back of the piston, and its percussive force would therefore tend, as our correspondent justly observes, "to impede the engine, if not stop it altogether."

The rest of our correspondent's remarks, since they have for object "to show that the Cornish single-acting engines are the only ones at present in which the percussive force of steam could act with any very great advantage, and that the locomotives are the very worst in which it could be used as a motive force," and thus suppose the fact of its advantageous action in the former to be already established beyond all question, cannot be regarded as an answer to our article above mentioned, but merely to the single remark already alluded to, and to which he has, as we have shown, attributed a meaning we never intended it to convey. It is difficult to assign a reason for his replying to the least important portion of our article, and passing over the main argument in silence.—Is it that he considers the question of the propriety of applying the principle of Percussion to the action of the steam as above discussion?—This was not very reasonable, since he has, so far as we are informed, the authority of but one writer, the infallibility of whose theories has not hitherto been established by experience; in proof of which, see the Count de Pambour's paper *On Momentum proposed by Mr. Josiah Parkes as a Measure of the Mechanical Effect of Locomotive engines*, and our Reviews of Mr. Parkes' paper on the same subject, in the Journal of last year, page 102. We must, however, assume this to have been our correspondent's motive for abstaining from any discussion of the principle of the percussive action of steam, as otherwise we should be reduced to the alternative of either supposing that he did not understand the reasoning by which we demonstrated, or attempted to demonstrate its fallacy, or that he followed Paddy's plan of beginning at the end. Be this as it may, the following remarks may perhaps induce C. S. to modify his opinions in some measure.

He observes that, "in a common double-acting rotative engine, where the steam is let into the cylinder when the crank is just passing the centre, it is evident that any percussive force of the steam striking upon the piston could not by any means have any effect in turning the crank." But he states farther on that "the action of this force is avoided in this case, as well as in that of the Locomotive engine, by the gradual motion of the slide, for as soon as the slide begins to open the steam way, the steam rushes into the cylinder, and strikes upon the piston, but with very little effect, on account of its being so much wire-drawn in consequence of the small size of the opening at first." It would naturally be inferred from this latter observation that our correspondent supposed the percussive action of the steam to be confined to the moment when the valve begins to open, in other words, that it is only *the first portion* of the steam which has any percussive action, and that this action is communicated instantaneously to the piston the moment that portion of steam passes through the valve; which, if it were true, would obviate the development of percussive action in Cornish single-acting engines as well as in those above mentioned; for the steam valve of a Cornish engine, though opened more suddenly than the slide valve, is nevertheless not opened instantaneously, but more or less gradually. If, on the other hand, we assume the development of this action to occupy some time, however brief, so as to allow of the opening of the valve of the Cornish engine, (which is equally necessary for the double-acting rotative engine), then must we also admit, not only that there is percussive action in the latter as well as in the former, but also that this action must assist in turning the crank, which will have passed the centre before it has ceased to operate.

We do not agree with C. S. in the opinion that "in order to render the percussive force of steam available to its fullest extent as a moving power in single-acting pumping engines, it would be necessary to have some medium interposed between the direct action of the steam on the piston and the pumps; so as to convert the ever-varying pressure on the piston into a regular and steady pressure on the plunger of the pump;" for the condition of a constant pressure on the pump bucket, is by no means indispensable, as the effect of a diminution of pressure on the steam piston, supposing such medium not to exist, would be simply a corresponding diminution of the velocity, or of the acceleration of the bucket and column of water, which would by no means affect the application of the percussive force of the steam. This column of water is, however, considered by C. S. as a medium interposed between the direct action of the steam on the piston and the pumps, which is curious enough, since the action of the steam works the pumps, and these raise the column of water.

We cannot make out that our correspondent's remarks have in any degree shown, as he supposes, "that in the Cornish engine we might use the percussive force of steam as a moving force to a very considerable extent;" for such negative evidence as that which he reproduces from Mr. Parkes' paper, viz. that the duty performed by those engines is greater than he could otherwise account for, cannot be admitted as rigorous. What is required of the supporters of Mr. Parkes' opinions is a *direct* proof that in Cornish or any other engines, the steam develops a power, by means of percussion, *in addition to* that measured by its elastic force, without which it is idle to enter into any discussion respecting the comparative fitness of different kinds of engine for the development of this additional power.

ON THE POWER OF THE SCREW.

We have received a letter from Mr. J. R. Cussen, in defence of the views set forth by him in a communication published in our Journal for May last, and which were partially refuted by a correspondent in the July number. We cannot insert this letter, since it is evident that the writer is in error on all points; but for his information, and the information of any other persons who may be led into error by his arguments, we shall point out clearly in what his mistakes consist, and how they have probably arisen.

As to his first objection to the theory laid down by the Rev. Mr. Bridges, our July correspondent alluded to above is undoubtedly right with regard to the meaning of d, which signifies the *height* of the inclined plane, or distance between the top of one coil of the thread of the screw and the top of the next, which is the distance through which the resistance is moved in one revolution of the screw, and is called the *pitch* of the screw: it could not possibly signify, as understood by Mr. Cussen, the distance from the upper side of one coil of the thread to the under side of the next, as that would admit of an infinite number of different solutions to the problem of finding the power necessary to overcome a given resistance, according as the ratio of the thickness of the thread to the interval between its coils might be more or less, which circumstance could not effect the result, since it is only the upper side of the thread, or that which is in contact with the resistance, which sustains the resistance. Mr. Cussen may, therefore, rest satisfied that all theorists agree with him in substance, if not in expressions.

Respecting his second objection, Mr. Cussen has overlooked the chief part of the theory of the *lever*, and, unless he objects to that theory also as now taught by *all* authors and professors without exception, the following reasoning will convice him of his error.

We will take his examples of the three screws, each of ½ inch thread, which, converted into intelligible mechanical language, is one inch pitch, and of 3, 6, and 9 inches diameter respectively, worked by a lever of 90 inches long, the lever moved by a windlass of one ton power. But it is necessary first to understand clearly what is meant by a lever 90 inches long. In mechanical language its signification is the distance in a straight line from the fulcrum (which is in the axis of the screw) to the point of application of the power, which does not, however, seem to be the meaning attached to the expression in Mr. Cussen's second letter; he seems rather to mean the distance from the *surface of the cylinder* to the point of application of the power, which is not the true measure of the power of the lever: we shall therefore take the liberty of understanding it in the former sense. This being premised, suppose for a moment that no lever is used; we shall have, by Mr. Cussen's, as well as by Mr. Bridges' formula:

in the first case $1 : 3 \times 3{\cdot}1416 :: 1 : w = 9{\cdot}4248$ tons,
in the second case $1 : 6 \times 3{\cdot}1416 :: 1 : w = 18{\cdot}8496$ tons,
in the third case $1 : 9 \times 3{\cdot}1416 :: 1 : w = 28{\cdot}2744$ tons.

Now the power is applied in the first case at a distance of 1½ inch from the fulcrum, in the second at 3 inches, and in the third at 4½ in. distance; so that, by applying it at a distance of 90 inches in all three cases, we shall obtain the following results respectively:

in the first case $1\frac{1}{2} : 90 :: 9{\cdot}4248 : w = 565{\cdot}488$ tons,
in the second case $3 : 90 :: 18{\cdot}8496 : w = 565{\cdot}488$ tons,
in the third case $4\frac{1}{2} : 90 :: 28{\cdot}2744 : w = 565{\cdot}488$ tons,

or the pressure independent of the diameter of the screw, which overthrows the second objection.

Mr. Cussen's third objection falls to the ground with the preceding, indeed it has no meaning at all; for he *virtually* multiplies by the circumference of the circle described by the extremity of the lever when he multiplies by the circumference of the screw and by the length of the lever, although he omits to divide by the semidiameter of the screw, as he ought in that case to do, and as it will be seen, on an inspection of the above calculations, we have done to obtain the final value of w. If we take the first case, we had finally

$$w = \frac{1 \times 3 \times 3{\cdot}1416 \times 90}{1 \times 1\frac{1}{2}},$$

and it is obviously the same thing whether we suppose 3·1416 to be first multiplied by 3, to give the circumference of the screw, and the product to be afterwards multiplied by 90 the length of the lever, and divided by 1½ the semidiameter of the screw, as above, or whether we suppose 3·1416 to be first multiplied by *twice* 90, to give the circumference described by the extremity of the lever, and as the factor 3 of the numerator is essentially twice the factor 1½ of the denominator, these two factors disappear. Or, to make it still more apparent, let r represent the radius of the screw, d its pitch, l the length of the lever (measured from the axis of the screw), P the power and w the resistance. Then the last equation would be

$$w = \frac{P \times 2\,r \times 3{\cdot}1416 \times l}{d \times r}$$

from which it is evident that, if we take the 2 from the factor $2\,r$, and multiply it by the two factors 3·1416 and l, we shall obtain the circumference described by the extremity of the lever, or by the power; and this product, multiplied by $P \times r$ will obviously be the same as if the product $2\,r \times 3{\cdot}1416$, which is the circumference of the screw, were multiplied by $P \times l$. But Mr. Cussen has committed the error of leaving out the factor r in the denominator, forgetting that when no lever is used, the power is applied at the circumference of the screw, and that the leverage is equal to r, so that when the leverage is increased to l, the resistance is increased in the ratio $\frac{l}{r}$. Having demonstrated Mr. Cussen's error, and shown its probable origin, we may now cancel the r in the numerator and denominator of the fraction, and it will remain

$$w = \frac{P \times 2\,\pi\,l}{d},$$

π being the ratio of the circumference of a circle to its diameter

If Mr. Cussen's remark "that one-third of the calculated power is lost by friction," is meant to bear upon the comparison of the effect of screws of different diameters but the same pitch, it will be found on investigation that the friction bears no fixed ratio to the resistance, but increases in a slightly greater ratio than the diameter of the screw, and thus gives a proportionate advantage to screws of small diameter.

ON THE ECONOMY OF FUEL IN LOCOMOTIVES CONSEQUENT TO EXPANSION AS PRODUCED BY THE COVER OF THE SLIDE VALVE.

Sir—Having observed several errors in Mr. J. G. Lawrie's calculations, published in your useful and interesting Journal for August last, allow me to point them out for the benefit of your readers.

I should premise that the formulæ he has given for the several distances travelled by the piston: from the commencement of the stroke to the commencement of expansion, from the commencement of the stroke to the opening of the eduction port (not to the end of expansion, for expansion continues, but more rapidly, and the effect during the rest of the stroke is not to be neglected), and from the commencement of the stroke to the position of the piston when the valve opens for the lead of the next stroke, are correct. I should however observe that the expressions under the radical sign in the values of a' and c' are identical, and may be reduced to $(1-c^2)\,[1-(l+c)^2]$; and perhaps it would be better if the expressions $(1 - l\,c - c^2)$ and $(1 + l\,c + c^2)$ in the same two values were written respectively

$$[1 - c\;(l + c)\;] \text{ and } [1 + c\;(l + c)\;].$$

The errors I have discovered are in the computation of the effect, which follow.

Mr. Lawrie finds the volume of steam of the initial pressure p admitted during the stroke to be equal to $s\left(a' - \frac{(2\,d - b)\,t}{p}\right)$, (at least I suppose this expression to have been meant by the writer, although the factor s is omitted and h is printed instead of p in the denominator,) which is a sufficiently near approximation, but I cannot comprehend how he can make this quantity equal to $2\,d \times 1$, although he observes with truth that the quantity of fresh steam must (whatever the expansion is) be constant; but a constant quantity is not necessarily an arbitrary one, as which it might be considered in this case, for we may give s any value we please, and it would follow that the quantity of steam used per stroke would be the same, whatever the area of the piston might be, provided the length of stroke, lead and cover of the slide were the same. And if we supposed the area of the piston $s = 1$ square foot (a reasonable hypothesis), the factor 1 in the expression $2\,d \times 1$ signifying (as I suppose) also 1 square foot, we should necessarily have $a' - \frac{(2\,d - b)\,t}{p} = 2\,d$, which is impossible, for $a' \angle\; 2\,d$. His expression of the value of s is therefore incorrect; besides it is obviously impossible to deduce the area of the piston from the length of stroke, cover and lead of the slide, and ratio of the greatest to the least pressure in the cylinder, without knowing how much steam is generated in the boiler.

Secondly, the effective working pressure during the expansion is found $= \frac{a'\,p}{x} - t$, x expressing the distance travelled by the piston from the beginning of the stroke; and this expression will give too great a value by 3 or 4 lb. per square inch, if not more: for t is used to express the least pressure of the steam in the cylinder, which it has at the moment when the eduction port is closed, and which probably scarcely exceeds the atmospheric pressure, and the mean resistance of the waste steam amounts to 4 or 5 lb. per square inch. Besides this, the formula given to express the quantity of work done during the portion b of the stroke makes no allowance for the diminution of temperature consequent on expansion; but this may be too slight to be of any consequence, as the expansion is inconsiderable in locomotives; nor is any allowance made for the waste space which has to be filled with steam. But the effect during the rest of the stroke is not to be neglected, that is, from the moment when the eduction port is opened to the termination of the stroke; for, on account of the very small opening of the port during that period, very little steam is enabled to escape, and it had previously been but slightly reduced in pressure by expansion, so that its mean pressure during this last portion of the stroke will bear a considerable proportion to its initial pressure, and cannot therefore be neglected. On the other hand, the effect of the compression of the spent steam of the pressure t, between the instant of shutting the eduction valve and that of opening the steam valve, is so small that it might much rather be disregarded; for it commences with a pressure of about 1 atmosphere and terminates with about 1·4, say on an average $\frac{1}{4}$ atmosphere through one-fortieth part of the stroke, or about one-tenth of a lb. through the stroke, due to compression.

Thirdly, Mr. Lawrie makes the inexplicable assumption that the safety valve be so loaded that $p = s$—the initial pressure of the steam in atmospheres = the area of the piston!—Supposing the square foot to be the unit of area, and $s = 1$ square foot: we should then have $p = 1$ atmosphere, and the engine would not move; but if the square inch were the unit of area, for the piston of the same size as before we should have $s = 144$ square inches, and consequently $p = 144$ atmospheres!—These results show the manifest absurdity of the supposition.

Lastly, the values of a', b and c', in the examples which close the paper, are not determined correctly from the formulæ which, I said above, are themselves correct, so that the whole paper requires revision and correction, except the first part, as I have explained.

Hoping that the above remarks may be found serviceable to your readers,

I remain, &c.,

M.

MR. JOSIAH PARKES IN REPLY TO COUNT DE PAMBOUR

Mr. Editor—M. de Pambour has recently repeated, in several of the weekly and other periodicals, certain virulent strictures on my writings. I am at a loss to conjecture on what grounds that individual should have indulged in these, as well as in his earlier, and nearly similar, attacks upon me. I have, hitherto, declined replying to them, and for two reasons; first, I did not wish to convict a man of M. de Pambour's celebrity of deliberate misrepresentation; nor, secondly, to expose, more publicly than he had himself done to persons really conversant with the steam engine, his lamentable ignorance of practical matters. But, his resumption of these attacks, in the present form, renders it incumbent on me to be no longer silent. I, therefore, avail myself of the same medium of communication, and shall confine my reply to the exhibition of one instance of his gross ignorance, and of one instance of his numerous, and injurious, falsifications of my opinions and writings.

Every engineer is acquainted with the *cataract*, an instrument nearly as old as Newcomen's engine, and used for the purpose of opening the steam induction valve, and thus starting an engine, after any required period of rest. This species of water clock is also occasionally employed to open other of the valves at definite times. The Cornish engineers appreciate its value, not only as a means of regulating the number of strokes to be made by a pumping engine, in a given time, but also as effecting the influx of steam into the cylinder in the most instantaneous manner. Neither they, nor any other engineer ever, probably, imagined the cataract to exercise an influence over the *production of steam* in the boilers of their engines. The Comte de Pambour, however, ascribes to the instrument this miraculous virtue, in the following passage:

"We will finally remark that it is customary in these engines to make use of the *cataract*. Under this circumstance the engine does not evaporate the full quantity of water, that its boiler would otherwise be capable of evaporating per minute; but, on introducing into the formulæ the evaporation really effected, the formulæ will always give the corresponding effects of the engine."—(*New Theory of the Steam Engine. J. Weale*, 1839, *chap.* xi., *Cornish Single Pumping Engine, p.* 278.)

This *is*, verily a *new theory*. No observations of mine are requisite to illustrate the absurdity of theories, and formulæ, emanating from a person who is so little practically versed in the mechanism, and auxiliary apparatus of an engine, as to jumble together, and confound, in one paragraph, the distinct functions of the *cataract*, the *boiler*, and the *engine*.

In a later work, M. de Pambour has devoted no less than 16 pages of introductory matter to a criticism of my Paper on the Locomotive Engine, (published in the Transactions of the Institution of Civil Engineers, vol. iii.), in which, among others, I had occasion to examine his own experiments. In that paper not a word will be found disrespectful of M. de Pambour; his sentiments are treated with courtesy; and, at the risk of being thought tedious, I prefaced each of my observations on his conclusions with a quotation of the matter commented upon. M. de Pambour's reply contains numerous misapprehensions of my meaning, and arguments, of which I do not complain; but every author has fair ground of complaint against the antagonist who perverts his text; who invents arguments for him; or who cites, as authentic quotations, phrases which he never employed. In no one instance has M. de Pambour quoted my own words; in lieu of which he has frequently invented words and opinions for me. The following extract affords a concise example of the veracity and style of the 16 pages of criticism.

"The want of using equations which facilitate so much accuracy in mathematical reasoning *(and the author accounts for it in telling us that he is more accustomed to handle his hammer than his pen,)* causes him to heap errors on errors, combining and complicating them unaware, till he arrives at a point where he does not produce a single result that is not erroneous."—(*A Practical Treatise on Locomotive Engines*, 2nd edition. J. Weale, 1840. *Introduction*, page xxxiii.)

The paragraph in italics is a pure invention. No such words even occur in my paper as *hammer* or *pen*.

The writer who resorts to the miserable tactics of falsifying the language and opinions of one who differs from him on subjects open to large controversy, exhibits a consciousness of inferiority in his arguments, which it would have been wiser, and far more manly to acknowledge, than to attempt to conceal, by expedients so unworthy, and so certain of detection. Such a man may, possibly, be a skilful mathematician, but he cannot claim rank among *philosophers*, whose sole objects are the discovery and propagation of *truth*. I consider myself exonerated from all obligation to reply, in greater detail, to an adversary who descends to such ignoble practices; but justice to my own reputation requires that I should expose them to public reprobation. This I do with the more regret as I have derived both instruction and pleasure from some parts of M. de Pambour's researches.

I remain, Sir, your obedient servant,

Josiah Parkes.

LONG AND SHORT CONNECTING RODS.

Sir—In your September number there are two communications animadverting on my paper on connecting rods in the July number. In this paper, my object was to establish the soundness of the connecting rod, *in general*, as a medium of moving force, and thereby to endeavour the settling of the controversy about long and short rods. For it is not disputed by any, I presume, that the strains and consequent friction between moving parts, in machinery, occasioned by connecting rods on the same crank, are in a certain proportion to their lengths; and I agree that herein longer rods have the advantage of shorter. But the question has been, whether, purely as transmitters of force, the former has any superiority to the latter, which leads to the question whether generally and abstractly, connecting rod motion is just as a medium of force. As I have said, it was my object to prove the affirmative of the question. Therefore, in this view of the subject rods of different lengths to the same crank ought to be one in effect.

Though certainly I did not notice the fact, I was aware that the connecting rod would not work on a crank of the same length in the usual style. We may mention, however, that a modification of this case is in fact practised in epicycloidal motion, a demonstration of which is given in March number for last year, in which the stroke of the piston is twice the throw of the crank, and the radius of the inner wheel is the connecting rod.

I am, Sir, your's, obediently,

D. Clark.

Glasgow, September 16, 1841.

Artesian Well at Grenelle.—M. Mulot, in some of his recent experiments at the Artesian well in the abattoir of Grenelle, succeeded in forcing the jet of water as high as 63 feet above the ground, and when it reached this height, the water assumed a bell shape, ten metres in diameter, which produced the most picturesque effect. Unfortunately the water continues muddy: therefore, though there is a certainty of being able to procure nearly 2000 litres of water in the course of a minute, at a height which admits of its being conveyed into the highest stories of the houses in Paris, it is not yet known to what purposes the water can possibly be applied.

EPISODES OF PLAN.

(Continued from page 290.)

THE breaks and interruptions occasioned by our "Episodes" being given to the reader piecemeal in monthly portions, are attended with no injury to our essay, and with some convenience to ourselves, by in some measure concealing abruptness of transition from one subject to another, and by enabling us to avail ourselves of such pauses, in order to bring such incidental remarks as we may deem expedient. Such being the case, we venture again to remind our readers that the plans here presented to them, are intended merely to furnish ideas in respect to form and arrangement: for, as we ourselves are perfectly aware, they would require to be more or less modified, in order to adapt them according to the other—and to us, of course, unknown—circumstances attending any given case. For more frequently than not, probably, it would be considered necessary to retrench and simplify them, to consult effect less and economy more. Accordingly there is very little danger of their being borrowed from in so direct a manner, that application of them would be tantamount to plagiarism, more especially, as hardly any two persons would produce the same design from the same plan.

Should any one be of opinion that those here produced might be greatly improved upon as regards further development of the ideas contained in them, great would be our satisfaction at finding any of them so turned to account, or otherwise corrected and matured. It is possible, however, that a very different construction may be put upon our motives, and that it will be thought to betray somewhat too much of self-complacency, if not of arrogance, on our part, to suppose that our suggestions can be of any value to other persons. Such presumption, if presumption it be, we, of course, partake in common with all who publish designs of their own; but with this difference, that while they give entire plans of houses, as if they were so many perfect models in every respect, we merely throw out partial hints, without presuming to dictate any further. In so doing, we of course leave it to be inferred that we think sufficiently well of our ideas as to imagine they may possibly prove serviceable to others, and of the two, it is surely less offensive to suppose that architects can have occasion for any promptings of such kind, than that they can at all require studies for the arrangement of ordinary houses, or can obtain fresh instruction from plans which are, for the greater part, of the most familiar and every-day character.

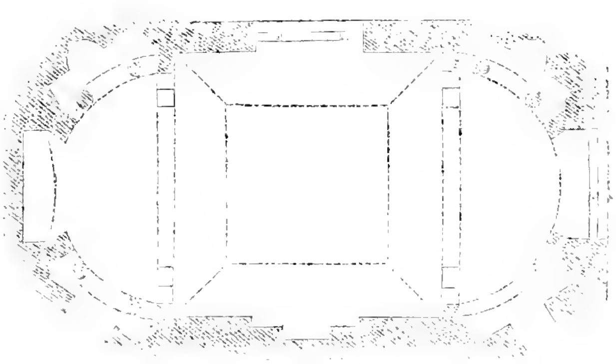
On the other hand, it may fairly be urged against ourselves and our Episodes, that the latter manifest too much straining after novelty and architectural display; that no regard is paid in them to economy, and that, in fact, they are applicable to general purposes, nor at all likely to suit the taste of persons in general. This is too true for us to attempt to contradict it: we leave persons in general, be they architects or those who employ them, to adhere to the present jog-trot system, taking no thought or study in regard to effects arising out of plan and varied combinations, but satisfying themselves that every thing in regard to plan is accomplished, provided that the number of rooms of the dimensions required be obtained, and mere convenience sufficiently attended to, which last, however, is far from being invariably the case, where the plan is only divided into so many squares and parallelograms.

It is not the least ill consequence of all attending the routine system we would fain break through and abolish, that by excluding variety of form in plan, it likewise excludes what would else suggest fresh ideas in regard to style of fitting up, and decoration. Most undoubtedly much character may be given to a room of the simplest and most usual form, yet it is seldom done, and seems to be as seldom attempted. On the contrary, there is a certain established uniform into which rooms of the same class are put almost indiscriminately, without regard to other circumstances. This is more particularly the case with regard to dining-rooms, for which it seems to be laid down as a rule that they have as little architectural attraction as possible bestowed upon them, in fact, show little more than plain walls of a single tint. As a general rule this is, we admit, a wholesome and safe one enough, because, if it admits nothing to gratify, it excludes much that might offend the eye. The very monotonousness and plainness are, besides, characteristic in themselves, so far as such a room is thereby sufficiently distinguished from the others in a house. Still, equal distinction, we conceive, could be kept up, equal propriety of character be maintained, with far greater variety of design; because simplicity and sobriety are by no means restricted to any one mode in particular; neither is the same degree of them desirable upon every occasion. What in one case would be modest elegance, may in another prove scarcely better than chilling nakedness and monotonous dulness. Where all else is plain and unpretending, an air of quiet homeliness and even snugness is becoming enough; but where plate is profusely displayed, and all the appointments of the table are of a sumptuous kind, some corresponding degree of show in the room itself can hardly be an inconsistency. Not only cheerfulness, but festivity of appearance will be perfectly in character, care of course being taken that the particular character be distinctly in accordance with the particular purpose of the room itself. Some variety of colouring is admissible, and though we would exclude *pictures*, we would freely admit *paintings*, that is of a light decorative cast, and as subsidiary to architectural character, such as borders and narrow upright panels at intervals, with arabesques or single figures *en camaieu*, or on a marbled ground. But as to oil pictures in frames, we consider them very ill-suited for dining-rooms, notwithstanding that they are frequently to be met with in them, and are almost the only decorations that are. As far as effect goes, the frames are of more importance than the pictures themselves, which, let them be ever so worthy of examination, are not likely to obtain it, unless attention be pointedly directed to them. Oil pictures are much better adapted for morning than evening rooms; since, so far from at all showing themselves to advantage by artificial light, many of them rather give a room a sombre though rich appearance at such time, unless the room happens to be lighted up expressly for the purpose of exhibiting the pictures themselves.

But all this while we are forgetting our "Episodes," or rather our main subject, and indulging in lengthy episodical remarks grafted upon it, and from which we will now make a transition by quoting an example of a dining-room that was certainly a frequent architectural episode in the interior of Carlton House, we mean the circular one on the principal floor, for the "Gothic" dining-room at the east extremity of the lower apartments towards the gardens, was a positive monstrosity—almost as vile and trumpery in taste as can be conceived. The other was an octastyle Ionic rotunda, extended by four deep recesses or alcoves radiating to the centre of the plan, consequently expanding inwards. We are not aware of any thing similar having been done in any other room of the kind; and yet not only is the plan exceedingly beautiful in itself, but one that admits of numerous variations, to say nothing of the great diversity of design it allows and even suggests, in other respects.

By way of contrast to the plans we gave in the first instance, we now show one for a dining-room whose ends are concave and semicircular, but whose plan is of peculiar character, there being small recesses with columns, between which there is at one end of the room a third recess for the side-board, at the other a window. Any arrange-

Fig. 5.



ment of this kind would produce an unusual degree of architectural play and richness, with somewhat of intricacy, but not such as to produce confusion or disturb the regularity, if not simplicity, of the ensemble, since the individual parts and recesses are sufficiently connected together by the columns and antæ, disposed semicircularly.

The idea itself admits of being so variously shaped, of being taken as the germ of so many distinct designs, not for a dining-room alone, but for apartments of other kinds, that were we at all at a loss for subjects, we could make it serve us for a great many Episodes. For instance, supposing the plan to admit of it, the same arrangement would be exceedingly well adapted for a library or morning-room with a window at each end, the four recesses, either with or without columns, being filled up with bookshelves, and either a single door opposite the fire-place, or two doors in the angles on that side of the room as circumstances might require. Else there might be a window there as at present, and three recesses for book-cases at each end of the apartment

In regard to the plan here shown as that for a dining room, it is not proposed as one capable of being strictly followed, because it would stand in need of more or less alteration in order to adapt and adjust it, so as to combine advantageously with the rest. Of course it is here presumed that there is nothing to hinder its being executed precisely as it is represented in the cut. The door near the sideboard is supposed to open into a corridor communicating with the offices, and the other from a vestibule or ante-room, as the case might be. There are four pedestals for candelabra, and there might be others in the two arches within the recesses: these, however, are not absolutely essential to the design, but might be adopted or omitted according as more or less decoration should be held desirable,—a point to be regulated by the scale of embellishment fixed upon. The recesses and semicircular ends of the room are supposed to be floored with ornamental tiles or mosaic (like the saloon of the Reform Club), and the square or centre part to be covered with a rich carpet. Or else the whole might be carpetted, and the same kind of distinction be nevertheless kept up, by putting down plain carpetting of some quiet neutral tint at the ends, for the purpose of giving more importance to the middle compartment of the room, and to the two extreme ones somewhat the air of being spacious semicircular alcoves with smaller recesses within them. After all, however, the propriety of so doing would depend upon whether any corresponding sort of distinction between the several divisions of the room was observed in the design of the ceiling. Should the situation of the room be such as to admit of the centre being lighted from above, the ceiling might then be raised by a cove, and have a lantern occupying the rest of it. In such case no side windows would be required, still the one at the end of the room might be retained, unless it should be preferred to make a second sideboard recess corresponding with that at the opposite end, or to have these folding doors opening from an ante-room, substituting a niche for the present door in the recess on the left hand.

(To be continued.)

ON THE FORMS AND PROPORTIONS OF STEAM VESSELS.

Though reluctant to call in question the opinions of so able a writer as "H. P. H." appears to be, I think he has no authority for multiplying the "sectional *area* of the immersed parts" of a steam vessel, into the (mean) *depth* below the surface of the water, in order to find the resistance to her motion. Doubtless this would be correct for "flood-gates," of which one surface only is exposed to the water, and the pressure is that arising from the *weight* of the fluid; but the case of a vessel is totally different, the resistance arising not from any weight of the fluid, (for the pressure on the after half of the vessel tending to push her forward, is exactly equal to the pressure on the fore part which tends to retard her,) but from a species of friction and from the inertia of the fluid. This resistance probably increases in porportion to the *density* of the water, not to its *depth*.

As the whole of the theoretical part of the article "On the Forms and Proportions of Steam Vessels," is founded on the presumption that the resistance is proportional to the section and depth, instead of section without regard to depth, as given in mathematical works, and as it will be completely erroneous if the above view is the correct one, it may be worth while for H. P. H. to reconsider the nature of the resistance of which he writes, and to favour the readers of the Journal with his opinions—waiting which I am,

Very respectfully,

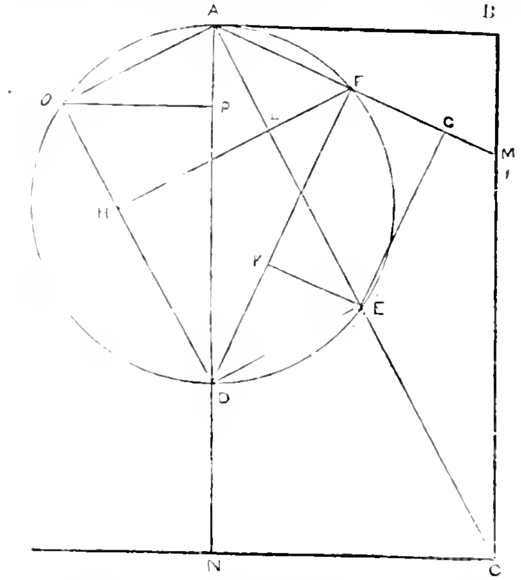
A. M.

Neath, 11th of 9th month, 1841.

ON THE STRAIN OF BEAMS.

Sir—It may be interesting to trace the effects on beams of strains acting on them in a parallel direction. In the common hand punch, for example, there is an upright beam bent at right angles at top to a convenient distance, the extremity being fitted to receive the reaction of the plates under the punch. Here the strain on the beam is upward. Instances of similar downward strains, too, are familiar, as in some portable balances, in which the scales hang from the extremity of an upright standard bent forward at the upper end.

Let A B C be an upright standard rising perpendicularly from the sole N C. and bent at right angles at B; let it be subjected to a force



acting downwards in the line A N parallel to B C. Then it would appear on a general view, that the part B C will be equally affected throughout, as the force, which let A D represent, has the same leverage on all points of B C.

But, more particularly, in estimating the action of the force on any point M, we may consider it as acting on M by the imaginary straight lever A M. The action of the force A D on M may be analysed by drawing D F perpendicular to A M; A D = A F and F D, the former being longitudinal pressure along A M, the latter, a lateral strain on the cross section at M by the leverage A M. Similar resolutions for other points in B C will form right angled triangles on the common base A D, and thus the locus of the vertices of these triangles is a circle described on the diameter A D, passing through point F, of course.

To ascertain how the forces A F, F D, acting on the section M, affect any other section, as that at the base C, draw A C cutting the circle at E, join D E, and complete the parallelogram O E; draw F H perpendicular to O D, cutting A E and O D at L and H. Then A F = A L and L F, and F D = D H and H F, these four resultants all acting at point A on lever A C; the sum of the longitudinal strains is A L + H D = A L + L E = A E; the lateral strains L F and F H, acting in opposite directions = F H — F L = H L = D E. Thus the resultants of the forces A F, F D, acting on the section M, are A E and E D on section C. But A E and E D are also the resultants of A D acting directly on section C. It appears, then, that the effect of the force A D on the section C is one, whether acting directly by A C, or indirectly by A M C. Again, the reciprocal action of the forces A E, E D, acting directly on C, upon the section M, may be had by drawing E K, E G perpendicular to D F, A M respectively. For we then have D E = E K and K D, and A E = A G and G E. Then G E or F K + K D = F D, and A G — K E or F G = A F. But A F and F D are the resultants of A D acting directly on M. Therefore, as M and C represent every two points in B C, and as the direct action of the force A D on either point is identical with its indirect action through the other point, we conclude, generally, that its action on every cross section of B C is constant, and therefore B C ought to be of equal dimensions from bottom to top. Draw O P perpendicular to A D, then A O = A P and P O, and D O = O P and P D, and as P O in these two quantities acts in opposite directions, we have A O and D O = A P and P D = A D, which intimates that there is no lateral thrust on the standard, so that the cross section of B C may at once be determined from the quantities A D, N C. The part A B ought to have the parabolic outline, modified when the corner B is rounded.

By supposing all the forces reversed in direction, the above demonstration will apply also to standards subjected to upward strains.

I am, Sir,

Your obedient servant,

Daniel Clark.

Phœnix Iron Works,
Glasgow, 20th Aug.

P. S. I think it would be a great improvement to introduce symbols to express the most common terms in papers of the nature of the preceding: ○ for *circle*, ⊥ for *perpendicular*, &c.

COMPETITIONS.

Sir—While I regret to find that so very little good, if any at all, should hitherto have been produced by all that has been said on the subject of Architectural Competitions, I am glad to perceive that you are not backward in aiding to correct the abuses now attending the present mode of conducting them.

The case stated in your last number is perfectly scandalous and flagitious, that were not the circumstances given upon Mr. Godwin's own authority, I should conceive it to be unfairly reported. And yet when I consider what sort of a design it was to which the highest premium was awarded in the first competition for the Royal Exchange,—a design that would be now utterly forgotten—had not that circumstance rendered it so memorable; when, again, I consider the result of the two competitions for the Nelson Monument, and that nothing more tasteful and original than the stale absurdity of an overgrown column could be picked out of all the designs and ideas submitted to the Committee, I am less astonished than I else should be at the *measures* which, it appears, have been taken by the "Tailors."

After especially inviting seven architects to make selection of the poorest design of all, certainly does look most awkwardly suspicious. Still, in this instance, I should say that the "honourable" Committee have perhaps done no more than act up to the very letter of their engagement, bestowing the prize on him who displayed *Superiority*—though it happened to be that of demerit.

It is some little consolation to reflect that such very flagrant instances may in time have the good effect of stiring up the profession to unite cordially and vigourously in devising such measures as should in future protect them from such swindling,—and to give it, would be almost to countenance it. Any sort of delicacy towards persons who scruple not to lend themselves to such dirty doings, would be sheer weakness. Better would it be were the names of all the parties—all the "highly respectable" individuals, concerned in such transactions, shown up to the public. A little pillorying of that kind would do a vast deal of good, and serve to render such respectable gentlemen either a little more cautious or a little more adroit. If they must be rogues there is no occasion for them to show themselves such arrant bunglers also, as they now generally do.

I remain, &c.

Vindex.

Sir—Eventually the evils arising from the present system of public and limited competitions will work their own cure, as architects who love their profession and desire to uphold its respectability will pause ere they lend themselves to the gross jobbing, and party interest which so generally occurs on such occasions. It seems to me that as a body we are heaping insult upon our own heads by the submission of designs (generally—if not always—the result of mature deliberation), to men seldom possessing an atom of architectural taste, or any other qualification requisite to render them efficient as judges of the works placed at their disposal for acceptance or rejection. I would advise my friend Mr. Godwin to keep an eye upon the Tailors he alludes to in your last number, (page 310), as no doubt they have been at their usual dirty work, and have "cabbaged" portions from each of the designs entrusted to their care; with regard to the Paddington Church job I happen to know very little about it, but should think, if all we hear is true, that for the credit of the Committee, "the least said is the soonest mended."

Having myself done with public competition, I may be permitted to add my opinion that architects competing should do so only upon the understanding that members of their own body should be their judges, as regards the comparative architectural merit and fitness of the several designs, and the more fairly to do so I would suggest that each candidate in turn should examine and compare the designs, and omitting his own, should give in a written opinion upon their several degrees of excellence; the decision thus come to could hardly fail in being a just one, while by this means the first, second and so forth would be pointed out without any chance of favouritism, and each of the judges having in his own case been compelled to study the whole work minutely, he would thus be the better qualified to give an opinion upon the productions of others; this proposal no body of persons advertising for designs could reasonably object to, if they wish to have erections throughout the land, which are to remain monuments of the talents of their respective architects, and of their own taste in expending the means committed to their disposal.

The success of some of the profession, who (like itinerant vendors of tea, millinery, &c.) scour the country in the various directions pointed out by the public advertisements, and earwig the Committees, may induce them for a time to follow up competition as a thriving trade; but I feel assured such a system cannot last, it only requires those architects who honour their profession, to unite in upholding its respectability, by refusing to enter into any competition unless it is regulated in some equitable and consistent manner, and in the long run they must succeed. The two last competitions that I had any thing to do with were the Infant Orphan Asylum and the Tower of Wandsworth church, at the first the architects were limited to 20,000*l.* as about the sum to be expended, and in order that this stipulation should be attended to, all the parties competing were required to furnish detailed quantities of their several designs, in defiance of this stringent clause, which of course sate like an incubus upon the ideas of the greater number who sent in—a design was chosen, the lowest tender for the execution of which was about 33,000*l.*; in this case two premiums were offered, one of 100 guineas and one of 50 guineas, the second of which only was awarded, thus: those who conformed to the printed regulations were excluded from participating in the first premium, while those who did not reaped the whole benefit; and I maintain that the Committee were bound in justice to those who obeyed the instructions, to have awarded both premiums, if to please themselves they chose to execute a more expensive design.

In the second case, namely, that at Wandsworth, the present Tower of the Church being in a very dilapidated state, the parish deemed it necessary that something should be done, and the result of their deliberations was that architects should be invited to send in plans, &c. for a new Tower, to cost 1,000*l.*, which sum they were willing to expend: but lo! when the designs came before them, they, contrary to the above case, considered economy to be the order of the day, and they in consequence awarded their premium to a design to cost 500*l.* only, and thus again those who conformed were laid on their backs, but it did not rest here, for after their economical decision in came the *extreme* economists of various denominations unconnected with the church, and at a subsequent meeting decided on curtailing the edifice of its intended fair proportions, by actually carrying a resolution to repair the already condemned and ruinous old Tower, at a still less expense; but the tables are turned, the work (I am given to understand) is stopped, the builder is afraid to proceed, and the architect refuses or rather suspends any other opinion but that he is to complete his contract; thus the parish are literally in a pretty situation between two stools, and have no one to thank but themselves. While from the want of rule in competitions as shown in the above cases, the profession never have any guarantee that their productions will be judged by any uniform and equitable rule, but find themselves put out of court sometimes because they are not sufficiently gorgeous, and sometimes because they are too expensive, while in both cases they have strictly conformed to the instructions given.

I am, Sir, your obedient servant,

John Burges Watson.

39, *Manchester Street, Manchester Square,*
September 7, 1841.

Sir—Reading in your valuable Journal for this month, some curious statements respecting "Competition Designs." I beg to state a case which happened to me some time since at Shrewsbury, which I think will surpass, in richness of facts, any I have yet read about.

A premium of 10*l.* was offered, publicly, for the best plan of a chapel to be erected near the town of Shrewsbury. The vestry were to be the judges.

They met at the publicly advertised time, and selected my design, and their officer informed me of the fact.

Not hearing any thing more about the matter for some time, I called at the vestry-room, and inquired how things were going forward.

And, Sir, what do you think was the answer I received, from the same functionary who had previously charmed my heart by giving the information previously stated? A cheque for the 10*l.* was—*not* handed over; nor was any order from the vestry given for me to proceed with the work. But still—"something" was given me which astounded me equally with either, and that was a grave address from the aforesaid officer, in the following words:—They have now given the premium to ———.* My feelings were of course those of surprise and astonishment, and almost *disbelief*; but the latter was soon expelled on receiving from my informant the *reasons* which actuated the "vestry." "The fact is this, Mr. —— assured some of our vestry that if they thought proper to give the premium to him, he would hand it over to one of the town charities, and they thought as how they could not commit a a nobler hact." This you will say *was* a noble act.

Your's, truly,

Veritas.

---

* An architect who lived in the town and parish.

NEW ACTS OF PARLIAMENT.

There have been introduced, by Lord Normanby (the late secretary of state) into the Houses of Parliament, three very important Bills connected with the profession, which demand their immediate and especial attention. The bills are too long to be transferred entirely into our Journal, but we shall give an abstract of the most important clauses in each Bill, which will show their general character.

REGULATION OF BUILDINGS IN LARGE TOWNS.

Abstract of a Bill intituled "An Act for regulating Buildings in large Towns," which has passed the House of Lords, and is now before the House of Commons.

1. Whereas disease is engendered and aggravated by the crowded and unhealthy manner of building the dwellings of the working classes in the large towns and populous places of this realm, and it is expedient to make provision for improving such dwellings: be it therefore enacted, &c., That the council of every borough which is within the provisions of an act passed in the sixth year of the reign of his late Majesty, intituled "an Act to provide for the Regulation of Municipal Corporations in England and Wales," or of any charter granted in pursuance of that or any subsequent act, and of every borough which is within the provisions of an act passed in the fourth year of the reign of her Majesty, intituled "an Act for the Regulation of Municipal Corporations in Ireland," and the magistrates and councils of every royal burgh and parliamentary burgh in Scotland, and of every burgh of barony or of regality in Scotland under the government of magistrates and councils, and also in England and Ireland the justices of the peace in general or quarter sessions assembled, and in Scotland the sheriff, having jurisdiction in any other town or place which her Majesty, with the advice of her privy council, shall order to be within the provisions of this act, shall, within six calendar months next after the passing of this act, or next after such order, and from time to time as vacancies shall happen, appoint a fit person, or so many fit persons as the council or justices or sheriff respectively shall think fit, not being surveyors of the estates of the mayor, aldermen, and burgesses of any borough, or of the corporation of any burgh, in which they are appointed, to be surveyors of buildings in such borough, town, or place, and to see that the several provisions of this act are observed therein; and each of the said surveyors shall have in his special charge such district of the borough, town, or place for which he is appointed as the council or justices or the sheriff shall in that behalf appoint; and each of the said surveyors shall hold his office during the pleasure of the council or justices or sheriff by whom he is appointed, and may, if the council or justices or sheriff shall so think fit, but not otherwise, have an assistant or assistants under him (such assistants being in all cases appointed by and holding their situations during the pleasure of the council or justices or sheriff); and the council or justices or sheriff shall have authority to fix the districts in which the said surveyors are to act within the borough, town, or place, and to do all things relating in anywise to the appointment and direction of such surveyors and assistant surveyors: provided always, that if a charter of incorporation shall be granted to any town or place in which such surveyors or assistant surveyors have been appointed, the future appointment of such surveyors and assistant surveyors shall be vested in the council, as if such town or place were incorporated at the time of the passing of this act.

2 and 3 enacts, that surveyors are to make declaration, to diligently, faithfully, and impartially perform the duties of the office; the council or justices or sheriff shall provide an office for the said surveyors.

4, Surveyors to be paid by fees, not exceeding for a first rate building 3*l.* 10*s.*, second rate 3*l.*, third rate 2*l.* 10*s.*, fourth rate 2*l.*, fifth rate 1*l.* 10*s.*, sixth rate 1*l.*; and for every alteration or addition to any building, a sum not exceeding half the above.

5, Powers given to councils of boroughs by this act to be exercised in Oxford by commissioners under act 11 G. 3, for improving the city of Oxford.

6, The surveyors appointed under any of the acts specified in the schedule (London, Bristol and Liverpool), shall be the surveyors for enforcing so much of this act as is to be enforced within the limits of the said several acts, and shall be entitled to receive for their trouble herein such additional fees as shall be ordered and settled by the authority by which they are appointed.

7. Notice of building or altering premises to be left at the surveyor's office.

Clauses 8 to 15, regulations for fees, duties of surveyors, penalties for default of notice, workmen offending and refusing inspection.

16, That it shall not be lawful to build within the limits of this act any house in which the floor of any room or cellar to be used as a dwelling* shall be below the surface or level of the ground in the immediate neighbourhood of such house, unless there shall be an open area not less than three feet wide from the floor of such room or cellar to the top of the area adjoining to the front or back of such room or cellar, and extending from one side or party wall to the other side or party wall; but this enactment shall not be taken to prevent any archway or covering which may be laid across such area for the purpose of approaching the doorway of the house.

* We consider that the words here used require to be particularly defined if they mean any room that is used for domestic purposes, such as a kitchen forming part of a dwelling house, the act will then effect a very serious injury on nearly half the houses in London: if dwelling mean a room wherein any person sleeps, then we do not see any objection to the Act, but in such case it would be better to alter the word *dwelling* to *sleeping room*.—Editor.

17. That in any house to be built within the limits of this act after the passing thereof it shall not be lawful to let separately, except as a warehouse or storehouse, or to suffer to be occupied for hire as a dwelling place,* any underground cellar or room not having a window and fireplace, as well as such an open area adjoining thereunto, as is herein-before specified.

18. Enacts, that in any house built within the limits of this act before the passing thereof it shall not be lawful to let separately, except as a warehouse or storehouse, or to suffer to be occupied for hire as a dwelling place, after the first day of January 1845, any underground cellar or room not having a window, or after the first day of January 1848, any underground cellar or room not having, in addition to such window, such an open area not less than two feet wide, as is herein-before described, or after the first day of January 1851, any underground cellar or room not having a fireplace in addition to such window and area.

19, Enacts, that every person who shall wilfully let or suffer to be occupied any underground cellar or room contrary to the provisions of this act shall forfeit and pay the sum of 20*s.* for every day that such cellar or room shall be so occupied, to be recovered by action of debt, either by the person occupying such cellar or room, or any other person who will sue for the same.

20, Enacts, that on any *new foundation* within the limits of this act it shall not be lawful to build any house, except corner houses, and houses built in a street or thoroughfare which was begun or laid out, before the passing of this act, under the authority of any act of parliament, unless there shall be a clear space of at least 20 feet wide between the back wall of such house and the back wall of any opposite house: provided always, that in estimating this distance no account shall be taken of any back addition or outbuilding belonging to either of such houses not more than half the height of the back wall of the house above the level of the street, and which addition or outbuilding shall not extend along more than two-thirds of the whole width of the house to which it belongs; but no such addition or outbuilding shall be nearer than seven feet to any other house, or to any addition or outbuilding to any other house, except privies, sheds, or other buildings, not more than eight feet high above the level of the street which may adjoin the fence or fence wall on either side.

21, Enacts, that it shall not be lawful to build any new street, alley, or public passage within the limits of this act, except such as were begun or laid out before the passing of this act, under the authority of any act of parliament, unless the houses therein shall be separated by at least 30 feet where there is a carriageway between such houses, or at least 20 feet in the case of alleys and foot passages where there is no carriageway.

22, Enacts, that it shall not be lawful to build within the limits of this act any new court or alley (except mews and stable yards) narrower than 30 feet, through which there shall not be an open passage at each end thereof at least 20 feet wide, and entirely open from the ground upwards.

23, Enacts, that the level of ground floor of every house which shall be built within the limits of this act shall be at least six inches above the level of the footway or road adjoining such house.

24, Enacts, that no room which shall be built within the limits of this act to be used as a dwelling on the cellar or ground floor, or elsewhere than in the upper story of any third rate house, or any house of a lower class or rate than the third, as defined by the said several acts named in the schedule (London, Bristol and Liverpool), within the limits of the said acts respectively, and elsewhere as defined by this act, shall be less than eight feet in height from the floor to the ceiling, and no room in the upper story of any such house shall be less than seven feet in height from the floor to the ceiling.

25, That there shall not be more than one story in any part of the roof of any house or other building which shall be built within the limits of this act.

26, That no third rate or lower rate of house, defined as aforesaid, except houses in a street or thoroughfare which was begun or laid out, before the passing of this act, under the authority of any act of parliament, shall be built within the limits of this act without an enclosed yard, which, exclusive of any buildings therein, except the privy (if any), or any shed or other building not more than eight feet high, shall be of the extent of one-sixth part at least of the ground covered by the house; and no house shall be built within the limits of this act without a privy, with proper doors and coverings to the same, either in the house, or in the yard attached to the house, and sufficiently screened and fenced from public view, to the satisfaction of the surveyor of the district.

27, All buildings erected contrary to this act to be abated.

28, Provides for preventing neglect or evasion of this act.

29, And whereas it is expedient that further provisions for security against fire should be made in such boroughs and towns as aforesaid which are not within the provisions of any of the acts named in the said schedule (London, Bristol and Liverpool); be it enacted, that all buildings begun to be built or rebuilt in any such borough or town not within the provisions of one of the said acts shall, after the passing of this act, be built and rebuilt according to the regulations herein-after contained, and the outer walls, party walls, separate side or end walls, chimney backs, and chimney flues shall be built according to the schedule (A.) annexed to this act: provided always, that where there is more than one story below the level of the street the walls of the lowest story shall be half a brick or four inches and a half thicker than is otherwise required.

The remainder of the clauses apply to provincial towns, and are framed somewhat similar to the Metropolitan Building Act. The annexed schedule explains the thickness of the walls and the classes of buildings.

SCHEDULE (A).

DESCRIPTION OF BUILDINGS.	THICKNESS OF OUTER WALLS.				THICKNESS OF PARTY WALLS.*				
	In Cellar Story to under side of Ground Story Floor.	In Ground Story to the top of joists in floor above Ground Floor.	Above to the top of the Wall, or, if a Parapet, to the upper side of the ceiling of the Top Story.	Parapet.	In Cellar Story to under side of Ground Story Front.	In Ground Story to the top of joists in floor above Ground Story.	Above to the top of joists in floor above First Story.	Above to under side of the ceiling of the Top Story.	Above through the roof to the Top.
First Rate. Every Church, Chapel, and other Place of Public Worship, Brewery, Distillery, Manufactory, Warehouse and other Building (not being a Dwelling House or a Building in the Fifth or Sixth Class) which is higher than 31 feet. Every Dwelling House which is higher than 50 feet, or which contains more than nine squares of building on the Ground Floor—every Dwelling House or other Building which has more than three clear stories above ground.	2 B. or 17½ In.	2 B. or 17½ In.	1½ B. or 13 In.	1 B. or 8½ In.	2½ B. or 22½ In.	2 B. or 17½ In.	2 B. or 17½ In.	2 B. or 17½ In.	1½ B. or 13 In.
Second Rate. Every Warehouse or other Building (not being a Building in the First, Fifth, or Sixth Class, or a Dwelling House,) which is higher than 22 feet, or which has three clear stories above ground. Every Dwelling House (having three clear stories and no more above ground) which is higher than 40 feet, and every Dwelling House which contains more than five and not more than nine squares of building on the ground floor.	1½ B. or 13 In.	1½ B. or 13 In.	1 B. or 8½ In.	1 B. or 8½ In.	2½ B. or 22½ In.	2 B. or 17½ In.	2 B. or 17½ In.	1½ B. or 13 In.	1½ B. or 13 In.
Third Rate. Every Warehouse and other Building (not being a Dwelling House or a Building in the first, second, fifth, or sixth class,) which is higher than 13 feet, or which has two clear stories above ground. Every Dwelling House (having three clear stories and no more above ground) which is higher than 37 feet. Every Dwelling House which contains more than three squares and a half and not more than five squares of building on the ground floor.	1½ B. or 13 In.	1½ B. or 13 In.	1 B. or 8½ In.	1 B. or 8½ In.	2 B. or 17½ In.	1½ B. or 13 In.	1½ B. or 13 In.	1½ B. or 13 In.	1½ B. or 13 In.
Fourth Rate. Every Warehouse and other Building (not being a Building in the first, fifth, or sixth class,) which is not higher than 13 feet. Every Dwelling House (having two clear stories and no more above ground) which is higher than 25 feet. Every Dwelling House which has not more than one clear story above ground, or which does not contain three squares and a half of building on the ground floor.	1½ B. or 13 In.	1 B. or 8½ In.	1 B. or 8½ In.	1 B. or 8½ In.	1½ B. or 13 In.	1½ B. or 13 In.	1½ B. or 13 In.	1½ B. or 13 In.	1 B. or 8½ In.

Fifth Rate.

Every Building (not being a Building of the first class or a Dwelling House) which is at least four feet and not more than ten feet from any Public Street, Road, or Way, and at least sixteen feet from any other Building not in the same possession, or connected with any such Building only by a fence or fence wall, may be built of any dimensions, but must be built either of brick or stone, or covered with incombustible materials.

Sixth Rate.

Every Building, not in the first class, which is at least ten feet from any Public Street, Road, or Way, and at least thirty feet from any other Building not in the same possession, or connected with any such Building only by a fence or fence wall, may be built of any dimensions and with any materials.

* Separate Side or End Walls between Buildings shall not be less than the length of one brick or 8½ inches thick, or, when the wall is higher than 24 feet, less than the length of one brick and one half, or 13 inches thick.

Where any Building is not founded on rock, every Outer or Party Wall shall have at least four footing courses below the level of the Cellar floor, each two courses projecting 2¼ inches on each side of the course or wall immediately above them; and all Inner Walls shall have at least two footing courses 4½ inches wider than the wall above them; and all such footings shall commence upon a firm natural or artificial foundation to be approved by the Surveyor.

DRAINAGE BILL.

Extracts from a Bill intituled "An Act for the better Drainage of Towns and Villages," which has passed the House of Lords, and is now in the House of Commons.

1. WHEREAS there is great need of sanatory regulations in the towns and populous places of this realm, especially for want of sufficient means of drainage, whereby disease is engendered and aggravated; be it therefore enacted, &c., that after the passing of this act it shall not be lawful to build any house within the limits of this act, unless a drain be first constructed to the satisfaction of the commissioners of sewers having jurisdiction there, of such material, size, level, and fall as they shall direct, which drain shall lead from the intended site of such house to such common sewer, common drain, or common watercourse as the commissioners shall direct, or if there be no such common sewer, common drain, or common watercourse within 10 yards of any part of the intended site of such house, then to such cesspool or other place as the commissioners shall direct, not more than ten yards from some part of such intended site.

2. That in all cases where any house built within the limits of this act, either before or after the passing thereof, shall not be drained by a sufficient drain communicating with some common sewer, common drain, or common watercourse, to the satisfaction of the commissioners of sewers, and if a sewer, drain, or watercourse of sufficient size, under the jurisdiction of the commissioners of sewers, and which they shall think fit to be used for draining such house, shall pass along any public thoroughfare or way in front of or behind any part of such house, it shall be lawful for the said commissioners to give notice in writing, signed by any surveyor or officer appointed by them for that purpose, to the occupier of such house, requiring such occupier or the owner thereof forthwith, or within such reasonable time as shall therefore be appointed by the said commissioners, to construct a covered drain of such materials, size, level, and fall as the commissioners shall direct, from the said house to the said sewer, drain, or watercourse; and if the owner or occupier of such house shall refuse or neglect, during 28 days next after the said notice shall have been delivered to such occupier or left at such house, to begin to construct such drain, or shall thereafter fail to carry it on and complete it with all reasonable despatch, it shall be lawful for the said commissioners to construct the same, and to recover the expences to be incurred thereby by distress and sale of the goods and chattels either of the owner or of the then present or any future occupier of such house as herein-after mentioned, by warrant under the hands and seals of six or more or the said commissioners.

3. That whenever any house shall be rebuilt within the limits of this act, the level of the lowest floor shall be raised sufficiently to allow of the construction of such a drain as is herein-before provided in the case of houses to be built after the passing of this act, and for that purpose the levels shall be taken and determined under the direction of the commissioners of sewers; and whenever any house shall be taken down as low as the floor of the first story, for the purpose of being built up again, such building shall be deemed a rebuilding within the meaning of this act.

4. The level of every new street, court, alley, and place which shall be made, and also the level of every street, &c. in which any new common sewer or common drain shall be made, shall be fixed under the direction of the commissioners of sewers.

5. The commissioners of sewers shall have authority, from time to time, as they shall see fit, to widen, deepen, embank, alter, arch over, amend, clean, and scour all or any of the sewers, drains, watercourses, sinks, vaults, cesspools, and privies within their jurisdiction, and also to cleanse, drain, amend, and abate all stagnant ponds and other nuisances whereby the health of the neighbourhood is or is likely to be affected, and to make new sewers, drains, sinks, cesspools, or vaults where none formerly existed, and also to make reservoirs, engines, sluices, penstocks, or any other works for better draining any place within their jurisdiction, in, under, or across all or any of the public ways, thoroughfares, or places within their jurisdiction, and, if needful, through and across all underground cellars and vaults which they shall find under any of the said public ways and thoroughfares, doing as little damage as may be, and making due compensation for the damage done to the owners and occupiers thereof; and in case it shall be found necessary, for completing any of of the aforesaid sewers or drains, to build, carry, and continue the same into and through any inclosed lands or other place, not being a public way, it shall be lawful for the said commissioners to build, carry, and continue the same into or through the said lands or other place accordingly, making due compensation to the owners and occupiers thereof; and all such sewers and other works and premises shall be at all times under the control, care, and management of the said commissioners, and of their surveyors and officers.

6. It shall be lawful for the commissioners of sewers, at their discretion, to abandon any common sewer or common drain running through narrow courts or alleys of houses or inclosed places, or through or under any place not being a public way, in all cases wherein a new common sewer or common drain shall be constructed, in any public streets, roads, or highways contiguous thereto, and capable of receiving the drainage of such courts, alleys, or inclosed or other places; and that upon such drainage being turned into such new sewer or drain the said commissioners shall not thereafter be obliged to maintain the sewers or drains so to be abandoned, but shall order the same to be filled up at their discretion, and that all branch drains communicating with any sewer or drain so to be abandoned shall be turned by the owners of the lands and tenements theretofore drained thereby into the new sewer or drain to be constructed instead of such abandoned sewers or drains, by making drains into such new sewers or drains, conformably to the regulations of the commissioners of sewers; provided always, that if such new sewer or drain shall not be brought within the distance of ten yards from the lands or tenements formerly drained by the abandoned sewer or drain, the cost of completing the branch drains beyond the length of 10 yards shall be defrayed by the commissioners of sewers.

7. Commissioners to give 28 days notice and provide a plan and section before making any new common sewer or common drain under this act, where no common sewer or common drain already existed, and before abandoning any old common sewer or common drain, and before abating any such nuisance as aforesaid.

10. That before making any drain or watercourse for the purpose of draining water directly or indirectly from any land or tenement into any common sewer, &c., and also before beginning to lay or dig out the foundations of any house therein, or to rebuild any house therein, 14 clear days notice in writing shall be given to the commissioners; such new drain or watercourse shall be made of such materials and workmanship, and laid at such level, as is provided by this act, and under such regulations as the said commissioners shall order.

11.* That it shall be lawful for the commissioners, or for their surveyor or such other person as they shall appoint, to inspect any drain or watercourse within their jurisdiction, and for that purpose *to enter at all reasonable times, by themselves, or their duly authorized surveyors, officers, and workmen, upon any lands and tenements, and also to cause the ground to be opened in any place they shall think fit,* doing as little damage as may be; and if such drain or watercourse shall be found to be made to the satisfaction of the commissioners, they shall cause the same to be closed and made good as soon as may be; and the expences of opening, closing, and making good such drain or watercourse shall be defrayed by the said commissioners out of the rates and assessments authorized to be made by them by the laws in force relating to sewers.

12. That all branch drains, *as well within as without the lands and tenements* to which they belong, and all watercourses used for drains, and all privies and cesspools, within the limits of this act, shall be under the survey and control of the said commissioners, &c., and shall be repaired and cleansed at the cost and charge of the owners or occupiers of the lands and tenements to which the same shall belong; and if the owner or occupier of any land or tenement to which any branch drain, watercourse, cesspool, or privy shall belong shall neglect to repair or cleanse the same in the manner required by the said commissioners, during 14 days after notice in writing for that purpose, signed by any such surveyor or officer, shall have been given to such occupier, or left upon the premises, it shall be lawful for the said commissioners to order such branch drain, &c., to be repaired and cleansed, and to levy and recover the costs and expences thereof by distress, &c., either of the owners or of the occupiers so neglecting to repair and cleanse the same.

21. Commissioners shall cause a map to be made of the district within their jurisdiction, on a scale not less than one inch to 400 feet, and to mark thereon the course of every common sewer, common drain, and common watercourse, and shall cause the same from time to time to be altered and amended; and such map, or a copy thereof, with the date expressed thereon of the last time at which it shall have been so amended, shall be kept in the office of the commissioners, and shall be open at all seasonable hours to the inspection of the owners or occupiers of any lands or tenements within the jurisdiction of such commission.

25. Where any common sewer or common drain shall be made by the said commissioners, under any public way where no common sewer or common drain formerly existed, the cost of making the same shall be borne, in the manner herein-after specified, by the several owners of the lands and tenements abutting on such public way on either side thereof, in proportion to the several lengths of frontage so abutting;† and it shall be lawful for the commissioners, when they shall have undertaken the construction thereof, to charge the said several owners with the cost of constructing a common sewer of the usual size‡ in the jurisdiction of the commissioners, to be paid by *five equal yearly instalments,* the first instalment being payable as soon after the completion of the work as the commissioners shall require the same.

26. And whereas by the laws in force relating to sewers the commissioners are empowered to lay separate and distinct rates, as occasion shall require, for every separate and distinct level, valley, or district within their commission, or for any part thereof, whenever they shall think fit to do so; be it enacted, that so much of the cost of making any common sewer or common drain above the usual size which shall exceed the charges herein-before laid upon the several owners of lands and tenements abutting on any public way, and also the costs of making those parts of any common sewer or common

* Clauses 11 and 12 contain very extraordinary powers, and such as are liable to be used with great abuse.—EDITOR.

† For corner houses there ought to be some provision, so as to make them chargeable for one frontage only, and not as is now the case for two frontages —EDITOR.

‡ We consider that the commissioners ought not to have the power for charging or enforcing in any case more than for what is considered in London as a *second size* sewer. If a *first rate sewer* be constructed, the extra price ought to be chargeable to the whole district drained by it, as provided in the following clause.—EDITOR.

drain which cannot be charged upon any particular owner of lands and tenements, and of widening or deepening any common sewer or common drain already existing, and of repairing and cleansing each common sewer and common drain when made, shall be borne by the owners of all lands and tenements within the level, valley, or district, or part thereof, for which such separate rates are made, wherein such common sewer or common drain is situated.

29. That, subject to the provisions herein contained, the instalments payable for making any common sewer or common drain, and all rates which the commissioners are empowered to assess and shall assess upon any lands or ments within their jurisdiction, shall be recoverable, if not paid, by distress, &c. either of the owner or of the then present or any future occupier of such lands and tenements.

30. No occupier of any land or tenement for a less term than from year to year shall be required to pay, more than the whole amount of rent which was due and payable from him at the time when the notice herein-before mentioned in each case shall have been delivered to him, or left upon the premises as aforesaid, or which shall thenceforth from time to time accrue and become payable by him, unless he shall neglect or refuse, upon application made to him for that purpose by or on behalf of the commissioners, truly to disclose the amount of his rent, and the name and address of the person to whom such rent is payable; but the burden of proof that the sum demanded of any such occupier is greater than the rent which was due by him at the time of such notice, or which shall have since accrued, shall lie upon such occupier.

31. In every case in which any tenant or occupier shall have paid any sum for making, repairing, or cleansing any common sewer, &c., or for making or repairing any branch drain, or any cesspool or privy, in respect of his occupation of such lands or tenements, he shall be entitled to deduct from his rent such part of the amount so paid by him as is herein-after specified; (that is to say,) if at the time of such payment he is a tenant for an unexpired term of 7 years, or any less term, he may deduct the whole amount paid by him; if for more than 7 years and not more than 14 years, he may deduct $\frac{4}{5}$ thereof; if for more than 14 years and not more than 21 years, he may deduct $\frac{3}{5}$ thereof; if for more than 21 years and not more than 28 years, he may deduct $\frac{2}{5}$ thereof; if for more than 28 years and not more than 35 years, he may deduct $\frac{1}{5}$ thereof; but if for more than 35 years, he shall not be entitled to deduct any part thereof: provided always, that any tenant under a lease containing a covenant for renewal thereof shall be deemed a tenant for the full term to which his holding may be extended under such covenant; and that every tenant for a term depending upon a life or lives shall be deemed a tenant for such absolute term of years as shall be of the same value as such contingent term, according to the government tables for the purchase of life annuities; and every lessor, being himself also a tenant or lessee of any lands or tenements, from whose rent any part of the amount so paid to commissioners shall have been deducted, shall be entitled in like manner to deduct from the rent payable by him to his lessor such part thereof as according to the provisions herein-before contained he would have been entitled to deduct from his rent had he paid to the commissioners as aforesaid the sum so deducted from the rent payable to him; and the receipt of the commissioners, or of their treasurer or clerk, duly authorized in that behalf, shall be in each case a sufficient discharge for so much of the rent as is hereby authorized to be deducted: provided always, that nothing herein contained shall be taken to affect any special contract between any lessor and tenant or occupier of any lands or tenements, whereby it is agreed that the tenant or occupier shall defray the charges of making, repairing, or cleansing all or any sewers, drains, cesspools, and privies belonging thereunto.

40. And be it enacted, that the limits of this act in England shall be the city of London; every place within six miles in a straight line from St. Paul, and also within the jurisdiction of any commission of sewers now in force for any part of the counties of Middlesex or Surrey, during the continuance of such commission; and also every place in England within the jurisdiction of any commission of sewers which shall be duly issued after the passing of this act, by letters patent, wherein it shall be expressly declared that such commission is issued in furtherance of the provisions of this act.

41. After the passing of this act it shall be lawful for her Majesty, &c., to issue commissions of sewers in furtherance of this act for any part of Ireland.

42. And be it enacted, that this act shall extend to Scotland, and shall include all royal and parliamentary burghs, burghs of barony and regality, and also all towns and villages in Scotland which her Majesty with the advice of her privy council shall from time to time order to be within the provisions of this act.

IMPROVEMENT OF BOROUGHS.

There is a Bill now before the House of Commons intituled "an Act for the improvement of certain Boroughs," which act is to grant powers for opening and widening close and narrow streets, alleys, passages and places therein, and for otherwise improving the town, such powers to be vested in the councils of such boroughs, under certain restrictions. The following clause is the most important, and explains when the council is empowered to take lands compulsory.

4. And be it enacted, that in any of the following cases the council shall be empowered, if they think fit, to take any lands which they shall require for the purposes of this act, with or without the consent of the several owners and other persons interested therein, subject nevertheless to the provisions for ascertaining and giving compensation for the value of such lands, and for the other purposes herein-after contained; (that is to say,)

1. When any such lands are needed for the purpose of opening a thoroughfare through any court or alley which is closed at either end:
2. When any such lands are needed for the purpose of widening any thoroughfare which is narrower than 20 feet:
3. When any such lands project 10 feet or more beyond the general line of the street:
4. When the council shall have agreed with the owners thereof for the absolute purchase of the lands on each side of the lands so required to be taken, the value of those already agreed for being at least 10 times the value of those not agreed for:
5. When any such messuages or tenements built before the passing of this act are contrary to the provisions of an act passed in this session of parliament, intituled "an Act for regulating Buildings in large Towns and Villages," and are not amended according to the provisions of the said act within six calendar months after notice thereof given by the council to the owner or occupier thereof:

Provided always, that it shall not be lawful for the council to take any such messuages, lands, or tenements, without the consent of the owners and other persons interested therein, unless with the approval of the commissioners of her Majesty's woods, forests, land revenues, works, and buildings.

NEW HOUSES OF PARLIAMENT.—VENTILATION, &c.

The following is a copy of the correspondence for the warming and ventilation of the two Houses of Parliament, laid before Parliament.

Office of Woods, Aug. 27, 1841.

Sir—The progress of the works at the new Houses of Parliament, and the necessity of laying down the foundations on which the flues for warming and ventilating the houses are constructed, induced me to desire Mr. Barry and Dr. Reid to make a joint report on these subjects, by which it appears that a sum of 86,000*l.* will be required for warming, ventilating, and securing the buildings from fire, according to the following statement:—

Ventilating tower		£20,000
Air and chimney flues in the walls		12,320
Apparatus		12,000
		£44,320
For securing the buildings from fire—		
Fire-proof floors under the roof	£20,680	
Brick floor on iron beams between the principal and upper stories	21,000	
		41,680
		£86,000

I must observe, that in this sum Mr. Barry has included the sum of 20,000*l.* for a centre tower, not intended in the original plan, but which will be so constructed as to suit Dr. Reid's new system of ventilation, which he considers will be a great addition to the beauty of the structure. I am unwilling to recommend so large a sum to the Treasury without the sanction of Parliament, although a considerable part will be necessary under any circumstances, if the houses are to be warmed and ventilated on the system adopted by Dr. Reid in the present temporary houses, and which appears to me to give general satisfaction.

From the prices at which contracts have been taken for the works already in progress, there can be no doubt, with care and attention, that a considerable saving will take place on the original estimate that was sanctioned by the committee of the two houses; and I therefore request you to bring the subject before the House of Commons, as the state of the works makes it necessary that some decision should be come to without delay; I will only add, that no unnecessary delay has taken place in bringing this subject forward, and that Dr. Reid has delivered in his estimate as soon as the state of the works allowed him to do so.

I have, &c.,

Duncannon.

The Right Hon. F. T. Baring, &c.

Westminster, Aug. 21, 1841.

My Lord—I beg to submit for your Lordship's consideration, a drawing of the river front of the new Houses of Parliament, showing the effect of a central tower of the height and diameter required by Dr. Reid for the purpose of ventilation, according to his first suggestion; and I have no hesitation in expressing my opinion, that the adoption of such a feature in the design would considerably improve the general effect and importance of the intended building.

I have, &c.,

The Viscount Duncannon. Charles Barry.

Whitehall Treasury Chambers, Sept. 14, 1841. T. F. Freemantle.

PROFESSIONAL CHARGES.

VIGNOLLES *v.* LEFROY.

At the last Summer Assizes held at Liverpool, August 30, the following important action was tried against the Hon. Thomas Lefroy, M.P., as one of the directors of the Central Irish Railway Company, to recover compensation for work and labour performed by the plaintiff as an engineer.

Mr. Dundas, Mr. Martin, and Mr. Watson were for the plaintiff; Mr. Cresswell, Mr. Wortley, and Mr. Cleersby for the defendant.

The details of the case were long and tedious, but the following were the principal facts:—

It appeared in the case for the plaintiff, that, in the year 1836 a number of gentlemen, connected with Ireland, were of opinion that a railway from Dublin to Sligo, running through the centre of the island, would be a desirable undertaking. Of these, the defendant was one of the most active. Preliminary meetings were held, prospectuses issued, the usual staff appointed, and other measures taken for carrying the project into execution. A provisional committee was formed, at whose meetings the defendant usually attended, and very frequently took the chair. The meetings took place, whether in London or Dublin, usually at the offices of Messrs. Young, Murdoch, and Leahy, solicitors to the company. The services of an engineer being required, some discussion took place on the appointment. A person of the name of Walker was mentioned, but it was afterwards decided, very much at the instance of the defendant, that the plaintiff, who had been the engineer of the North Union, the Midland Counties, and the Dublin and Kingstown Railways, should be requested to undertake the office. The solicitors for the company communicated with him, and he accepted the situation on the 4th of June. Immediate steps were taken for completing a survey, and a number of Mr. Vignolles's pupils and assistants were set to work upon the line. He himself paid frequent visits to Ireland in superintendence of the work up to the 21st of September, during which time frequent meetings of the committee had taken place in London and Dublin, at which the defendant presided, and on which occasions resolutions were come to as to the course which should be adopted, and the measures which should be taken in advancement of the project. One subject of discussion was, the site for the Dublin terminus, and on this point some correspondence took place between the plaintiff and the defendant with reference to a meeting to discuss the matter in Dublin, and the course which should be adopted respecting it. In one of these letters the defendant says, that the terminus at Kilmainham would not go down with the Dublin people, and that he must rely upon the skill and industry of Mr. Vignolles to select a better one. On the 21st of September a meeting of the committee took place, at which the possible appointment of Mr. Vignolles to the office of engineer to the Irish Railway Commission was brought under their notice, and it was agreed that his name should cease to appear as the engineer to the company, being replaced by a Mr. Nimmo, one of his assistants, who had previously been carrying on the survey under his superintendence. It was, however, for the plaintiff, alleged that he continued really to superintend the work as before, and that Mr. Nimmo was acting under him, and not as an independent engineer. The plaintiff went to Ireland repeatedly, and carried on a correspondence with Mr. Nimmo when in England. The work was then completed, the surveys made, and the necessary maps and books of reference deposited in the Parliamentary offices. Mr. Nimmo died in 1839. The present action was brought by Mr. Vignolles for the balance due to him for these engineering services. He had received 500*l.* His charge was 40*l.* per mile on a line of 126 miles. Much more, it was said, had been surveyed, including the lines which had been abandoned as not eligible.

For the defendant it was contended that there was no contract between him and the plaintiff, and that though, as a public man and a member of Parliament, he had encouraged a project which it was supposed would be of public benefit, he was not himself one of those embarked in the speculation, had never taken or been allotted any shares, and had merely given the provisional committee his assistance and advice. It was alleged that at all events the plaintiff had resigned his office of engineer in September, when appointed to the Royal commission; and that, even supposing he had executed all the work, the charge of 40*l.* per mile was excessive. Considerable payments had been made to Mr. Nimmo.

The case occupied the whole day, and at nearly 8 o'clock the Court adjourned, postponing his Lordship's summing up until the following day, when his Lordship having gone through the facts of the case,

The Jury retired for a considerable time, and brought in a verdict for the plaintiff—Damages 1,980*l.*, being the balance due up to September 21, when they were of opinion he ceased to be engineer to the company.

Exportation of Machinery.—The select committee of the House of Commons, lately appointed to inquire into the operation of the existing laws affecting the exportation of machinery, have just published their second report to the House. This report is much too long to allow of any detailed reference to it, but we subjoin the final recommendation of the committee on the subject, which is to the following effect, viz.:—"That, considering that machinery is the only product of British industry upon the export of which restraints are placed, the committee recommend that the law prohibiting the export of machinery should be repealed, and the trade of machine making be placed upon the same footing as other departments of British industry."

STIRLING'S AIR ENGINE.

Messrs. Stirling have constructed an air-engine, now working at the Dundee Foundry, which fully realizes the expectations of the inventors: its superiority over the steam engine consists in an immense saving of fuel, and in its capability of being contained in a very small space. For the purposes of navigation these properties are invaluable. We subjoin a description of the air-engine, furnished us by a friend well acquainted with mechanics.

The air-engine now working at the Dundee Foundry, for which a patent was lately taken out, is the joint invention of the Reverend Dr. Stirling, of Galston, and of his brother, Mr. Stirling, engineer, Dundee.

The principle of the invention consists in alternately heating and cooling two bodies of air confined in two separate vessels, which are arranged so, that, by the stroke of two plungers worked by the engine, while the whole of the air contained in one of the vessels is at the lower end immediately over the furnace, and is consequently quite hot; the whole of the air contained in the other vessel is at that time disposed at the upper end, which is cut off from any communication with the furnace, and is therefore comparatively cold.

The expansion caused by the heat renders the air in the one vessel much more elastic than that in the other; and the two ends of the working cylinder, which is fitted with a piston similar to that of a steam-engine, being respectively connected with the two air-vessels; a preponderating pressure is produced on one side of the piston, and it is thereby pushed to the opposite end of the cylinder. By the alternate action of the plungers in the two air-vessels, this end of the cylinder then comes in its turn to be subjected to the pressure, and the piston is thereby pushed back again to its former position, and so it continues a reciprocating motion, and is applied to turn a crank in the same way that a steam engine does.

It has been satisfactorily shown that this engine may be worked with very great economy of fuel as compared with a steam engine; and the principal means of producing the saving is this; that, of the heat which is communicated to the air from the furnaces, only a very small portion is entirely thrown away when the air comes again to be cooled; for, by making the air, in its way from the hot to the cold end of the air-vessel, to pass through a chamber divided into a number of small apertures or passages, the great extent of surface with which it is thereby brought in contact, extracts in the first place, but only temporarily, the greater part of the heat from the air; and afterwards restores it to the air on its passage back again from the cold to the hot end of the vessel. The process of cooling is finally completed by making the air to pass through between a number of tubes in which there is a current of cold water, and thus far the heat cannot be made available again, but the portion which is abstracted in this way is very small.

As a sufficient expansive power could not be attained from using air of the common density of the atmosphere; without either making the diameter of the cylinder, and all the other parts of the engine inordinately large, or subjecting the air to greater alternations of heat and cold than would be convenient; the air is used pretty highly compressed, and a much greater power is thereby obtained upon a given area of the piston.

It is necessary therefore to employ a small air-pump to keep up the air to the requisite density: but very little power is expended on this; for, as the same body of air is used over and over again, all that is required of the air-pump, after the engine has been once charged, is to supply any loss that may arise from leakage; and this is found to be very trifling.

The machine has been working occasionally for about six months, and it has been proved, to the satisfaction of the inventors, to be capable of performing advantageously the amount of work which they had reckoned on, from their calculations, and from former experiments made on a working model of about two horses' power. It has now, for upwards of a month, been doing work in driving all the machinery employed at the extensive engineering works of the Dundee Foundry, which a steam engine of approved construction had hitherto been employed to do; and it has been ascertained that the expenditure of fuel is, *ceteris paribus*, only about one-fifth part of what was required for the steam engine; but, as considerable improvements are contemplated in some of the details, it is confidently expected that a much greater saving of fuel eventually will be effected.

The whole machine, including its furnaces and heating apparatus, stands in about the same space that a steam engine of equal power would occupy without its furnaces and boiler; and, taking into account this saving of space, along with the vast saving of fuel, the invention must necessarily be of immense importance for all ordinary purposes requiring motive power; and, as an instance, it would reduce the expense of the power employed in driving machinery in Dundee alone by at least 25,000*l.* or 30,000*l.* a year; but, viewed in reference to the purposes of navigation, the application of this invention must lead to results still more extraordinary, and will render a voyage to India round the Cape, by machinery, a matter of perfectly easy accomplishment.—*Dundee Advertiser.*

Herculaneum—It is stated that the Neapolitan government have resolved upon undertaking some new excavations at Herculaneum and its neighbourhood, and it is added that they will be on an extensive scale. Negotiations have commenced already with this view for the purchase of various estates on the spot: and so soon as these purchases have been completed the works will be commenced. A commission of antiquaries and architects is to be appointed by the Minister of the Interior and the Royal Academy of Sciences to preside over the operations of the workmen; and no doubt discoveries will be made to add largely to the present knowledge of this interesting ruined city, and the manners and customs of its former inhabitants.

THE ZINKING PROCESS.

We derive from the *Revue Generale de l'Architecture* the materials for the following notes on the process of zinking iron, as described by the Baron Menn de Mesnil, in the Report of the Committee of Inquiry to the Minister of Marine in France. On the importance of preserving iron from oxydation it is unnecessary to make any remark, we may just observe that the only effective modes hitherto used have been tinning and glazing. In 1742 M. Maloin presented to the Royal Academy of Sciences a memoir on the analogy which he had observed between iron and tin, and points out a mode of zinking iron similar to the modern one. Whether the price of zinc was then too high or other difficulties stood in the way, it was not until 1836, that the process of zinking was made effective by M. Sorel, who took out a patent for it under the name of Galvanization of Iron. On the 28th September 1838, a committee was named by the Minister of Marine to make experiments in the dockyard at Brest on zinking iron, by them a first report was made recommending experiments to be made on a larger scale, which latter commenced on the 14th of May 1840, and it was on the 30th April of the present year that they made their report.

The process consists simply in dipping an iron article, previously cleaned with acid, for 3 or 4 minutes into zinc infusion, then taking it out progressively, shaking it in the air to get rid of the excess of zinc, and at last plunging it suddenly in cold water; after which it only requires to be rubbed over with fine sand and dried. What is called Galvanization is therefore nothing more than a process similar to tinning: but while iron is rendered more oxydable by contact with tin, and oxidizes rapidly, if by any mistake in the preparation the iron is left uncovered in any point: in zinking, on the contrary, a true alloy of zinc is formed on the surface of the iron, and the parts accidentally left unzinked alone rust, and the evil is soon stopped. This latter fact is enough to prove that the iron is not protected by any Galvanic effect as is the opinion generally received. Thus in the operations preparatory to zinking, such as cleaning by acid, &c., great care is taken to free the surface of the iron by scraping from it all matters which would resist the action of the acid, and prevent zinc from attaching to the iron all over.

The cleaning with acid is an operation which requires much care, for while it is indispensable that the iron subjected to the acid should be wholly free from rust, care must also be had that the iron be not too strongly acted upon by the acid, but be taken out at the proper moment. Very weak acids only are used for the cleaning as a mixture of nine parts of sulphuric acid with 100 of water. In France the refuse acid used in purifying vegetable oils is also employed; after a certain time the acid can no longer be used, as it is almost wholly turned into sulphate of iron, a salt which may be readily extracted, and which would bring more than the worth of the acid used. The time during which the iron is kept in the acid varies according to the degree of rust from 12 to 24 hours.

The pieces after coming out of the acid bath are cleaned and passed rapidly into hydrochloric acid of 15°, and then put in a stove to be quite dried. It is in this state of absolute dryness that they may be plunged into the zinc infusion. At the time of immersion the object is powdered over with sal-ammoniac, a great part of which volatilizes, and then decomposes, and the remainder, the acting portion, cleanses the object a third time, and makes the zinking certain and perfect. The use of this salt, on account of its value and the large quantity used, forms a great part of the cost of zinking. The zinc bath soon becomes covered with a black fluid matter, without adherence to the surface of the bath, on which it forms a continuous layer. The workmen consider it as advantageous to the zinking, and therefore take it out of the bath after the day's work, and put it in again the next morning, when they go back to work. During the night the zinc it kept in fusion, and the surface exposed to the air, is tarnished and oxydized, and it may be therefore allowed that the black matter acts so as to dissolve the oxide formed, and thus to restore the surface of the zinc to the purity requisite for zincing properly. An analysis of this black matter, made at Brest by M. Langonné, First Class Naval Apothecary and Member of the Committee, shows it to be composed of a great quantity of chlorure of zinc, a small portion of chlorure of iron, and an insoluble compound of ammoniac and zinc. As we know therefore that chlorure of zinc and ammoniac are good detersives, it is not surprising that the black matter, having an analogous composition, should be equally efficacious. The time that objects remain in the zinc bath depends on the dimension, if they are thin, they must be only rapidly passed through, if massive they must be left some minutes. In general it is enough to take the objects out as soon as they leave off giving out smoke or rather steam.

The immersion of the zinked object, still quite hot, in cold water, is for the purpose of preventing the formation of oxide of zinc, which tarnishes the surface, but this operation gives the iron a kind of tempering, which added to the effect of a layer of alloy covering the surface, renders it more brittle. Sheet iron in particular, on account of its thinness, is subject to this inconvenience, and can no longer be bent with ease. An improvement has however been recently made, which avoids the dipping, the slight layer of oxide of zinc which is formed on the surface, and which does not stick, is easily got rid off by rubbing after the object has been cooled in sawdust and sand.

When objects have just been zinked, they have a metallic lustre, which they will keep for a long time, when free from damp, but when left in the air they by little and little tarnish, become covered with a whitish efflorescence, which increases, acquires consistency, sticks to the metal, and soon forms a continuous and solid layer, which preserves the surface from ulterior alteration. This transformation is slow in taking effect, and appears to be complete only after 15 or 18 months' exposure to the air. Even the weakest acids and the alkalis attack and dissolve the zinc with the greatest facility and bare the iron. Heated red for several minutes the layer of zinc in excess soon peels off, but the iron is not yet bared, as the alloy of zinc and iron, more adherent, harder, and less fusible, long repel the action of heat.

The thickness of the zinc layer is very small; on cannon balls it was only 16 hundredths of a millimeter, on sheet iron it was from 7 to 12 thousandths of a millimeter, 9 thousandths is the mean. The thickness has little effect on the windage of cannon balls, but the committee suggest that zinking might be employed to increase the diameter of deficient balls. The committee farther suggest that experiments should be made to zinc old iron objects in order to preserve them. The thickness of the layer of zinc, although so very small, is amply sufficient, when we consider that an alloy is formed with the iron, which extends its protective influence deeper into the metal.

The influence of the air or water is very little on the zinked iron, if entirely exposed, but if subjected to the action of water and air alternately, they are more affected. Zinked apparatus produces no injurious effect upon drinkable water.

As to the various articles on which they experimented the committee report that the zinking appears very effective for roofs and cisterns. Zinked nails and bolts are recommended for shipping, but the committee are not yet prepared to recommend them to supersede copper. These nails are recommended for the decks of ships, as the ordinary nails soon produce a black spot on the surface of the wood, which penetrates and affects the fibres, gallate of iron being produced. Zinked nails are strongly urged as substitutes for iron in securing slates on roofs, as the iron nails soon rust, particularly near the sea, and in high winds are the chief cause of the slates falling. The zinked gutters the Committee consider will supersede tin. For the flues of stoves the zinked iron is recommended, and zinked wire also meets with their approbation. They had not made sufficient experiments as to chains, but they reported that those which they had tried, when put to the hydraulic test, supported it well. For locks and bolts in lighthouses and sea buildings, zinking is exclusively advocated. An advantage which zinc possesses for ear-rings for sails is that it does not rust the sails, which is apt to rot them.

The Committee conclude by making several recommendations. They report that zinking of wrought and cast iron can easily be practised in all ordinary circumstances of the use of that metal, that zinking shows every symptom of durability, and that it is of the greatest advantage to the navy. They consequently recommend a contract to be made with the patentee for the use of zinc in the arsenals of France, being convinced of its efficacy.

S. L. AND CANDIDUS.

The question at issue between S. L. and myself seems as it were about to be protracted as interminably as a Chancery suit. However we now seem to understand each other somewhat more clearly than at first:—at least there is one point on which he expresses himself decidedly, and on which I can cordially agree with him; since so far from attempting to defend, he unscrupulously reprobates that sickly soidisant *Greekism*, and pseudo-classical style, which during the last thirty years have given us so many "insipid abortions," where opportunities—now, alas! not to be recovered—presented themselves for achieving noble and original works.

Most certainly S. L. is not mistaken, when he imagines I will admit that Grecian and Roman architecture affords resources not yet worked out, ideas so capable of being yet further extended, that they may be said to be as yet only very partially developed, whereas they have only been studied and cramped in the mechanical productions of the school. My chief surprise is that he should for a moment doubt or affect to doubt my sentiments on that head, when I have more than once plainly stated—though perhaps in the very same terms I now use—that I am not an admirer of any one style in particular, however excellent it may be, to the exclusion of all others. My architectural creed is of a more liberal and comprehensive kind: it is free from those narrow sectarian prejudices that blind some to all beauty—all merit that does not come under the standard of their favourite style. So very far am I from being one of those who can not only tolerate, but admire even inferior productions, provided they do but belong—if only nominally—to what they consider the only legitimate mode, that as far as æsthetic value is concerned, I hold the manner in which a style is treated to be even of more importance than the question of style itself. So long as the work itself manifests artistic spirit, feeling and power, the particular language of the art, it happens to be composed in, is comparatively of little or no moment, however important it may be from other considerations attending any given case;—so far at least adopting Pope's doctrine that

"Whate'er is best administered is best."

By no means, was it my intention in what I first said to uphold the Gothic in preference to all other styles, nor did I conceive that it would be so construed by any one. And having thus cleared up S. L.'s misconceptions—or at least his doubts, I may now leave him to call Welby Pugin to account, as being a far greater offender—not only a staunch advocate for Gothic, but so exceedingly intolerant withal, that he would, were it in his power, exclude and uproot every thing else. Yet, should he have read the Professor's "True Principles," S. L. will probably not care to measure his strength with so redoubtable a champion. In case they should ever so encounter each other in argument, they may probably be so well matched that each will make a convert,—as such things have happened before now, and that S. L. will be converted to Puginism, while Pugin goes over to "Paganism."

PROCEEDINGS OF SCIENTIFIC SOCIETIES.

INSTITUTION OF CIVIL ENGINEERS.

April 6.—The President in the Chair.

Experiments on the strength of Iron Girders. By Thomas Cubitt, Assoc. Inst. C. E.

This communication gives in a tabular form the results of experiments upon upwards of 60 pairs of cast iron girders, varying in length between 7 ft. 6 in. and 27 feet, with corresponding depths, and of all the forms usually adopted for beams for buildings. They were proved in pairs by a hydraulic press placed between them, the ends being retained by wrought iron ties. The deflexion was noted at each increase of pressure, and in many instances the beams were fractured.

Sketches of the girders, and of the apparatus used for proving them, accompanied the paper; from them five drawings have been made at the Institution to facilitate a reference to the information contained in the communication.

Description of an improved Level and Stand. By G. Townsend.

This improvement being intended to procure a firmer basis and greater facility of adjustment than by the ordinary level, the author has adopted the principle of the triangular plate, with three levelling screws. In the ordinary instrument, with two pairs of screws, it has been found that the antagonist screws, besides being apt to wear unequally, and to indent the lower plate, are sometimes bent, and thus cause an unequal action upon the upper plate. To obviate these defects, the screws in the tripod level are made to work into inverted cones, which are fixed in the three grooved arms of the stand head; the weight is more equally distributed, and the telescope more speedily brought to a level.

The telescope is fixed to the levelling plate by an upright limb, and to this is added a small longitudinal cross level, as in Gravatt's instrument. In the improved stand, each of the legs is attached to two arms of the lower tripod plate, by which means a firmer basis is obtained. The usual locking plate, to secure the levelling screws, is also attached to this instrument, and kept in place by a spring catch; there is also a metal ring fixed on the upright limb, above the arms, and which falls into three spring catches in the table plate, by which any derangement from accidental violence, or in removal from one station to another, is effectually prevented.

A small circular spirit level is fixed in the stand in order to adjust it before the instrument be placed on it, by which means the labour of adjustment is considerably abridged.

April 20.—The President in the Chair.

Experiments for determining the position of the Neutral Axis of rectangular beams of Cast and Wrought Iron and Wood, and also for ascertaining the relative amount of compression and extension at their upper and under surfaces, when subjected to transverse strain. By Joseph Colthurst.

These experiments were undertaken in consequence of the difference of opinion which has long existed respecting the position of the neutral axis of extension and compression of iron and wood.

First experiment.—Two series of experiments were made to determine this point by cutting through the centre of each of a set of eight girders, each 6 ft. 6 in. long, 5 in. deep, and half inch thick, the first to the depth of half an inch, the second to the depth of 1 inch, and so on, to the eighth girder, in which only 1 inch of metal remained unsevered. The spaces cut out were then filled with carefully fitted wrought iron keys, and the girders were broken by the application of weights, in the expectation that these weights would be some indication of the neutral point of each girder. The results were, however, so irregular, that no satisfactory deductions could be drawn from them.

Second experiment.—The next attempt was made in the manner suggested by the late Mr. Tredgold, by drawing two fine lines, $2\frac{3}{4}$ inches apart, on a polished surface at right angles to a girder, in the middle of its length; it was then subjected to strain, and dimensions were sought to be taken to determine where their divergence and convergence commenced, but the differences were too small to be susceptible of accurate determination, otherwise than by a fine micrometrical operation, which at the time the author had not an opportunity of applying. The following plan was therefore adopted.

Third experiment.—In the side of a cast-iron girder, 6 ft. 6 in. long, 7 in. deep, and 1 inch thick, a recess was planed at the centre, 3 in. wide by $\frac{1}{4}$ in. deep. This was filed up very true, and fourteen small bars of wrought iron, with conical ends, were placed in it at regular distances of $\frac{1}{2}$ an inch apart. These bars were of such lengths as to hold sufficiently tight to carry their own weight, and yet that the slightest touch should detach them. The girder was then subjected to strain. The supports were 6 feet apart; with a strain equal to 100 lb. the lower bar fell out; as it was increased, they continued to drop, and with 1500 lb. all those below the centre had fallen. The strain was then increased to 7000 lb., but no more bars fell. The centre bar remained exactly as when put in; all those above the centre became firmly fixed, and were evidently under considerable compressive force. The strain was then gradually taken off, and all the bars above the centre fell out, their ends having become compressed by the sides of the recess pressing on them; they were of course too short when the girder resumed its former condition, and the recess its previous width. These experiments were repeated several times, with pieces of fine wire and dry lance-wood charred at the ends.

The result in every case showed that the *neutral axis* of extension and compression was certainly situated within $\frac{2}{10}$ of an inch of the centre.

Another experiment was still more decisive. A girder 9 ft. 6 in. long, 8 in. deep, 1 in. thick, was cast with two brackets or projections on the side, each 9 in. on either side of the centre. A brass tube bar, with circular ends and a sliding adjustment, was fixed between the brackets, which had been filed true. The clear bearing was 7 ft. 6 in.; a strain of 50 lb. was sufficient to cause this bar to drop out; and with 250 lb. the whole effect of the previous experiment was produced. The tube, when placed loosely, 1 inch above the centre, was held fast by a strain of 1000 lb.

Wrought Iron.—Similar experiments were then made on wrought iron, with precisely the same results, showing that the neutral axis, if not actually situated at the centre, was nearly identical with it.

Wood.—A similar series of experiments, made upon wood beams, gave exactly the same results as regarded the position of the neutral axis.

From all the foregoing experiments, the author concludes that the neutral axis of extension and compression in rectangular beams of cast and wrought iron and wood, is situated at the centre of their depth, when those beams are subjected to transverse strains.

Extension and compression. Cast Iron.—Experiments were also instituted to ascertain the amount of extension and compression of cast and wrought iron and wood.

Upon a bar of cast iron, 3 inches square, and 9 feet long, two strips of thin hoop iron were attached, the one on the upper, and the other on the lower side, each strip being fastened to the bar at one end only, while the other end was left free; any change which occurred in the length of the surface to which it was applied was clearly indicated. The differences were recorded by very fine lines on a polished surface. The strips were 7 ft. 6 in. long, and were bound to the whole length of the beam by bands of fine wire, wound round and enclosing them at every 9 inches; the beam was then subjected to strain, and the following results were obtained:—

Weight. lb.	Deflection. inches.	Compression. inches.	Extension. inches.
1000	0·22	..	..
2000	0·45	$0·04\frac{1}{2}$	$·04\frac{1}{2}$
3000	0·65	0·06	0·06
4000	0·87	0·08	0·08
5000	1·20	0·11	0·12
6000	1·50	0·13	0·14

6240 the beam broke; good iron, showing a good clear fracture.

It will be perceived, that until rather more than two-thirds of the breaking weight was put on, the amounts of extension and compression did not sensibly differ, but between that point and the breaking weight, extension yielded in a higher ratio than compression.

Wrought Iron.—Similar experiments were next made on bars of wrought iron, 2½ in. square; the supports were 13 ft. 6 in. apart, and the strips of oop iron were 12 feet long.

Weight. lbs.	Deflection. inches.	Compression. inches.	Extension. inches.	Elasticity. impaired.
500	0·55	0·03	0·03	..
1000	1·55	0·06	0·06	..
1280	1·45	0·07	0·07	0·15
1560	1·85	0·08	0·08	..
1800	2·20	0·09	0·09	..
2000	2·70	0·11	0·11	0·65
2280	4·15	0·18	0·19	2·05

With this weight the beam was permanently bent, and its elasticity nearly estroyed.

These experiments showed that, differing from cast iron, the amounts of extension nd compression in wrought iron continue to be equal up to the complete destruction of the elasticity of the beam.

Fir battens.—The amounts of extension and compression in rectangular beams of fir tiober, when subjected to transverse strain, were next determined; the manner of proceeding was precisely the same as in the preceding experiments.

A batten, 4 in. by 3 in., with the supports 8 ft. 2 in. apart, and with strips 7 ft. 6 in. long, when subjected to transverse strain, gave these results:—

Weight. lb.	Deflection. inches.	Compression. inches.	Extension. inches.
500	1·10	0·12	0·12
1000	2·30	0·24	0·24

Results.—From these experiments on the amount of extension and compression of cast iron, measured at the under and upper surfaces of rectangular beams, subjected to transverse strain, the author assumes, that within limits which considerably exceed those of elasticity, and equal to at least two-thirds of the breaking weight, there is no sensible difference between the amounts of compression and extension, and that as the breaking point is approached, extension yields in a higher ratio than compression, and gives way first.

It would appear certain that up to the point when the elasticity of wrought iron is completely destroyed, and the beam is bent, the amounts of compression and extension continue exactly equal, and it is therefore probable that this equality would continue to the last.

It is clear that the amounts of extension and compression up to three-fourths af the breaking weight do not sensibly differ in fir battens, but that as the ultimate strength of the beam is approached, compression yields in a much higher ratio than extension, and may be actually seen to give way first.

He states also, that the amounts of extension and compression are in direct proportion to the strain, within the limits of elasticity, and that even after those limits are greatly exceeded, and up to three-fourths of the strength of a beam, they do not sensibly differ.

The apparatus with which these experiments were made was exhibited, and presented by the author to the Institution.

Mr. Donkin eulogised the novel and ingenious manner in which Mr. Colthurst had conducted the experiments, which he considered to be highly satisfactory. They not only determined the position of the neutral axis of the beams experimented upon, but showed also the relative amounts of compression and extension, so as to demonstrate that the elasticity of a body was the same in compression as in extension. These experiments also confirmed the correctness of Tredgold's opinion as to the pernicious effects of attempting to produce peculiar forms in beams by cambering and inserting wedges into their upper sides.

Mr. Vignoles reminded the meeting of the discussions which had taken place relative to the position of the neutral axis in the railway bars, which had the upper and under tables similar; it was contended that the neutral axis was situated close beneath the upper lip, or table of the rail, whereas, if Mr. Colthurst's mode of experimenting had been adopted, a different and more correct result would have been arrived at.

Mr. Cubitt accorded great merit to Mr. Colthurst for the experiments, which had determined the question as regarded rectangular beams. It appeared that no attempt had been made to use the same mode of proceeding with beams of irregular figures; in them, therefore, it might be concluded, that the neutral axis would be found in the centre of gravity of the section of the beam.

Mr. J. Horne remarked, that these experiments perfectly accorded with those which he laid before the Institution in 1837. His object had been to show that the neutral axis was always in the centre of gravity of the section, as well as to determine the figure which should resist the greatest amount of pressure with a given quantity of materials; the strongest form was shown to be a prism, placed with the base upwards, and the same figure reversed was the weakest; the strength of the former figure exceeded that of the latter by at least oue-third.

April 27.—The President in the Chair.

Memoir of the Montrose Suspension Bridge. By J. M. Rendel, M. Inst. C. E.

Previous to the year 1792, the passage of the River Esk at Montrose was effected by common ferry boats; at that period an act of parliament was obtained for the construction of a wooden bridge, with numerous arches, or rather openings formed by beams, supported upon piles, with stone abutments at either end; the action of the tide undermining the piles, and the usual progress of decay causing great expense for repairs, it was decided in the year 1825, to erect a suspension bridge, the iron work of which was contracted for by Captain Samuel Brown, R.N., for the sum of £9,430, and the masonry of the towers for £9,080. The total cost being £18,510, exclusive of the land arches and approaches; those of the old bridge being preserved for the new one.

The dimensions of the new bridge were—

	Feet.
Distance from centre to centre of the towers	432
Deflection of the chain or versed sine of the catenary	42
Length of the suspended roadway	412
Width of ditto	26
Height of ditto above low water	21
Ditto of the towers above ditto	68
Base of the towers at the level of the roadway	40 by 20
Archways through the towers	16 wide, 24 high

The towers were built of red sandstone ashlar, raised on a base of the same material, carried upon piles.

Construction.—There were two main chains on each side, arranged above each other in parallel curves, 12 inches apart. Each chain was composed of four bars of iron, 5 inches wide by 1 inch thick, and 10 feet long, united by short plates, and strong wrought iron pins. The roadway was suspended to these chains by perpendicular rods. 1¼ inch in diameter, attached at intervals of 5 feet, alternately to the upper and lower lines of main chains, at the joints, which were arranged so that those of the upper chain should be over the long bars of the lower one; at the lower end of each suspending rod was a stirrup, which received and carried the cast-iron bearers for supporting the roadway.

Upon these bearers was laid and rivetted longitudinally a flooring of fir planks, 3 inches thick, and well caulked; upon this a sheathing of fir, 1½ in. thick, was placed transversely, and spiked to the lower planks; over all was spread a coating of about 1 inch thick of fine gravel and sand, cemented with coal tar.

The suspending rods were without joints. The main chains rested upon detached cast iron saddles, built into the masonry of the towers, and passing down at either extremity, were secured behind cast iron plates in masses of masonry, 10 feet under ground.

The construction was commenced in September, 1828, and was finished in December, 1829, a period of only sixteen months.

Accident to the Bridge.—On the 19th of March, 1830, about 700 persons assembled on the bridge to witness a boat race, when one of the main chains gave way, and caused considerable loss of life. The injury was speedily repaired, but a careful survey of the structure was ordered, and it was discovered that the intermediate or long links of the chains bore so unequally upon the saddles as to be bent and partially fractured. Mr. Telford, who was consulted on the subject, proposed the addition of two other main chains placed above the original ones, and having the same curve, so as to increase the sectional area 40 inches—thus giving six chains of 20 inches area each, instead of four chains, as originally constructed.

Mr. Telford's decease occurring at that period, the author was instructed to report upon the state of the bridge, and advise such alterations as he judged to be necessary.

After a minute personal inspection he concurred in Mr. Telford's idea of the necessity of increasing the strength of the bridge, but instead of augmenting the number of the chains, he advised the addition of two bars in width to each of those existing, by which means the required strength might be gained. He was led to this by an opinion that, in all cases, it is desirable to have as few chains as possible.

It appeared that there had been but little precision in the workmanship of the chains; for on releasing them they immediately became twisted; thus showing that all the links had not a true bearing. On taking them apart, many of the traversing pins were found to be bent, and some of them were cut into, evidently by the friction of the links. This was to be rectified, and new saddles of a different principle and stronger form were recommended: also, that those parts of the chains which rested in the saddles should be entirely composed of short plates. Additions to the masses of masonry holding the chains were likewise deemed advisable.

Between the years 1835 and 1838, all the principal works, with many minor improvements, were executed.

In the author's report on the state of the bridge, he noticed what he deemed defects in the construction of the roadway, but as there was no positive symptom of failure, it was allowed to remain. He conceived, that in the anxiety to obtain a light roadway, mathematicians and even practical engineers had overlooked the fact, that when lightness induced flexibility, and consequently motion, the force of momentum was brought into action, and its amount defied calculation.

On the 11th of October, 1838, the roadway of the bridge was destroyed by a hurricane, the effect of which upon this structure is the subject of a paper by Colonel Pasley, published in part 3, vol. 3, of the Transactions of the Institution C. E. To that account the author refers for the principal details, only adding, that on inspecting the bridge, he found the chains, the saddles, and the fastenings or moorings, quite sound; the principal portion of the roadway had been completely carried away, and the remainder much injured. He then gives some account of the undulatory motion observed during the storm. This motion was greatest at about midway between the towers and the centre of the roadway; but the waves of the platform did not coincide with those of the chains, either in magnitude or in order; no oscillatory motion was perceived either in the roadway or in the chains, although particular attention was directed to them.

It appears that the centre of the platform fell in a mass. This the author attributes t the failure of the suspension rods, which having no joints, were twisted off close to the floor by the undulatory motion. A similar occurrence at the Menai Bridge* induced Mr. Provis to adopt the joints in the suspension rods, which the author had previously introduced at the Montrose Bridge.

The author had long been convinced of the importance of giving to the roadways of suspension bridges the greatest possible amount of stiffness, in such a manner as to distribute the load or the effect of any violent action over a considerable extent.

The platforms of large bridges, in exposed situations, are acted upon in so many different ways by the wind, that he had an objection to the use of stays or braces to counteract movements which ought rather to be resisted by the form of the structure.

Holding such opinions, he determined to adopt a framing which, although connectedly rigid in every direction, should nevertheless be simple, composed of few parts, capable of being easily renewed; should distribute its weight uniformly over the chains, not be subject to change from variation of temperature, and not augment the usual weight of suspended platforms.

The details of the alterations, and general repair of the bridge, are then given; a few may be mentioned.

An entirely new set of stronger suspending rods was introduced; they were $1\frac{1}{4}$ of an inch in diameter down to the flexible joint at the level of the platform; below that point the diameter was increased to $1\frac{3}{4}$ of an inch, and a strong thread was cut on to the lower end, so as to adjust them to the requisite lengths.

In the place of the cast iron bearers cross beams were substituted, composed of two Memel planks, 13 inches deep, $3\frac{1}{2}$ inches thick, bolted together, and trussed with a round bar $1\frac{1}{4}$ inch diameter; every sixth beam had a deep trussed frame on the under side, so as to give great stiffness. Above and beneath the cross beams, on each side of the carriage way, were bolted two sets of longitudinal timbers, four in each set; they were further united by cast iron boxes, at intervals of 10 feet; and the ends were secured to beams of English oak, built into the masonry of the towers. A curb of Memel timber, 11 inches by 6 inches, was attached to the ends of the cross bearers, and extended the whole length of the platform.

The planking of the footways was composed of narrow battens, 2 inches thick, laid transversely from the inner longitudinal beam to the outer curb piece, with an inclination or drip of $1\frac{1}{2}$ inch in 5 feet.

The carriage way was formed of four thicknesses of Memel plank; the two lower layers, each 2 inches thick, were placed diagonally with the transverse beams, crossing each other so as to form a reticulated floor, abutted against the longitudinal beams; they were firmly spiked to the beams, and to each other, at all the intersections, and upon them was laid and spiked a longitudinal layer of Memel planking, 2 inches thick. Over the whole was fixed, transversely, a layer of slit battens, $1\frac{1}{4}$ inch thick. Each layer was close jointed and caulked, and the upper one was laid in a mixture of pitch and tar. A composition of fine gravel and sand, cemented with boiled gas tar, was laid over the whole, to the thickness of 1 inch, forming the road track.

To add to the stiffness afforded by this construction, the author caused to be passed through the spaces between the pairs of longitudinal beams, a series of diagonal truss pieces of Memel timber, 6 inches square, with their ends stepped into the cast-iron boxes, which, at every 10 feet, grasp the beams. On the other ends of these diagonal truss pieces, cast iron boxes were fixed, which received the straining pieces, placed 3 ft. 6 in. above, and the same depth below, the roadway: an iron screw bolt, $1\frac{1}{4}$ inch diameter, at every 10 feet, and a contrivance of wedges in the cast iron boxes, enabled any degree of tension to be given to the framing.

The roadway was thus stiffened by two of the strongest kinds of framing, in parallel lines, dividing the carriage way from the foot-paths; it was deemed preferable to disconnect them from the suspending rods, and, by bringing them nearer together, to avoid a twisting or unequal strain. The whole formed a compact mass of braced wood work, the diagonal planking giving the horizontal stiffness, and the two trussed frames insuring the vertical rigidity.

The weight of the new roadway was—	Tons.	Cwt.
Wood work	130	19
Cast and wrought iron about ditto	36	6
Wrought iron in the suspending rods	20	14
Ditto in the fencing	8	18
Gravel concrete	30	0
Total	226	17

Or 47.5 lb. per square foot, superficial, for the entire roadway.

* Minutes of proceedings, pages 167, and 204.

The weight of the original roadway was—	Tons.	Cwt.
Wood work	69	0
Cast iron about ditto	92	0
Wrought iron in the suspending rod	12	9
Gravel concrete	30	0
Total	203	9

Or 23 tons less than the new roadway.

Cost.—The platform described is 412 feet long, and 27 feet wide; it cost £4026 or about 7*s*. 3*d*. per superficial foot.

The works were completed in the summer of 1840; the bridge has borne without injury the gales of the last winter; and the stiffness of the platform has given confidence in its strength to all who have examined it.

Five elaborate drawings of the bridge, giving all the details of its construction on a large scale, accompanied this communication; they were presented by Mr. Page on his election as an Associate of the Institution.

Mr. Seaward agreed with Mr. Rendel in the advantage of reducing the number of suspension chains, and thus rendering the whole construction as simple as possible. The trussed framing, which appeared to be the main feature of this bridge, was particularly deserving of commendation, as it imparted a degree of stiffness to the platform which had not hitherto been attained in other cases, although it was demonstrated to be the best method of preventing the undulation which was so prejudicial to the suspension bridges.

Mr. Rendel had, on a previous occasion,* explained his view of the action of wind upon the platforms of suspension bridges, and of the necessity of a certain degree of stiffness in the construction; this he conceived would always be better attained by having a simple well-trussed framing to prevent undulation, than by the application of braces or stays to check either undulation or oscillation—the latter being in his opinion only the result of the former.

He would now only insist more forcibly upon those points. The roadway should be so stiff as to prevent as much as possible all tendency to motion, because it added to the natural decay of every part of the structures; for instance, he found on taking down the chain of the Montrose Bridge, after seven or eight years' wear, that the pins of the links were cut some depth into; demonstrating how great had been the amount of motion among the links. In constructing suspension chains, after this experience, he should be inclined to abandon the circular form for the pins, and forge them of a long oval shape in their transverse section; making the apertures in the links by drilling two holes, and cutting out the metal between them with a machine; this form of pin would allow sufficient play for the necessary curve of the chain, while the pin itself would be stronger, would weaken the link less than the large circular hole, and would be less expensive to manufacture. He disapproved of all the complicated contrivances for allowing expansion of the main chains; he had found that plain saddles of proper form were quite sufficient to permit the expansion of the back chains, which was all that required attention.

Mr. Palmer mentioned, on the authority of Mr. Chapman, the destruction of a suspension bridge in America, caused by the sudden passing of a drove of cattle when frightened. This was peculiar, as it always had been considered that an irregular motion was innocuous, but that when any regular impulses were communicated, there was danger of fracture of the bars.

Mr. Vignoles eulogized this excellent communication for the practical conclusions which it contained. Mr. Rendel had materially assisted in affording facility of communication by the introduction of the floating bridges, in communication with railways, and it was not difficult to foresee that, by carrying out the system of adapting well-trussed framings to the platforms of suspension bridges, sufficient rigidity would be attained for locomotive engines and carriages on railways, to traverse rivers or ravines by means of these bridges, instead of by costly viaducts or heavy embankments.

Mr. Rendel saw no difficulty in giving any required amount of rigidity to the platforms; it was only necessary to increase the strength of the framing, to enable the roadway to bear with perfect safety the passage of an engine and a train of carriages.

The President directed the attention of the members to what he considered the most valuable part of this interesting communication—the detection of the errors in the original construction of the bridge. This was the most useful class of papers which members could present to the Institution, and they were particularly valuable when they were illustrated by such complete drawings as those now communicated by Mr. Page on his election. He hoped this example would be extensively followed. He mentioned that an attempt had been made to carry a railway across the Tees by a suspension bridge, but it had been abandoned.

Mr. Rendel understood that the weight of the trains had so stretched the chains, or rather forced the moorings of the back chains of the bridge over the Tees, that the platform sunk in the centre so as to prevent the passage of the carriages; piles had therefore been driven beneath each bearer of the roadway, and the chains now remained merely to show that it had formerly been a suspension bridge.

May 4.—The PRESIDENT in the Chair.

"*Supplementary Account of the Use of auxiliary Steam Power, on board the 'Earl of Hardwicke' and the 'Vernon' Indiamen.*" By Samuel Seaward, M. Inst. C.E.

* Minutes of Proceedings, page 205

The advantage of the employment of auxiliary steam power, on board large sailing ships, had been shown by the author in a former paper (p. 63); it was now further exemplified by the result of the recent voyages of the "Earl of Hardwicke" and the "Vernon."

Earl of Hardwicke.—This vessel, of 1000 tons burthen, with one engine of 30-horse power, effected the voyage from Portsmouth to Calcutta in 110 days, a much longer time than usual; but still with an advantage of 29 days over the "Scotia," a fine vessel of 800 tons, which sailed one week before the "Hardwicke," and arrived 22 days after her. During the voyage, the "Hardwicke" used her engine 364 hours, and was propelled by it 946 knots; an average of nearly three knots per hour: while in a calm, with the ship steady, she made five knots per hour. The total consumption of fuel was 90 tons.

The "Vernon," which sailed one month after the "Hardwicke," made her passage to Calcutta in 97 days; passed the "Scotia," and arrived seven days before her, gaining 42 days upon her during the voyage. The "Vernon's" consumption of fuel was also 90 tons, but the copy of her log not being arrived, the number of hours during which steam was used, could not be ascertained.

The "India" steam ship, of 800 tons burthen, with engines of 300 horse power, had not arrived at Calcutta, although she had been out 109 days, so that the "Vernon," with only auxiliary steam power, had already gained 12 days upon her.

The comparison between the advantages of these two vessels, in point of expense, is then fully entered into, and shows a saving of £3733 in favour of the "Vernon," on a single voyage, while she gained at least 12 days upon the "India," in point of time.

This communication is accompanied by a copy of the log of the "Earl of Hardwicke," and by letters from the captains of that ship and the "Vernon," speaking in the highest terms of the assistance of the steam power in certain parts of the voyage."

"Description of an improved Levelling Staff, and a modification of the common Level." By Thomas Stevenson.

In enumerating the advantages of this improvement, the author passes in review the different levelling instruments in general use. He describes the self-reading staff as very useful, but ill adapted to the extreme accuracy generally necessary in the operation of levelling.—He considers the running level to be equally inadequate, from the difficulty of attaining a precise coincidence in the cross wires and the vane line.

On the authority of Mr. Simms, in his Treatise on Mathematical Instruments, he states that these evils are in some measure remedied by Mr. Gravatts' rod, but he still considers that instrument to be imperfect. He therefore caused a rod to be constructed by Mr. Adie, of Edinburgh, the vane of which is adjusted by tangent screws. The range of this staff is 12·7 feet, and the graduation so perfect as to be read by verniers to the $\frac{1}{1000}$th of a foot. On the right of the lower portion of the rod there is a screw, which, on being tightened, clamps the vane, and on the opposite side is the tangent screw for adjusting it. Supposing in practice that the level line strikes the lower half of the rod, the vane and screw are then easily moved by the hand to within ¼ inch of the point, and then, by means of the tangent screw, perfect correctness can be attained.

After having sent his communication to the Institution, the author learnt from the Secretary that adjusting screws had already been used in two other levelling staves by Captain Lloyd and by Mr. Bunt. He was not, however, aware of this circumstance, and he considers that these instruments being adapted only for scientific purposes, are hardly suitable for the ordinary use of the engineer.

Improved Level.—The author also introduced a ball and socket joint at the junction of the legs of the common level, retaining at the same time the parallel screw plates, and adding beneath a small sluggish spherical level. By these means the surveyor is enabled to station the instrument, regardless either of the inequalities of the ground, or of the inclination of the telescope to the horizon.

When in use the clamp of the ball and socket is released, and the head of the level moved until the bubble shall be in the middle of the circle; the socket screw is then clamped, and the telescope brought to the absolute level by means of the parallel screws. It becomes thus unnecessary to move the legs of the instrument when once fixed.

"An improved mode of Paving Streets." By Edward Lomax.

In this communication the author proposes to remedy the danger and difficulty of stopping or turning horses during wet or frosty weather on wood pavement. His plan is, that a breadth of 2 feet 6 inches, near each side of the street, should be paved with stone, for the horses to travel upon, the carriage wheels still running upon wood; by which means all the advantages of that kind of pavement would be preserved without risk to the horse. In very wide streets a centre track might also be paved with stone.

By this plan the labour of the horse would be greatly diminished, a consideration portion of his power being now lost, because the wood pavement is less favourable for the footing of the horse than for the motion of the wheels.

The author is therefore of opinion, that granite pavement for the horse to travel upon, and wood pavement for the wheel way, would form a road on which the horse would work with the least loss of power, and the greatest safety.

A model of the proposed improvement accompanied the paper.

"Specimens of Sea-weed used for sea defences."

Mr. Macneill presented three specimens of the Sea-weed with which the Sea Embankments are formed in some parts of Holland.—He described one of the specimens in its natural state as resembling the weed which is collected by the peasantry on the western and north-western shores of Ireland, and used by them for bedding.—The second specimen was taken from near the bottom of the embankment at Niewe Diep, the entrance of the grand canal near the Helder. It was much compressed, but elastic.—The third specimen was less compressed; it was taken from the same embankment, above the range of the ordinary neap tides.

This embankment is of considerable width, and has very little slope towards the sea: the work appeared extremely compact and solid; he saw it when a heavy sea was running in, and each action of the waves against it caused a vibration throughout the whole mass—thus proving the elasticity of the material when consolidated, and corroborating the Hon. Mr. Stewart's description of the same effect upon the peat sod embankments, in a paper shortly to be laid before the Institution. Mr. Macneill spoke with confidence of the efficiency of the peat sod for sea defenees, as he had used it with good effect, although at present only to a limited extent.

The attention of the Members of the Institution was especially directed to the sea embankments of Holland, as affording excellent study and ample materials for communications for the meetings.

On Lead Sheathing for Ships. By J. J. Wilkinson.

The commencement of this communication, which is the continuation of the paper on the "Wood sheathing of Ships," which was read March 23rd (page 318), examines in great detail the various uses to which metals were put in the earliest period of which any record exists, and then it traces the first application of lead to the protection of shipping.

There are very early instances of ships and vessels being covered with lead. In the 15th century, a boat, 30 feet in length, was found in the Mediterranean sunk in 12 fathoms water; it was built of cypress and larch. The deck was covered with paper and linen, and over all with plates of lead, fastened with gilt nails; this covering proved so impervious to moisture, that parts of the interior were perfectly dry. It is supposed to have lain there above 1400 years. A Roman ship was also found sunk in the Lake of Nemi. The hull was of larch; bitumen had been applied to the outside, over which was a coating of a reddish colour, and the whole covered with sheets of lead, fastened by gilt nails. The interior had a thick coating of cement made of iron and clay. The seams of the planks were caulked with tow and pitch.

Some of the ancient domes at Ephesus were sheathed with lead, and it appears that the column of Constantine at Constantinople was formerly covered with metal.

It is certain that lead mines were worked in Britain by the Romans; and long before the Conquest, plates of lead were used as coverings for ecclesiastical buildings. These coverings being designed to endure, were of very thick lead.

Water pipes.—In 1231, water was brought from Tyburn to London in pipes; but the material of the pipes has not been ascertained. In 1285, the great conduit in Cheapside was supplied with water conveyed through pipes from Paddington; these pipes are expressly stated to have been of lead. It has, however, been averred, that lead pipes for conveying water were first introduced by Robert Brook, in the reign of Henry the Eighth.

Sheet lead was used in Spain and Portugal for sheathing ships, and for covering the rudders, long before it was employed in England. It was used in Holland in 1666, and at Venice in 1710.—It is probable that we are indebted to Sebastian Cabot for its introduction into England; it is stated in his Memoirs that he first saw it used in 1514; he was then in the service of the king of Spain, which he entered in 1512, and was appointed pilot major; he afterwards returned to England, and in 1553 was named by Queen Mary, "Governor of the Mysterie and Company of Merchant Adventurers, for the discovery of Regions, Dominions, Islands, and Places, unknown."—Three vessels were fitted out for this purpose, under the command of Sir Hugh Willoughby, one of which was sheathed, or at least partly so, with thin plates of lead, then first mentioned as an "ingenious invention." This expedition was unfortunate—Sir Hugh Willoughby, with the crew of two of his ships, being frozen to death; one of the commanders, and his crew, alone escaped. This expedition was the origin of the trade to Russia, and of the Spitzbergen Whale Fishery.

In the reign of Elizabeth a patent was granted to one Humphrey, for melting lead, but was afterwards recalled, the plan not being new.

Milled lead.—It appears that, up to about 1670, cast sheet lead was used for sheathing; at that time milled lead was invented, and a patent for milling lead was granted to Sir Philip Howard and Francis Watson; by this process the inequalities, as well as the defects from air holes, in the former mode of manufacture, were remedied; the whole surface was rendered smooth and uniform, and the weight greatly reduced. This invention met with much opposition from the plumbers, who averred that it could not be durable; an offer was therefore made on the part of the Milled Lead Company, to keep in repair during 41 years all milled lead of the weight of 7 lb. per square foot, at the rate of five shillings annually per each hundred pounds worth in value.—One of the earliest vessels in the royal navy thus sheathed, was the Phœnix, a fourth rate. This was done at the express command of Charles II. This vessel made two voyages to the Straits, apparently for the express purpose of testing the new invention, and on her return in 1673, was careened at Deptford, and personally inspected by the King. An order was then issued that his Majesty's ships should in future be sheathed only with lead, excepting by especial order from the Navy Board. It appears that about 20 ships of the royal navy were consequently sheathed with milled lead, and fastened with copper nails.—Even the royal protection could not save this invention from cavillers, so that, in 1677 and 1678, complaints were made by Sir John Narborough and Sir John Kempthorne, that the rudder irons of the Plymouth and the Dreadnought were so much eaten, as to render it unsafe for those vessels to proceed to sea; these complaints were repeated in 1682.—The patentees maintained, on the contrary, that the damage to the rudder irons could not possibly arise from their being covered with lead, as it had been the invariable practice for a great many years, to secure the iron work of ships, generally, by lead covering, and especially by capping the heads of their bolts, under water, with lead, seized to and nailed over them. Reports too in favour of the invention were made by Sir Phineas Pett, and by Mr. Betts, master builder, at Portsmouth, in which the latter stated, that lead had effectually prevented the vessels becoming what is technically termed "iron-sick," meaning that the bolt-holes became so widened by corrosion, that the bolts were loosened; he recommended, however, that the lead sheathing should be stripped every seven years, on account of the decay of the oakum in the joints; declaring, too, that it became less foul on the voyage than wood sheathing, and was much more easily cleaned. These different opinions led to the issue of an Order in Council in 1682, for the appointment of commissioners to examine and report upon the alleged injury to the iron work by milled lead covering: it is probable their report was unfavourable, as it is said that the use of lead covering, fastened with copper nails, was abandoned on account of the rapid corrosion of the rudder irons. A controversy appears to have arisen on this subject, the merits of which it would be difficult to ascertain after such a lapse of years. Government, however, subsequently determined to make another trial of the value of lead covering; accordingly, the Marlborough was so sheathed, and laid up in ordinary, at Sheerness. A few years after, she was docked, at Chatham, in 1770, when it was found that the lead sheathing was covered with weeds, and the iron fastenings very much decayed: the lead was in consequence removed, and a wood sheathing substituted.

Mixture of metals.—Several patents were afterwards obtained for different mixtures of metal for this purpose, none of which seem to have succeeded, being all subject to the same inconveniences as the simple metal: among which was the influence of the sun in the torrid zone, which was said to reduce the lead, in the course of five or six years, to a calx.—Among these patents, for mixed metals for sheathing, is mentioned that of Mr. Bulteel, in 1693; it was found to have all the inconveniences of lead. Mr. Donithorne, in 1780, obtained a patent for sheathing, of a mixture of 112 parts of tin to 10 parts of zinc; this was also as objectionable as lead.—Slade's patent for sheathing with copper laid upon lead, and the patents of Wetterstedt, and of Muntz, for mixed metals, are examined; and the author promises a continuation of the subject, with the history of copper sheathing.

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

Eleventh Meeting, 1841.

(From the reports of the Athenæum.)

"*On Truscott's plan for Reefing Paddle Wheels.*"

Mr. Chatfield described, by reference to a model, an improved paddle-wheel, the principal feature of which was a new application of the principle of feathering and reefing. Each paddle or float is attached to an axis passing through its centre, with a crank at the extremity of the axis, and the feathering is effected by the motion of a roller attached to this crank, and moving in a groove eccentric to the wheels. The radii of the paddle wheel are connected at their extremities by a chain instead of a rigid rim, and the reefing is effected by drawing the radii together, like the folding of a fan, by means of a peculiar arrangement of the clutch box at the centre of the wheel.

"*On a Plan of Disengaging and Reconnecting the Paddle Wheels of Steam Engines.* By J. Grantham.

There are four cases in which it may be desirable to disconnect the paddle wheels from the steam engine in steam vessels, viz., when the vessel is on a long voyage, and the fuel must be economized as much as possible by using the sails on every favourable opportunity; when the engines are damaged, and, the vessel being close to a lee shore, it is necessary to disengage the engines quickly, to allow the vessel to make sail; when some derangement has taken place, and the engines are allowed to continue to work imperfectly to the end of the voyage, rather than detain the vessel by causing the paddles to drag through the water while the engines are stopped; when, the vessel being at anchor, the action of the swell and tide on the paddle floats, while stationary, causes a great additional strain on the cables, which would be obviated could the wheels play freely. The Admiralty had called attention to the subject, by inviting plans for effecting it. Several had been proposed for disconnecting the paddles, but Mr. Grantham is not aware of any plan having been proposed by which the wheels could be readily reconnected in a heavy sea. The crank pins are usually fixed in the cranks of the intermediate shaft, a little play being allowed in the eye of the crank of the paddle shaft, to prevent the crank pins from breaking when the centres of the three shafts vary from a straight line by the yielding of the vessel. For the purpose of disengaging and reconnecting, a brass box of a rectangular form is inserted in the eye of the crank of the paddle shaft, which can be moved several inches by means of a screw at the back of the crank. The eye of the crank is so made that two of its sides may be cut away, and through these openings the crank pin can pass when the box is drawn back, or the disengaging effected. The brass box has one of its sides, which restrain the crank pin when in gear, cut away one or two inches to assist in reconnecting the engine, which is effected by screwing the box out one or two inches, or just so far that the crank pin can pass the side which has been cut away, and come in contact with the higher side. This is the correct position for reconnecting, which is accomplished by a single turn of the screw.

Mr. Grantham, in reply to a question from Capt. Taylor, R.N., stated that he should consider it very dangerous to disconnect the paddle wheels without having first stopped the engine.

"*On the Propulsion of Vessels by the Trapezium Paddle-wheel and Screw.*"

Mr. G. Rennie gave an account of the various experiments to which he had been led, on the propulsion of vessels by various forms of paddle floats and by the screw. It was generally admitted that the paddle wheel was the best means of propulsion with which engineers were at present acquainted, and various attempts had been made for its improvement. There are several objections to the square or rectangular floats, particularly the shock on entering the water, and the drag against the motion of the wheel on the float quitting the water; both of which give rise to considerable vibrations. He had been led, in considering the improvement of the paddle wheel, to have recourse to nature: and the form of the foot of the duck had particularly attracted his attention. The web of the duck's foot is shaped so that each part has a relation to the space through which it has to move, that is, to the distance from the centre of motion of the animal's leg. Hence he was led to cut off the angles of the rectangular floats, and he found that the resistance to the wheel through the water was not diminished. Pursuing these observations and experiments, he was led to adopt a float of a trapezium or diamond shape, with its most pointed end downwards. These floats enter the water with their points downwards, and quit it with their points upwards, and then arrive gradually at their full horizontal action, without shocks or vibrations; and after their full horizontal action, quit the water without lifting it, or producing any sensible commotion behind. After a great variety of experiments, he found that a paddle wheel of one half the width and weight, and with trapezium floats, was as effective in propelling a vessel as a wheel of double the width and weight with the ordinary rectangular floats. The Admiralty had permitted him to fit Her Majesty's steam ship *African* with these wheels, and he had perfect confidence in the success of the experiment. Another means of propulsion was the screw, which had been applied with success by Mr. Smith in the *Archimedes.* In examining the wings of birds and the tails of swift fish, he had been particularly struck with the adaptation of shape to the speed of the animals. The contrast between the shape of the tail of the cod-fish, a slow moving fish, and the tail of the mackerel, a rapid fish, was very remarkable,—the latter going off much more rapidly to a point than the former. From these observations he was led to try a screw with four wings, of a shape somewhat similar to these, but bent into a conical surface, the outline being a logarithmic spiral. He found also that certain portions of these might be cut off without diminishing the effect. With respect to ascertaining the friction of the screw on the water, great difficulty existed; but he would refer to his experiments, published some years ago in the Philosophical Transactions, in which he measured the friction of the water against a body revolving in it, by the time which a given weight took to descend; this body consisted of rings, and he found that the friction or resistance through the water did not increase in proportion to the number of rings.

"*On a Floating Breakwater.*" By Capt. Taylor, R.N.

The breakwaters hitherto constructed have generally consisted of solid masonry, thus presenting an unyielding obstacle to the waves, and permitting accumulations of mud and sand behind them, and not affording the security to shipping and life which is required, and may be afforded by other means. The floating breakwater consists of floating sections framed of timber, moored to piles; these sections yield to the shocks of the sea, and admit the wave to pass under, over, and through them, and by thus dividing the waves, reduce them to an open and harmless state. The forms of these sections vary according to the situations in which they are employed. The sea in the most tempestuous weather is said to be tranquil at the depth of sixteen or eighteen feet below the surface; a breakwater, therefore, immerged to that depth, and presenting six or eight feet above the surface, is sufficient to form a safe harbour on the most boisterous coast. The angle of inclination which the section presents to the wave is that pointed out by nature in the Mew-stone, viz. 35 degrees. Stone breakwaters check the ground tides, and cause accumulations of mud and deposits which otherwise would go seaward, and are peculiarly subject to the action of the teredo, constantly at work below the dove-tailed stone; and cavities being formed, large portions are occasionally blown up. The destruction by the teredo may be obviated or arrested in the floating breakwater by tarring the wood with a preservative mixture, or by restoring from time to time such portions as are injured. The distinction between waves and breakers is very important, the former being an undulation, the latter being accompanied with a translation of the mass, and capable therefore of exerting extraordinary forces on the masses opposed to them.

Some remarks were made on statements in another Section, respecting the destruction to which the limestone of which the Plymouth Breakwater is exposed from certain animals (*Saxicava rugosa*). These animals do not, however, meddle with granite, and probably timber payed over with hot tar would resist their ravages, as animals of this nature seem peculiarly averse to the smell of tar and similar substances.

"On Forms of Vessels."

Mr. Scott Russell reported the progress made by "the Committee on Forms of Vessels" during the past year. The object of the experiments is two-fold —to advance our knowledge of the laws of resistance of fluids,—and to obtain data for the practical improvement of the art of naval construction. Many and expensive are the experiments formerly made on this subject. Unfortunately, these experiments had been made with imperfect apparatus, or under circumstances different from the conditions of bodies moving on the surface of the water, or on solids of a form unsuitable to the formation of ships, or on so small a scale as to render them unworthy of the confidence of the practical constructor. In the present series of experiments a more simple apparatus was employed than in any former series of experiments. The forms of body experimented upon were those of actual ships, or bodies analogous to those in use: it was the object of the experiments to supply the actual desiderata of hydrodynamics and of practical ship building. The experiments were made on vessels of every size, from models of 30 inches in length to vessels of 1,300 tons. The experiments were also made upon vessels in water of variable depth and in channels of various dimensions, so as, if possible, to embrace all the elements of the resistance. A minute description of some of the apparatus was then given, along with some general illustrations; but as the experiments were still in progress, and to be continued during the following year, no general statement of results was entered into at the present meeting. It was expected that by the next meeting the whole would be concluded.

"On Captain Couch's Chock Channels."

Mr. Snow Harris explained and illustrated, by a model and drawings, the safety chock channel, for allowing the masts and rigging of vessels to be easily disengaged when the masts are carried away. Many cases have occurred in which, with the rigging and ordinary channels, the greatest danger has been incurred, in consequence of not being able to get clear of wreck. The ordinary channels may be blown up by the sea; whereas, if made solid, on Capt. Couch's plan, all danger from this source will be avoided, and the sailors would be at once able to clear the vessel of any wreck.

"On Arnott's Stove, and the Construction of Descending Flues, and their Application to the purposes of Ventilation." By J. N. Hearder.

The general advantages of Arnott's stoves in economizing fuel, avoiding smoke, and regulating the temperature, are well known; but these stoves are attended with some disadvantages, of which the danger of explosion, and imperfect ventilation, are the most serious. The liability to explosion, Mr. Hearder considers to arise from the construction of the stove, in having the door air-tight; the only aperture for air being the valve aperture of the ash-pit. The air so admitted is immediately decomposed, and nearly the whole of its oxygen is abstracted, so that by the time it has passed up through the fuel, and reached the upper chamber of the stove, it has not oxygen enough left to support combustion. The heat evolved by the lower stratum of fuel, acting upon the upper stratum of fresh or unignited fuel, liberates from it the inflammable gas which it contains, and which also accumulates in the top of the stove. A mixture is then formed analogous to the fire damp of coal mines, ready for explosion whenever the requisite oxygen or degree of temperature shall be present. Under these circumstances, should the door be opened, a burst of flame outwards may be the result; or should a puff of wind down the chimney carry the mixture down through the ignited fuel, an explosion may ensue. Other causes, such as the sudden shutting or opening of the doorofan apartment, may occasion the downward draught and consequent explosion. Now carburetted hydrogen will not explode when the proportion of the air to the hydrogen exceeds a certain limit, so that if air be supplied to the top of the stove, so as greatly to preponderate over the hydrogen, the latter will burn off in a flame at the moment of its formation, or be carried up the flue. Mr. Hearder, therefore, proposes as a remedy, perforations through the lower edge of the door, so that air may be admitted on a level with the top edge of the fire brick, through which a constant in-draught of atmospheric air will be insured, sufficient to obviate the evil. The heat evolved by the perfect combustion of this inflammable gas, under these circumstances, will, he says, more than compensate for the admission of cold air into the upper part of the stove. The perforations just mentioned will also obviate, in a great measure, the want of ventilation. The author suggests a small rarefying apparatus, to be inserted in the vertical shaft connected with a descending flue.

"Some Experiments showing the possibility of Fire, from the use of Hot Water in warming Buildings, and of Explosions in Steam Engine Boilers." By Mr. Goldsworthy Gurney.

After detailing several instances of fire which arose from the steam pipes of water apparatus used for warming houses, the author proceeds to describe some of the experiments likely to be of practical value. From a tubular boiler, driving a high pressure engine, the injection pump was cut off—half an hour after the supply pump was stopped, no water appeared on opening the gauge cocks, and the engine was observed to slacken its rate and to move sluggishly—it had dropped from 50 to 30 strokes a minute. The steam pipe from the boiler to the engine was 10 feet long, and was carried for convenience through the open air, thickly wrapped round with woollen cloth to prevent radiation: soon after the engine became sluggish, the woollen cloth was observed to char near the boiler, which soon extended along the whole length of pipe; the engine still working, but with more apparent difficulty, making only 16 strokes per minute; the pressure gauge, which usually ranged between 30 and 40 pounds, now stood at 15, and was gradually sinking. In about five minutes after the woollen cloth had charred, a lead flange, used as a packing at the cylinder joint, melted, and was followed by a loud escape of elastic matter. The engine stopped working, and on bringing a lighted match into the escapage, it took fire, and burnt with the lambent flame of hydrogen gas. The author's impression was, that the escaping vapour was not pure hydrogen. Water condensed on a piece of cold iron held in the flame, but no water condensed on the cold iron after the flame was extinguished. On examining the boiler, all the tubes were found red hot. This experiment was repeated with many modifications. The temperature of the escaping vapour was ascertained by means of bars, previously prepared to melt at different temperatures; these indicated a temperature of about 400°. In about eight minutes a piece of pure lead melted—woollen cloth was charred, and a piece of tow held in the escapage took fire. In other experiments it was found, that the pipes became sufficiently hot to explode gunpowder, and many chemical preparations. Having satisfied himself of this property of heated steam or elastic matter, formed from the last portions of water in a boiler, the author proceeded to examine, as far as possible, its chemical nature—to determine whether any decomposition, or new elementary formation, took place. He found that the elastic matter was not condensible over cold water, and would not in many cases burn, or show any indications of the presence of hydrogen, or other inflammable matters. In some experiments it was found it would extinguish flame. The experiments with copper vessels afforded the same results as those manufactured from iron. From these experiments it appeared, that whenever the heating apparatus falls short of water, the elastic matter formed over the fire will carry sufficient heat through close pipes, to any distance, to set fire to wood and other combustible bodies, and that whether the hot water apparatus be under pressure or not, or whether the heating surface be of tubes, plates, or cylinders. On the other hand it would further appear, from some experiments enumerated, that in no case is there danger when a given quantity of water is present. Mr. Gurney suggests, that if both ends of the circulating series in hot water apparatus, namely, the part which immediately goes from the heating surface beyond the furnace, and that part where the circulation returns to it before it enters the furnace, was made of a metal which would not melt at the fair working temperature of the water, but which would melt at a temperature of from 5 to 600° of heat (say lead pipe), there would be little, if any, danger from fire.

It was mentioned that some experiments made many years since, by Woolfe, on some of the boilers of the Cornish steam engines, corroborated the facts now stated. It was also mentioned by Mr. Hunt, on the authority of Capt. Tregaskis, that where the boilers had been covered with sawdust, it was found in some instances, and in a very short time, to be charred.

"Account of the Strata penetrated in sinking an Artesian Well at the Victoria Spa, Plymouth." By Dr. Edward Moore.

The author pointed out the mode by which the operations were conducted. The strata penetrated were as follows:—Earthy clay slate, 20 feet; limestone, 150; blue slate, 20; red sandstone, 3; red slate, 37; limestone, 50; sandstone, 4; red and blue slate, 30; dunstone, 8; earthy clay slate, 20; red sandstone, 12; making a total of 365 feet. The earthy slates were of the character of those generally found under the limestone, but they were interspersed with blue shillat slates, similar to those which occur above it. From the circumstance of the slate rocks immediately below the red sandstone being in each instance tinged red, the author imagined that their colour might in these cases, if not in all, arise from the iron of the red bands affecting them by percolation. He next remarked that from the alternations of slate and limestone, the former appearing, from a consideration of the section, to come up in wedges through the latter, it might be possible that the opinion that some of the Plymouth limestones might have been formed in a manner analogous to the modern coral reefs, was founded on correct data, although in many other localities in the vicinity the bands belong to the same uninterrupted series of deposits. The quantity of water obtained was at first considerable, and overflowed the pipe; at present it generally remains about two feet below the surface, from whence it is carried to the saloon by a pump; it is clear and sparkling, and of a saline taste; it has been examined by Professors Faraday and Daniell, and found to contain in the imperial pint 8·100 cubic inches of carbonic acid gas, and 151·66 grains of dry salts, thus:—

Chloride of Sodium	96·64
Muriate of Magnesia	18·68
,, ,, Lime	15·10
Sulphate of Soda	9·55
,, ,, Lime	8·94
Carbonate of Lime	2·06
,, ,, Iron	0·69
	151·66

Its specific gravity at 62° is 1013·3.

Prof. Sedgwick, after reviewing the general principle of Artesian wells, described two districts in which these operations were attended with very different results. In the eastern part of Essex the chalk is covered by sandy beds of the plastic clay, and these by several hundred feet of impervious strata of London clay, all dipping together towards the east. The arenaceous beds below the London clay rise higher towards the chalk than the clay does, and absorbs a considerable part of the water from the high grounds. By boring through the clays to this sand, springs of water immediately rise above the surface, and are carried off by natural channels. By this supply of water, the value of the land has been materially increased, since the country, though abounding in peat bogs, and stagnant ponds during winter, suffers much from the summer drought. The other attempts to form Artesian wells, referred to by Mr. Sedgwick, were made near Lincoln, which, though surrounded by fens, covered with water in the winter, is not sufficiently supplied during the summer. But the clays supporting the fens of the Bedford Level are below the chalk, and though there are pervious beds beneath them, which rise to the north-west, yet the clays are of such enormous thickness that they have never been penetrated; and even were that accomplished, the high land is so distant that intervening fissures, filled up with impervious materials, might intercept the supply. Expensive sinkings have been made at Lynn, and also at Boston, and after boring through many hundred feet of clay they have utterly failed, and in any future operations in this district the chance of success would be very remote. Mr. Sedgwick then observed with respect to the red colour of rocks mentioned by Dr. Moore, that he considered it simply owing to the red oxide of iron which might be present or not in any bed; sometimes the tinge was only superficial. In Nassau the red colour was owing to vicinity of trap rocks. He also observed, as to the condition of limestone rocks, that although they sometimes appear in masses, presenting a brecciated appearance, shells and broken corals being cemented together, yet generally they occur as regular parts of the series repeated without any regularity, in formations of all ages. In position and inclination they resembled their associated rocks, and partook in all their contortions and dislocations, except so far as their solid masses would resist mechanical movements, better than yielding deposits of sediment and mud. The organic remains found in limestones only differed from those in the other beds of the same age as far as the conditions differed under which each was deposited. At the present day different families of corals grow upon a solid and a soft bottom.—The Rev. W. D. Conybeare pointed out the similarity between Artesian wells and mines sunk in the coal measures. Artesian borings had been made with success near the outcrop of certain strata, but at a distance from this, although the combination of strata was the same, they had failed, from the great depth necessary to be penetrated. Now it is certain that the coal exists in many places beneath the new red sandstone and magnesian limestone, but at such depths that it would be hopeless to attempt to reach it. He therefore recommended to the attention of miners the formation of a series of Artesian borings in some of the coal districts, beginning where the probability was greatest, and proceeding from that point till the depth became too great. Such a series of experiments would show the nature and depth of the strata below, and over what extent coal might be worked without sinking shafts at enormous expense and with the risk of complete failure.—Mr. Bartlett observed, in confirmation of one of Dr. Moore's remarks, that where limestones abounded in corals, as at Berryhead, their structure was homogeneous, and exhibited little trace of stratification; when the corals were rare, the bedding became distinct.

"*Some Inquiries into the Causes of the increased Destructibility of Modern Copper Sheathing.*" By Mr. Prideaux.

In May 1840 Mr. Prideaux was applied to by Mr. Owen, of Her Majesty's dock-yard, to analyse some sheet copper from the sheathing of the *Sanspareil*, which had been on thirty years, and was still in good condition. The sample gave about 0·25 per cent. of alloy, chiefly zinc and tin. This contrasted well with a sample rendered unserviceable in a very short time (in only one year), and in which no quantity of alloy sufficient to weigh had been found; and the two agreed with two recorded analyses of Sir H. Davy and Mr. R. Phillips, the former having detected, in a very good sample of sheathing, about $\frac{1}{400}$ of tin; the latter having found the sheathing of the *Tartar* frigate (almost destroyed in four years, though never out of Sheerness harbour,) the purest copper he had ever analysed; and further with the reputed inferiority of the recently prepared sheathing of the Royal Navy, which must have been much purified by the repeated fusions it has undergone. The inference adduced was, that the presence of tin and zinc was favourable to the durability of the copper. Mr. Prideaux, however, proceeded with the analyses in other cases. Four were selected, viz.

From the	Copper on	Annual loss.
Minden	17 years	0·45 per cent.
Plover	only 5	11

Linnet, copper rapidly destroyed, could not be taken off sound enough to weigh a sheet.

New-sheathing prepared at Her Majesty's mills, Portsmouth.

There was no conformity between the results in these and the former experiments; they did not show any coincidence between the composition of the sheathing and its durability. The next step, therefore, was to examine how far it might be referred to any of the physical properties of the metal. To ascertain this, slips from each sample, all of equal surfaces (4 + 0·5 inch), were immersed each in a pint of sea water: the five vessels being placed side by side, so as to set them all in like conditions. Sea-water being electro-neutral, and acting *slowly* on copper, a little sal-ammoniac was added, to quicken the action without affecting the neutrality. The greatest waste was on the *Sanspareil'* copper, which had worn the best of all; the least on that of the *Plover*, one of the worst. Thus, in the laboratory, under parallel circumstances, they do not observe the same order of durability and waste as they had done in use. The cause of comparative waste appears, therefore, to be in part at least, due to *external conditions*, and of these two classes may be noticed: one depending on the connexion with the ship, the other on the circumstances of her employment. Of the first class two suggested themselves—the position on the ship's side, and the nails by which the copper is fastened. The lower part of a ship's copper seems to suffer much less than the upper, so long as she continues in deep water; but when she grounds at low water, if on black mud, this part suffers most from the action of sulphuretted hydrogen, peeling off in blue flakes. The influence of the nails offers rather more chemical interest. They are never of pure copper, and being very numerous, all in contact with the copper sheets, whilst their heads present also a considerable metallic surface to the salt water, they may produce very decided effects, either preservative or destructive, by a slight electro-chemical difference. Mr. Prideaux therefore examined a vessel which they were just then stripping, her copper being worn out in four years. It was found that round some of the nails the copper was quite entire, for an inch or two, though worn ragged in other parts; whilst elsewhere, and sometimes on the same sheet, the copper round other nails was quite gone, though other fragments of the sheet remained. Here some of the nails appeared to have exerted a protective, others a destructive influence. To ascertain the effect of the nails, five slips of new copper from the same sheet, and of the same size, were suspended equidistant, and at the same depth, in a vessel of sea water from the West Indies. The result was, that all the nails, except one (which was from Her Majesty's dockyard), appeared to act destructively. Here appears to be *one* instance of a protective nail, not enough so to prevent all waste of the copper, which experience has shown not to be desirable; but doubtless the preservative power may be increased to any requisite degree by attending to the composition of the alloy. The copper is alloyed chiefly with tin; but if the nail is at once hard and flexible the manufacturer is satisfied without examining what other metals are present. If they were always made just so much electro-positive to the copper as to protect the sheathing, so far as compatible with their own durability, they would seem to offer the simplest, most perfect, and most convenient means of electro-chemical protection. The damage to which the copper is subjected is affected by the circumstances of the ship's employment. Sheathing suffers most where most subject to wash and air, for friction is an agent in the waste as well as oxidation. It is also well ascertained that the copper sheathing suffers most in hot climates, which might be expected, upon a common chemical principle, that chemical action increases with the temperature; and it became a question whether this effect of heat, as well as its tendency to promote organic production and decomposition, might not form an important element in this destructive agency. Mr. Prideaux therefore obtained water from different parts of the Gulf Stream, with and without the weed, from the Caribbean Sea, and from Falmouth harbour, where the packets moored, the waters of which might possibly be affected by the mine drainings discharged into the river. Whilst these were being collected, Prof. Daniell's announcement of large quantities of sulphuretted hydrogen in the waters of the Guinea coast came before the public. To try the action of these different waters five copper slips, of the same dimensions, cut from the same sheet, were suspended in a pint each of the following samples of water:

1. Heart of the Gulf Stream.
2. Ditto with the weed.
3. Caribbean Sea.
4. Falmouth harbour.
5. Plymouth harbour.

After thirteen days they were taken out and reweighed, having been put in all bright, but cleaned, on taking out, only with a brush in soft water, as in the other experiments:—

	1.	2.	3.	4.	5.
Put in 16th........	180·26	182·56	190	169·01	176·41
Out 29th	178·45	182·3	189·6	168·55	176·1
Loss in 13 days....	1·81	0·26	0·4	0·46	0·31

No. 1, came out clean and bright, the others with tarnished surfaces, except No. 2, which was blotched and speckled. The Falmouth water presented no indications of being more corrosive than that of Plymouth, and Mr. Prideaux attributed the great difference of waste in these two cases to same unobserved difference of conditions in the experiment. But the excessive action of the Gulf Stream water, he considered too decided to be doubtful. Not only the quantity wasted, but the metallic clearness of the surface, showed a marked distinction. "But to whatever extent the recently increased waste of sheathing may fairly be charged upon the greater velocity, more constant employment, and greater consequent liabilities of weather and climate of our ships, particularly of the commercial classes, as well as to difference in the nails, I am inclined," said Mr. Prideaux, "to fear the fault is still to be sought in the copper itself. I have it on the authority of Mr. Moore, that the *Quarantine* cutter, generally at anchor in our harbour, was coppered in October 1832, and her copper is now in a very good state. Her last sheathing held good 14 years. The Eddystone tender, which also moors in Catwater, was coppered in July 1838, and is now in much worse condition than the *Quarantine*, which has been on six years longer. That the waste on the Eddystone tender is not owing to her work, is evident, from the fact, that the upper part of her sheathing, which suffers the wash and friction, continues sound, whilst from beneath her floor the copper peels off in blue flakes. That this is attributable, in a great degree, to her occasionally grounding upon the black mud, which generates sulphuretted hydrogen and other corrosive matters, is very probable; the other never grounds, and does less work. Yet the difference is too great to be thus satisfactorily accounted for. The one is in good condition for nine years, the other comes to patch before the end of three: both lying the most of their time in the same harbour. On neither was there any distinct indication of protective or destructive influence in the nails." "Meanwhile, as nails must be used, and present a large metallic surface to the salt water, as well as numerous points of contact with the copper, calculated to give great effect to small electro-chemical differences, either in protection or destruction, it would seem that we ought to render them slightly electro-positive to rolled copper, by the addition of zinc, which would not injure their flexibility nor enhance their cost. The test, by the galvanometer, would be easily applied (after a little practice) in making up the metal for casting them, if it is of importance to continue the present system of their manufacture."

There is another method of protection, which came out in the course of these investigations; and which is beginning to occupy public attention. It was before noticed, that the upper part of the copper on the Eddystone tender, which bears the wash and friction of the waves, continues sound; whilst the bottom is fast wearing out. This exception, or rather subversion of the usual conditions, is owing to a coat of fish oil, laid on when the copper was new, to keep it bright; and not extended over the parts out of sight. Such a permanent effect could never have been anticipated from an oil which is not drying, and strongly indicates the facility, as well as efficacy, of this mode of protection. A still more striking case presented itself in the vessel which supplied the observations on the apparent influence of the nails. During our examination, we observed the complete preservative effect of some coal tar, which had trickled down over the copper, from the wood-work above. This had crossed the sheets just where most subject to the wash and friction; and whilst the naked metal had been quite worn away, the coal-tarred streaks remained entire, the surface of the copper, on melting off the tar, being as perfect as when fresh from the roll. Hence coal tar seemed to be an efficient preservative; but then recurs the question—will it keep a clean surface, free from organic adhesions and earthy incrustations? To embrace the opportunity for experiments, the vessel was sheathed with copper on one side and yellow metal on the other; and her fore-quarters to her mid-length varnished with coal tar, laid on hot, upon the metal also heated, by fires of chips round the sides. She has now been twelve months at sea; and, according to the last account, the varnished as well as the metallic surfaces, kept quite clean.

METHOD OF PREVENTING THE OXYDATION OF IRON.

By M. F. L. Allamand.

This composition, of a metallic nature, preserves iron and steel from oxydation, by entering into the pores without in any degree affecting their external appearance, or leaving the least blemish, so that steel instruments (including razors), fire-arms, &c., retain their polish, and are in some degree better fit for use, after having been subjected to the metallic application. Articles either plain or chased appear superior to platina, and retain, after the application, all the hieroglyphic characters, figures, letters, and other engravings, or cuttings, which were there previously.

COMPOSITION OF THE MATERIAL.

Pure Malacca Tin	120
Silver filings	4
Yellow tincal	12
Purified Bismuth	12
Purified Zinc	12
Regulus of Antimony	4
Nitre	11
Salt of Persicaria	1

Method of Purifying the Metals.—The tin ought to be melted separately 18 times. Each melting should remain about 20 minutes exposed to the action of caloric, and the impurities which arise on the surface should be carefully removed; it is thrown afterwards into a ley formed of vine twigs and persicaria (herb) in equal proportions. The bismuth, the regulus of antimony, and the zinc are also melted separately, but they only require it twice, and they are carefully run into an ingot mould, so that all impurities may remain at the bottom of the crucible. The tincal does not require any purification.

Mixture of the different substances.—The tin is the first material that is melted; the silver is afterwards added to it in small quantities, and in a few minutes afterwards the tincal, then the bismuth and the zinc in succession. As soon as it ascertained by the flames that the alloy is effected, the two kinds of salt are thrown in together, and are left to burn with vigour, and the alloy is stirred with an iron rod; after which it is carefully skimmed and poured into a vessel, to be made use of for the metallic application.

Method of applying the substance.—Before the piece of iron or steel is dipped in the recipient which contains the metallic mass already liquified, its surface must be rubbed well with a composition of sal-ammoniac and cream of tartar, in the proportion of 5 per cent. of tartar to the sal-ammoniac; the iron must then be dipped in the melted alloy, where it must remain only for a few seconds, and till it is perceived to be covered with a certain quantity of the metal. It is next placed in a wooden box of its own size, and in which there has been previously put a small quantity of sal-ammoniac and cream of tartar, in the proportions already indicated. It is again rubbed with a handful of tow, and a small quantity of the powder is put on the surface. In the course of this operation the steel loses its colour, and assumes that of silver. When this is done it is again plunged into the metallic mass for a few seconds, and when it is taken out it is again lightly rubbed with the tow to remove any superfluous particles. The article being perfectly clean and shining, it is plunged into a basin of cold water, into which there has been poured a bottle of spirits of wine of forty degrees of strength, in the proportion of ½ per cent. After having withdrawn it from the water, the article is rubbed carefully with a linen, then it is rubbed as carefully with some fine sand, that has been moistened, to remove the spots of smoke: it is at last rubbed a second time with dry sand, then with a linen, and finally with a leather. After all these operations, which require great celerity in the execution, the iron will remain impervious to oxygen, and by care it will preserve all its whiteness.—*Inventors' Advocate.*

APPARATUS FOR DISTILLING SEA WATER.

We have seen in operation, at Mr. Robinson's manufactory, Pimlico, an apparatus for evaporating water in large quantities. An authentic account of the apparatus has been given in the *Inventor's Advocate*, from which we give the following details:—

The principle on which the patent "Distillator" is constructed, is that of the continuous transfer of heat through a series of vessels by evaporation. Thus, steam being generated in the boiler, is admitted into a chamber surrounded by water, where it is condensed, forming distilled water. From that chamber the water is permitted to run off into a suitable vessel. The heat transferred from the condensed steam to the water with which the condensing chamber was surrounded, produces renewed evaporation, and the steam from that second boiler is conveyed to a second condensing chamber placed in a third vessel of water. The process is repeated in that vessel, and may be so continued through five or six condensing chambers. In the apparatus we inspected at Pimlico there are only three condensing chambers, and the hot water in the last vessel is pumped back to the first boiler until it becomes saturated with salt, and then it is blown off.

As in the ordinary process of distillation only one condensing vessel is used, it is evident that a positive saving of fuel must arise from the addition of other vessels in which a similar process can be carried on without the addition of fresh fuel. In the apparatus already constructed, it is found that by the addition of two chambers to the ordinary still, an increase of distilled water is obtained equal to from 130 to 140 per cent. The produce of the three condensing chambers, at a *minimum*, are three measures from the first, two from the second, and one from the third; the two last being equal to the evaporation from the boiler heated by fuel. At a *maximum* the quantities are: from the first, five measures; from the second, four; and from the third, three. This is equal to a gain of 140 per cent.

In the report of experiments made to the Lords Commissioners of the Admiralty, it was proposed to produce 20 lb. of distilled water by the combustion of 1 lb. of coals. This was actually produced by the apparatus, under a working pressure of steam in the boiler of 10 lb. to the square inch; but, as in subsequent trials, the working pressure has been reduced to 5 lb. the square inch, as a measure of safety, the effect falls short of 20 lb. of water for 1 lb. of coal, in a slight degree; but in a new apparatus, this can be amply compensated, by giving an increased evaporative power to the first boiler of the series, and by coating the whole with felt, so as to prevent the radiation of heat. In a trial of three hours duration, 59 gallons were evaporated from the three vessels as now constructed.

It is proposed, as a matter of convenience and safety, when the apparatus is employed on board ship, that the fire should be placed on the upper deck, and the distilling or condensing chambers on the lower deck, or in the hold. By this arrangement it is expected that the same fire which is used for cooking may be made the means of producing a constant supply of fresh water.

By the use of this invention, the necessity of encumbering a vessel with the usual cargo of water and tanks for a long voyage is entirely obviated, by merely substituting five per cent. of that cargo in coals for the distillation.

FRESCO PAINTING.

Mr. Haydon, with characteristic energy and enthusiasm, has made a trial in fresco, on the wall of his painting room; and the result of this first and hasty attempt is decisive of two important points—the beauty of fresco painting as a means of decoration, and the ease with which a knowledge of the practice may be acquired. The subject is a study for the archangel Uriel, the bust and arms only, of the life size; it was painted at once on the plaster, without a cartoon to work from, in four hours; the painter's hand trembling with apprehension for the success of his experiment, and incompetent from inexperience to do full justice to the means. It is a rough sketch, in short, made without the boldness and firmness of pencilling that certainty of purpose and mastery of hand alone can give. Yet the figure stands out from the wall, solid in form, lively in colour, and brilliant in tone, making the pictures beside it look poor, flat, and muddy in comparison; its flesh tints surpassing in purity the freshest oil painting. It has a majestic presence, that seems to enlarge the space it occupies, and to give new radiance to the light reflected from it; but while it thus fills the sense and elevates the mind, it is not obtrusive. In describing the impression made by this piece of fresco, our object is not to compliment Mr. Haydon, or to praise his design. We do but record the effect produced upon us by the work; though the conception and style of the painter must have had their share in producing this impression, we endeavoured to regard only the physical qualities of the art. The large scale of the design and the breadth and simplicity of the painting, have unquestionably a material influence over the mind; but these characteristics belong to all fresco, and constitute its chief recommendations; the greatness of the style powerfully aids the grandeur of the idea, and the largeness and boldness of the handling inspire the painter with congenial vigour of execution, which the cartoon he works from would prevent from running into exaggeration. As the tendency of high finish in cabinet pictures is to contract the focus of the mind and cramp the execution, so that of fresco is to enlarge the conception and expand the style. Fresco painting is the school of greatness in painting; it daunts and depresses only the little mind; it fires and elevates the noble and aspiring genius; the artist works with that grand gusto of which we hear so much and see so little. Mr. Haydon tells us, and we can well believe, that there is a fascination in the very manner of painting which is inspiriting and stimulating to fresh exertions; and he now regrets not having followed the advice of Sir David Wilkie twenty years ago, to apply himself to fresco. Any zealous artist might easily make the experiment; the same means of information are open to all. The book authorities for the Italian method, we are told, are Vasari, Armenini, and Cennini. Messrs. Latilla, of London, Bell, of Manchester, and Barker, of Bath, are the artists in this country whom Mr. Haydon consulted; Mr. Lane, of whom we spoke, is not, we believe, in England. The method is simple; chip off the outer surface of the plaster from a dry wall, and substituse for it a coating of wet plaster, composed of two parts of river sand and one of lime, well mixed together with water to a proper consistency; this applied to the wall will remain sufficiently moist to work upon for four hour; no greater space should be plastered at once than can be covered in that time. Every touch is indelible; but it may be gone over again when the plaster is moist. The pigments used are of the common kind, being earths, and are dissolved in water; the lime itself is white; the difficulty is to allow for the change of tint in drying.—*Spectator.*

REVIEWS.

Illustrations of Arts and Manufactures. By Arthur Aikin, F.L.S., F.G.S., &c., late Secretary to the Society of Arts. London: Van Voorst, 1841.

Arthur Aikin is the scion of a literary house prolific in respectable names—we need only mention Dr. Aikin, Lucy Aikin, and Mrs. Barbauld. For a long while he was, as Secretary of the Society of Arts, the friend and adviser of the majority of the mechanical world, and well did he sustain his own position and the character of the institution. As a popular lecturer on subjects connected with the practical arts few could exceed him, for while he possessed the art of riveting the attention of his auditory, he was remarkable for a precision of idea and expression, which, even without the aid of diagrams or engravings, enabled him to give complete and correct ideas of most intricate and complicated machinery. So well was this known to be Mr. Aikin's characteristic, that Lord Brougham, himself no mean authority, is reported to have recommended a friend to apply to Mr. Aikin, as he knew "no other man but he who could make a specification without drawings." When Mr. Aikin retired from the post, which he had occupied so long, it was to the general regret, but still we hoped that one who had led a life so active and useful as his has been would not remain idle in his retirement, although he has well earned repose. We feel pleasure, therefore, in welcoming this first fruit of his retirement, which, as it is natural, is devoted to his ancient pursuits and connected with his former haunts. It is, what it purports to be, illustrations of arts and manufactures; it may, indeed, be considered as a manufacturing sketch or series of essays. The subjects treated on are pottery, limestone and calcareous cements, gypsum, furs, felt, bone, horn, &c., iron, engraving and paper. In their original form these papers were delivered before the Society of Arts, at their evening meetings, where we recollect the interest they excited; their republication therefore is likely to prove valuable.

From the article on pottery we have, at another page, given long extracts relative to brick-making, so that we cannot do better than here to take up the subject of limestones and calcareous cements. After tracing the origin of cement to brick-building countries, in the use of bitumen in the plains of Babylon. Mr. Aikin proceeds to allude to the improvements in its application which were made by other nations. To the Romans, however, he justly awards the palm among the ancients for their use of calcareous cements, on account of the extent to which they applied it in hydraulic works. They had also an advantage in discovering the use of puzzolana (vide C. E. & A. Journal, Vol. IV. p. 300.)* In alluding to the monuments of the Romans in this country our author says that the most ancient limestone quarries in this part of the empire, and which continue in full activity, were first opened by the Romans at Tadcaster, in Yorkshire, which, in the Roman itineraries, is named Calcariæ. In giving this praise to the Romans, it is to the Gothic style that we must refer the great extension given to the use of cement, the intricacy and elaborateness of its parts, its richness and multiplicity of ornament, not allowing the use of large blocks of stone. Limestones, Mr. Aikin divides after the usual arrangement into four classes. The first contains the pure limestones, including white statuary marble (which is of no use for mortar), white chalk, oolite, and gray limestone. In the second family are placed the swinestones and bituminous limestones, which are of value. Magnesian limestones come next, and lastly limestones containing so large a proportion of iron and clay as to enable them to form cements, which have the property of becoming solid under water, and are for this reason called water or hydraulic cements. (On this subject see also M. Vicat, p. 3 of our present volume). Among these are gray chalk, chalk marl or Dorking lime, found in large quantities at Dorking, Merstham and Halling: blue limestone, lying betweeen the lower oolite and the new red sandstone running across the country from N.E. to S.W. from Whitby to Lyme Regis, sending out a branch to Monmouth and Glamorgan. The entire thickness of this deposit is 450 feet, and among its chief quarries are Watchet, Aberthaw, Barrow and Bath. In the three former, according to Smeaton, the proportion of iron and clay appears to be the same, or about 11 per cent., but in the time of Barrow, according to that authority, 21·3, but according to Mr. Marshall, 11. In the upper and lower beds of the lias formation, and in all deposits of bluish slaty clay containing carbonate of lime, are balls of a compressed globular figure, less clayey than the slate marl, but less calcareous than the limestone. In the London basin these balls in the blue clay are called septaria or cement stone. They may be observed in the cliffs of London clay forming the eastern coast of the Isle of Sheppey, and in the low cliff at Southend in Essex. They were met with frequently in the cutting for the Highgate Railway and Primrose Hill tunnel. Of late years these stones, burned and reduced to powder, have been very extensively used under the name of Roman cement, in all water building and other masonry requiring particular care, with such success as to have entirely superseded the employment of puzzolana and terras. These two materials should also be noticed; the first comprehends a few calcareous substances, the essential ingredients of which appear to be oxide of iron and burnt clay; the latter is quarried at Andernach on the Rhine for millstone, and the fragments are ground up in Holland, and mixed with lias lime to form a cement for dykes and other works of the water-staat. In England, Rowley rag, a basalt obtained from the Rowley Hills in Warwickshire, and in composition similar to the Andernach stone has been used for the same purposes with good effect. The Egyptians, as it will be seen under the head of Ancient Engineering, used black basalt from Abyssinia. With regard to sand, the use of pit-sand is objected to unless previously cleaned by washing, but sand having a yellow colour, caused by ochre, and having chalybeate springs rising from out of it, will produce a cement of great hardness, provided that it be used soon after it is dug. But limestone and sand are not enough of themselves: the limestone must be deprived of its carbonic acid, and used as soon as possible, as it reabsorbs carbonic acid from the atmosphere. When packed in close casks, lias lime will keep good for a long time, and Smeaton's experience goes as far as seven years, but in this case, the lime was previously reduced to powder by slacking with water, and then was trodden down into the casks. The lime having cold water poured upon it, becomes hydrate of lime or slacked lime, and in this state and not that of pure lime, enters into the composition of mortar. The proportion of sand in mortar depends partly on the fineness or coarseness of the sand itself,

* It was an ancient law in Rome says Pliny, that after the ingredients of mortar had been rubbed together with a little water, the mass should be kept in a covered pit for three years before being used; and we are expressly informed that buildings erected during the operation of that law were not liable to cracks.

and partly on the nature of the lime, but on account of the cheapness of sand there is always a disposition to deteriorate mortar by a too liberal employment of it. The proportions given by Pliny are 1 of lime to 4 of sharp pit-sand, and 1 of lime to 3 of round grained sand from the sea or river, an improvement, he says, may also be made by the addition of a third part of pounded tiles. The common London mortar is made of one part of white chalk lime and 2½ of clean sharp river sand, but not unfrequently, dirty pit-sand is substituted, and the lime itself, being imperfectly burnt, the mortar never becomes hard, and has not sufficient adhesion to the bricks. White lime, when really good, will take a larger proportion of sand than the brown limes do, but it is an additional proof of the badness of common chalk lime, that in the London practice the reverse generally prevails.

Upon the question whether any chemical action takes place between the lime and silica in mortar, Mr. Aikin admits that it is difficult to come to a decision, but he alludes to several facts which seem only explainable by the existence of chemical acts.

In enumerating the water cements our author states, on the authority of Vitruvius, that the cement used by the Romans in the construction of moles and other structures in the sea, was one of lime and two of puzzolana, from which the proportions of Mr. Smeaton's cement, used in the construction of Eddystone Lighthouse do not materially differ, namely, equal quantities of Aberthaw lime in the state of hydrate and in fine powder, and of puzzolana also in fine powder; the cement was also well beaten till it had acquired its utmost degree of toughness. The Dorking gray chalk is used in proportions of 1 of lime to 3 or 3½ of sharp river sand; and for filling in the interstices of thick walls, 1 of lime to 4 of coarse gravelly sand. In setting the bricks, that form the facing of the London Docks to the depth of 14 or 18 inches from the outside, a cement was used of 4 lias lime, 6 river sand, 1 puzzolana, and 1 calcined iron stone.

This sketch of Mr. Aikin's mode of treating one subject will be sufficient to give an idea of the work, which we leave with the conviction that it is one highly useful and instructive.

Letter from Sir Frederick Trench to Viscount Duncannon. London: Ollivier, 1841.

In this letter Sir Frederick proposes a railway from London Bridge to Hungerford Market, to run in the river parallel to the northern bank. This is to consist of an embankment one mile and three quarters in length, faced with stone or plates of cast iron to imitate stone; on this, 4 feet above high water Trinity mark, is to be a promenade, bearing on iron columns, 13 or 14 feet high, a railway thirty feet wide, to be worked by fixed engines on wooden rails. At intervals in the embankment are to be arches for the passage of barges. The embankment, railway and all, as far as we understand is intended to pass under the arches of the bridges. With regard to the bed of the river between the channel and the shore. Sir Frederick proposes to leave it as a space for a carriage road, wharfs, warehouses, houses, docks, or open mud banks as the case may be. The estimate given on the authority of Mr. Bidder and Sir Frederick Smith is, for the embankment £110,000, elevated platform £100,000, machinery £70,000, stations £25,000, interest £30,500, for filling carriage road, paving, lighting and sewers £100,000. Total £435,500. The time for the works is calculated at two years.

Sir Frederick urges the necessity for an embankment on account of the changes made by London bridge and the embankment before the new Houses of Parliament, from which he says have resulted a great increase of shoals, and the production of a number of mud-banks covered with vegetation, and in a pestilential state of decomposition. These are evils which are but too apparent, and it is evident both as a measure of health, commerce, and ornament, that some plan of embankment should be adopted, whether Sir Frederick's, Mr. Walker's, or Mr. Martin's, we do not say; but we feel sure that the day is at hand when a great and general improvement will be effected on the metropolitan river, and placing it on a par with its Parisian and Dublin rivals.

To the plan of Sir Frederick Trench there are many objections, and some, and not the least, are those suggested by considering it as a plan for the adornment of the metropolis. Passing, as this railway proposes to do, through three bridges and touching a fourth, it is evident that it will not only abstract from the grandeur, but absolutely spoil the view of those noble monuments, without any adequate compensation. The view of Somerset House will not be improved, and St. Paul's will be the only edifice which will derive any advantage, so that on that ground we fear that any measure so extensive is inexpedient. How the railway is to pass under the bridges we confess we do not see, and as to passing over them, it is out of the question A stronger objection is as to the effect such an embankment will have in producing depositions of silt and off below Woolwich, which may be looked upon as a certain result. As to the estimates, although a good foundation may in most places be obtained, we are decidedly inclined to think that they are too low.

We are willing, however, as we before said, to support some plan of embankment, but one so general we do not think under all circumstances is applicable. That the terraces of the Temple, of Somerset House, of the Adelphi, and of Hungerford Market, should be united, we are ready to admit, but we are well aware that there are great difficulties in the way. As to the consideration of making a profit from the undertaking, we think that they need not be taken into account on the present occasion, for the urgency of some plan of embankment is such that the funds must be furnished regardless of any other objects than the public benefit to be effected.

In thus dissenting from the details of Sir Frederick Trench's plan, we cannot do so without expressing how much the public are indebted to the gallant General for the great exertions he has made for the improvement of the Thames, and how much the successful result will be owing to his counsels and active co-operation.

CANDIDUS AND THE VENTILATION FOLKS.

"Cease rude boreas, blust'ring railer."

This humble petition is addressed to Candidus, who last month took out "a licence to blow on whom he pleases." We pray that he may abate his sweeping gale against the "ventilation folks," who most humbly acknowledge their fault in daring to acquaint the public that carbonic acid gas from a chimney—or sulphuretted hydrogen from a drain, do not strengthen the lungs, refresh the nerves, and invigorate the constitution. We will say with Candidus that the vocation of a tailor is more conducive to longevity than is that of a ploughman—that there is real salubrity below deck under London Bridge—even that a cargo of slaves enjoy the most refreshing change of air, and that their sickness and death of 50 in a hundred, is a proof of their sullen ingratitude to their owners. We will say that the metropolitan improvement trustees are egregiously in error not to consult Candidus. That old London may be revived with its neighbour-like projections, its lanes and alleys, so contributary to disease; its overground kennels, its annular visitation of plagues and pestilence, its lamentations and cries, bring out your dead; we will turn all serious proofs of modern blessings into frivolity for a month. We will say with Candidus, that the great orb of day, "is sun or moon, or a penny rushlight," to appease his anger; and when in cool reason he will debate upon this question upon which we live and die, "we will argue with him upon this theme until our eyelids will no longer wag."

Some of the Ventilation Folks.

THE NEW ROUTE TO INDIA BY THE EUPHRATES.

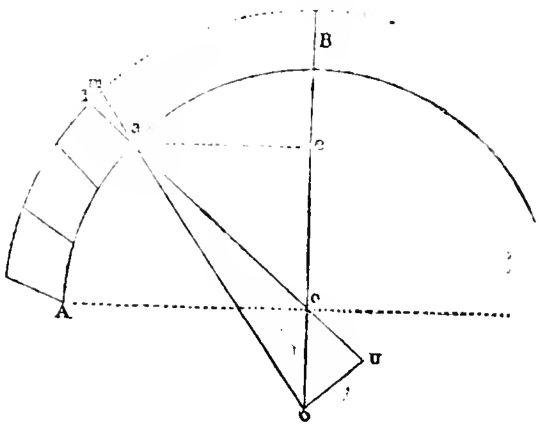
The *Commerce* publishes some private correspondence dated Aleppo, June 10, 1841, which states that the English steam boats Nimrod and Nitocris had arrived at Beles, on the Euphrates, after a navigation of 16 days and a distance of 375 leagues. Lieutenant Campbell, who commanded the expedition, had ascertained that both the Tigris and Euphrates are navigable for large vessels, and that those rivers present a new passage to the British possessions in India. "Documents stolen from M. Lascaris at Alexandria, in the year 1814," continues the writer, "contained important information collected by this gentleman. who was despatched by the Emperor Napoleon to explore Mesopotamia and the Euphrates, in order to ascertain the possibility of discovering a passage to India by the Orontes. The British Ministry determined to verify those plans. Colonel Chesney was deputed on this mission in the year 1835. Great Britain then ascertained that the Orontes. which falls into the Mediterranean, was navigable as far as Latakia (the ancient Antioch). That the ancient harbour of Selencia, situate at the mouth of this river, could be rendered an excellent harbour at a small expense. That it was easy to make a road to Aleppo, and thence to the Euphrates through the valleys, and that the distance, 45 leagues, could be easily traversed. A coal bed was discovered at the foot of Mount Taurus, 16 leagues from Tarsus. Near this coal bed, which is of considerable extent, has been discovered an iron mine, which gives 60 per cent. of metal. These mines are surrounded by oak woods of great value.

The writer calculates that the journey may be made from Bombay to Liverpool in 34 days—viz., from Bombay to Beles 16 days; from Beles to Alexandrette, 3 days; thence to Liverpool, 15. The letter concludes by stating that there is no doubt but that in a few years the English will monopolize the trade of Bagdad, Bassora, Aleppo, and all Mesopotamia.

ON THE CONSTRUCTION OF OBLIQUE ARCHES.

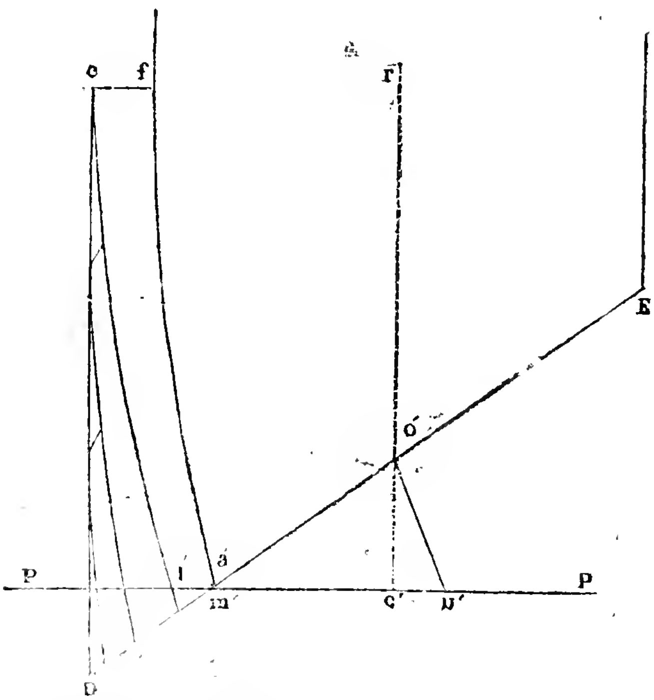
Sir—In compliance with the request contained in your letter of the 10th, I forward you the method by which the formula and construction given in your last number, for finding the angles between the joint lines in the face and soffit of an oblique arch, were obtained. The approximations thus arrived at are as accurate as it is possible to work to, the discrepance being much too small to be detected practically. As the subject is somewhat complex, I must be excused if the explanation here given is not strictly mathematical, the deductions however will be found correct.

Fig. 1



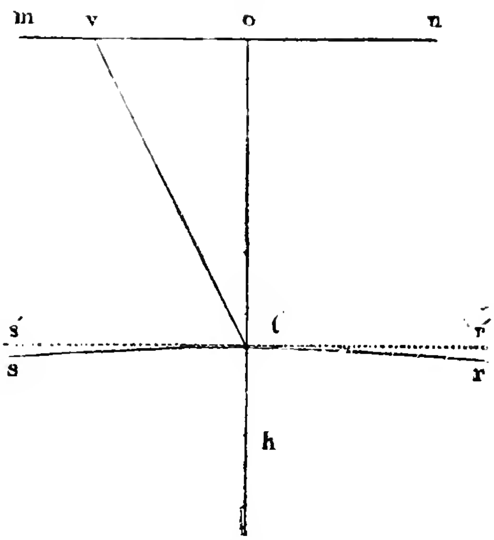
Let A B (fig. 1,) be the elevation of an oblique arch, on a plane at right angles to the axis of the cylinder on which it is formed, and let c be the centre, and *a* the point at which any joint *a m* in the face of the arch meets the intrado.

Fig. 2.



Let C D E (fig. 2,) be the plan of the same, (part of the arch being supposed to be removed), and let *a'* be the position in plan of the point *a* (fig. 1.) Suppose a vertical plane P P to pass through the point *a'*, intersecting the spiral surface *c f a' m'* in the line *a' l'*. From *l'* let *l' m'* be drawn a tangent to the spiral line of the extrado meeting D E in *m'*. And because the plane P P is perpendicular to the axis of the cylinder, the line of intersection *l' a'* will be a straight line at right angles to the tangent *l' m'*. The triangle *o' l' m'* is therefore the projection of a right angled triangle; and in the short distance *l' m'* the tangent very nearly coincides with the plane of the spiral surface, hence the angle *l' a' m'* will be a very close approximation to that formed between the chord of the curved joint in the face and the line *l' a'*; which is the angle represented by *v t o*, fig. 3, and that which it is required to find.

Fig. 3.



From *o'* where the axis intersects D E in plan draw *o' u'* parallel to *l' m'*, meeting P P in *u'*, produce *r o'* to c'. In fig. 1 let *l a* be the projection in elevation of the line *l' a'*; join *a c* and produce it to *u*, making *l a* : *a u* : : *l' a'* : *a' u'*. Through *u* draw *u o* at right angles to *a o*, meeting the vertical line B *c* produced, in *o*; and through *l* draw *l m* at right angles to *a l*, meeting *o a* produced, in *m*.

From the nature of the spiral surface it follows that *l a* and *a u* will be in the same straight line, and without going through the detail of each part of the construction, it will be seen that the triangle represented by *a o' u'* in plan, and *a o u* in elevation, is a right angled triangle similar to, and in the same plane with the trangle *a' m' l'*, having the angle *o' a' u'* equal the angle *l' a' m'*. Also that the side represented by *a o* and *a' o'* is the hypotheneuse, and is the line drawn from the point where the joint intersects the intrado to the point of convergence of the joints in the face; and that the side represented by *o u* and *o' u'*, which is the perpendicular of the triangle *a u o*, is the hypotheneuse of another triangle whose perpendicular is *c' o'*, and the angle *c' o' u'* equal to the angle of extrado. In the construction given in your last number, it will be seen that these are the two sides made use of to obtain the angle *u' a' o'* = *l' a' m'*, but in the formula it is more convenient to work with the base of the triangle *a' u' o'*, which is the line *a u* in fig. 1, and represented by *a' u'* in fig. 2, for when we have given

$\angle$ C D E $= \theta$ the angle of obliquity.
$\angle$ $c'\ o'\ u' = \varphi$ the angle of extrado.
$\angle$ $a\ c$ B $= \lambda$ the angle from the vertical,
and $a\ c = r$ the radius;

then drawing *a c* at right angles to B *c* fig. 1,

(Fig. 1) $a\ c = r \sin.\ \lambda, = a'\ c'$ (fig. 2).
(Fig. 2) $o'\ c' = r \sin.\ \lambda, \cot.\ \theta.$
(Fig. 2) $o'\ u' = r \sin \lambda, \cot.\ \theta, \sec.\ \varphi =$ the perpendicular.
(Fig. 1) $o\ u = r \sin.\ \lambda, \cot.\ \theta, \tan\ \varphi.$
(Fig. 1) $u\ c = r \sin.\ \lambda, \cot.\ \theta, \tan.\ \varphi, \cot.\ \lambda = r, \cos.\ \lambda, \cot.\ \theta, \tan.\ \varphi.$
(Fig. 1) $a\ u = r + (r \cos.\ \lambda, \cot.\ \theta, \tan.\ \varphi) =$ the base.

$$\text{Therefore } \tan \angle\ u'\ a'\ o' = \frac{r \sin.\ \lambda, \cot.\ \theta, \sec.\ \varphi}{r + (r \cos.\ \lambda, \cot.\ \theta, \tan.\ \varphi)}$$

Separating the constant from the variable quantities, and calling

$r \cot.\ \theta, \sec.\ \varphi = a,$
and $r \cot.\ \theta, \tan.\ \varphi = b,$

$$\tan.\ \angle\ u'\ a'\ o' = \tan.\ \angle\ l'\ a'\ m' = \frac{a \sin.\ \lambda}{(b \cos.\ \lambda) + r}.$$

Hence if the arch be a semicircle on the square section, the expression for the angle *l' a' m'* at the springing will be $\tan.\ \angle\ l'\ a'\ m' = \cot.\ \theta, \sec.\ \varphi.$

From the above may be proved the existence of the property discovered by Mr. Buck, namely, that the chords of all the joints in the face converge to one point below the axis; for $c\,o$ the distance of that point below the axis (fig. 1,) will be $o\,u \times$ cosec λ.

And $o\,u = r$ sin. λ, cot. θ, tan. φ.

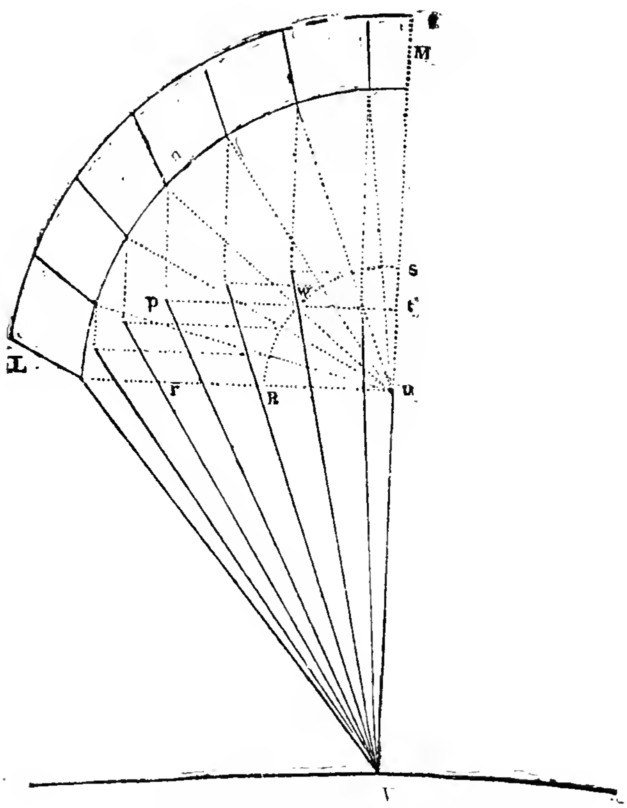
Therefore $c\,o = r$ sin. λ, cosec λ, cot. θ, tan. φ.

Whence the variable angle λ disappears, and $c\,o = r$, cot. θ, tan. φ.

This like the formula previously given for the angles, has reference to the line $m\,a$ (fig. 1,) and not to the true chord of the curved joint of the face; the approximation is however exceedingly close. If the angle of intrado be used instead of the angle of extrado, the results obtained by both formulæ apply to the *tangents* of the joint lines in the face, drawn from the points at which the joints intersect the intrado, and these results are *theoretically true*, though not available in the practical working of the case.

The formula tan. $\angle\, l'\,a'\,m' = \dfrac{a \text{ sin. } \lambda}{(b \cos. \lambda) + r}$ leads to another construction for finding the angles between the joint lines in the face and soffit which possesses some advantages over that already mentioned.

Fig. 4.



* The dotted line $n\,p$ should be produced to r, and V u produced to t—the dotted line $p\,t$ should be a full line.

Let L M (fig. 4) be the elevation of the face of an oblique arch, on a plane at right angles to the axis of the cylinder on which it is formed, $n\,u$ being the radius.

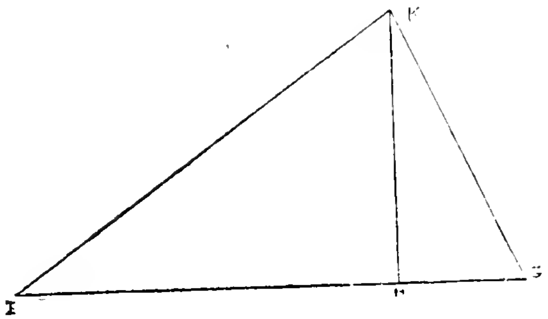
From the point K in the straight line K H, (fig. 5,) draw K F and K G, making the angle H K F equal the angle of obliquity of the arch, and the angle H K G the angle of extrado. Set off K G $= n\,u$ the radius, and through G draw G F at right angles to K H, intersecting K H and K F at H and F. Upon the vertical line M u produced (fig. 4,) set off $u\,v =$ F H, and from v with the distance H G describe the arc R W S. Then to find the angle formed out any joint n. Join $n\,u$ and through W where $n\,u$ intersects the arc R W s, draw $p\,t$ parallel to L u, and from n draw $n\,r$ parallel to M u, intersecting $p\,t$ in p. Join $p\,v$ and the angle $p\,v\,t$ is the required angle. For let F H $= r'$ and using the same letters for the angles as before.

$$\left.\begin{array}{l} \text{K H} = r' \text{ cot} \\ \text{K G} = r' \text{ cot. } \theta, \text{ sec. } \varphi. \\ \text{H G} = r' \text{ cot. } \theta, \text{ tan. } \varphi. \end{array}\right\} \text{fig. 5.}$$

$$\left.\begin{array}{l} t\,u = r' \text{ cot. } \theta, \text{ tan. } \varphi, \text{ cos. } \lambda. \\ u\,v = r'. \\ t\,r = r' + (r' \text{ cot. } \theta, \text{ tan. } \varphi, \text{ cos. } \lambda.) \\ \text{And } p\,t = r\,u = r', \text{ cot. } \theta, \text{ sec. } \varphi, \text{ sin } \lambda. \end{array}\right\} \text{fig. 4.}$$

Hence the ratio of $p\,t$ to $t\,r$ is the same as a sin. λ is to $(b \cos. \lambda) + r$, and therefore the angle $p\,r\,t$ is the same as that obtained by the formula.

Fig. 5.



The angles for the remaining joints being found in the same manner, and the mould of curvature of the spiral line of the intrado applied at V, the curved bevels or templates for all the voussoirs on both sides of the arch are at once obtained as shown in the figure.

I am, Sir, your obedient servant,

W. H. Barlow.

Brereton, September 17, 1841.

N. B. Will you be so good as to make the following corrections in my last communication.

In Fig 1 the letter A is omitted at the intersection of the lines E K and D C.

Fig. 4 should be Fig. 3, and Fig. 3 should be Fig. 4.

In Fig. 3 the straight line S T R should be S' T R'.

Page 292, line 3. For *draw G H* read *through E draw G H.*

THE NEW ROYAL EXCHANGE.

The contract of Messrs. Webb for the foundation of the new Royal Exchange was finished on Tuesday evening, and the Gresham Committee met on the 1st ult to receive tenders for the second contract, which is for the completion of the whole of the edifice.

Fourteen of the principal builders of London had, as we formerly stated, been applied to, and it was also determined that each tender should contain two prices—the one being for executing the mason work with the best Portland s one; the other, the additional price for using magnesian limestone, similar to that introduced at the Houses of Lords and Commons.

The amount of the several tenders were as follows. September 1. 1841 :—

Tenders	Portland. £		Magnesian limestone. £
Thomas Jackson..........	115.900	..	124.700
Baker and Sons	122.765	..	127.300
Henry and John Lee	126.390	..	131 900
Samuel Grimsdell	126.762	..	133.548
Grissell and Peto	127.400	..	132.000
Piper and Co.............	128,700	..	131.100
John Jay	129.609	..	1 4.905
John and Joseph Little ..	129.800	..	134.300
Webb and Co.............	130,150	..	131,150
Joseph Bennett	131,500	..	133,500
Bridger	131.519	..	138,660
William Cubitt	132.200	..	135.700
Nicholas Winsland	134.219	..	136,620
H. Ward	135.500	..	138.500

The tender of Mr. Thomas Jackson was, of course, accepted. The whole of the works are to be completed by Midsummer. 1844

The amount of the first tender for the foundations was £8121. See Journal, Vol. III. page 299.

Australian Steam Navigation.—Notwithstanding the wreck of one of the steamers, others have been sent out, and everything is now going on well.

Havannah.—A steamer has been started this month from Liverpool to Madeira, the West India Island and the Havannah

SHANNON IMPROVEMENTS.

We have much pleasure in noticing the very spirited and energetic manner in which the Commissioners for the improvement of the navigation of the River Shannon, are carrying into effect the powers vested in them by Government—besides the various works in progress on the lower Shannon at Kilrush, Kilteery, Killisart, and Foyn's Island, and in our immediate vicinity at Bannaroon, Plassy, and Killaloe. We learn that the same exertions are manifested to complete as soon as possible the numerous projected works on the middle Shannon, particularly at Meelick, Banagher, and Athlone, together with the important operation of dredging the bed of the river.

The principal feature of the improvements to be executed at Banagher, appears to be the erection of a new bridge over the Shannon, in place of the present old bridge, which measure has been found absolutely necessary, no less for the safety and accommodation of the public, than for the proper drainage of the country. The present bridge is built of rubble masonry, and consists of 17 arches of various dimensions, the piers of which occupy nearly one-half of the entire width of the river, the clear waterway being but 295 feet, whilst the total width of the piers is 244 feet. This structure is in a very dilapidated condition, and has lately shown numerous symptoms of its inefficiency as a means of communication between the King's County and Galway. It may however, be considered, (from its having been built in the reign of King John,) if not the oldest bridge over the Shannon, as at all events possessing an age which few other bridges can so satisfactorily trace, and is on that account, a very highly interesting work of antiquity. In its construction we find all that characterizes the early specimens of bridge architecture; the small arches for allowing the passage of the water, and, as before mentioned, unnecessarily wide piers, which have large angular projections not only to throw off the force of the current, but for the purpose of enabling passengers to retire into, to avoid carriages and horsemen when passing along its narrow roadway, the width between the parapets being only 12 feet.

The works of the foundation of the new bridge having been sufficiently advanced on the King's County side of the river, the first stone was laid by Colonel Jones, on Saturday, the 21st August; over which a brass plate was laid, bearing the following inscription:—

"SHANNON COMMISSION."

(Under the Act 2nd and 3rd Vic. Cap. 61.)

"By virtue of an Act passed in the second and third years of the reign of Her present Majesty Queen Victoria, the first entitled an Act for the improvement of the Navigation of the River Shannon, the following are the names of the Commissioners appointed for carrying the works into execution: Major-General Sir John Fox Burgoyne, R.E.K.C.B., K.T.S., &c. &c.; Lieut.-Colonel Harry David Jones, R.E., M.R.I.A., M. Inst. C.E.; Richard Griffith, Esq., C.E., F.R.S.E., M.R.I.A."

"This Bridge over the River Shannon at Banagher, was designed by Thomas Rhodes, Esq., C.E., M.R.I.A., M. Inst. C.E., the Commissioners' principal engineer, and the first stone laid on the 21st day of August, in the year of our Lord 1841.—Henry Buck, Esq., C.E., district engineer; Henry Renton, Esq., C.E. A. Inst. C.E., resident engineer; William Mackenzie, Esq., C.E., M. Inst. C.E., contractor.—Edward Hornsby, Secretary."

Having had an opportunity of inspecting the plans and other documents relative to the bridge, we are enabled to give some particulars which, perhaps, may be acceptable to our engineering readers. It is to consist of six semielliptical arches, of 60 feet span each, with a cast iron swivel bridge, of 45 feet span, to allow masted vessels and steamers an uninterrupted passage at all times. The following are the principal dimensions:—Span of stone arches each, 60 feet; rise of ditto, 16; thickness of abutment, 13; ditto of piers, 8; ditto of swivel bridge pier, 40; total length of bridge, including wings, 721; width of bridge, in clear of parapets, 24; ditto of carriageway, 16; ditto of each footpath, 4; thickness of arch stones at springing, 5; ditto crown, 2 feet 8 inches. The foundations will be all laid on a bed of strong gravel, at a level of about six feet below the bed of the river: the stone of which it is to be built is blue limestone, of a very fine quality, procured from a quarry recently opened adjacent to the works. The contract is stated to be about £23,000, and the whole of the works are expected to be completely finished in two years.

Mr. Fairvelle is the contractor for building the much required pier at Kilrush, which is to extend 150 feet into the sea in a westerly direction, and there are 120 men now daily employed in the immediate neighbourhood quarrying stones for the work. The masonry embankment forming on the northern shore close to the present pier is very forward, and will be a great improvement.

Mr. Vignolles, C.E., son of the celebrated engineer of that name, is appointed resident engineer to superintend the construction of the piers or quays at Kilrush and Cahircon.

Mr. Sykes, of York, is declared contractor for building the pier of Cahercon, under the Shannon Navigation Commissioners, and the preparatory works will be commenced immediately.

The new pier, or quay, at Kilteery, between Glin and Loughill, in progress under the Shannon Navigation Commissioners, will be completed against winter, and admit of sailing vessels and steamers coming to there, in 21 feet of water, while the new road from Abbeyfeale, through the interior of the country, will render this a work of great public benefit to the farmer and trader—hitherto deprived of a market for their produce.—*Limerick Chronicle.*

Railway in the Brazils.—A railway has received the sanction of the Brazilian legislature and the support of the government, which is to run from Rio Janeiro to communicate with the provinces of St. Paulo and Matto Grosso. It has only one chain of hills to cross, the Serra de Parahyba.

STEAM NAVIGATION.

The Cairo.—A new steamer bearing this title made her first appearance in the Thames on Friday, 17th ult., and excited general attention. She was built by Messrs. Ditchburn and Mare, of Blackwall, for the Peninsular and Oriental Steam Navigation Company, for the navigation of the Nile, and is intended as a branch steamer to convey passengers and luggage to and from various places on the banks of that river. The Cairo is a remarkably elegant vessel, similar in appearance to those very fast and pretty steamers called the Watermen, running between London and Woolwich, and built by the same firm. The Cairo, however, is four feet longer and flat bottomed, to adapt her for the shallow waters of the Nile, her draught being only two feet. She is propelled by two engines of 16 horse power each, from the factory of Messrs. Penn and Son, of Greenwich. The cylinders are oscillating, and the machinery, which occupies a very small space, is precisely similar to that in the Watermen, and of the same dimensions. The cabins, fore and aft, are tastefully fitted up with bed places and other conveniences for passengers. The Cairo is an iron vessel, and divided into five compartments with water-tight bulkheads separating each, which adds much to the safety of the vessel. The engines and machinery occupy such a small space that 100 persons can be accommodated in the cabins, and there are two spacious stow-rooms for luggage only, between the engine-room and the fore cabin, and the engine-room and after-cabin. The Cairo made a trial voyage from the Blackwall pier to Gravesend and back, and with all the disadvantages attendant upon the working of new engines and machinery, she passed every thing on the river, the Star, a large Gravesend steamer, only excepted, and fully came up to the expectations of the builder and engineer. Mr. Ditchburn and Mr. Penn, jun., who entertained a select party of gentlemen connected with steam navigation on board, have guaranteed the average speed of the Cairo at 15 miles an hour; but for the Nile, a light draught of water is her greatest recommendation. Several other iron steamers, of similar dimensions, are to follow the Cairo to the Nile, and her design and appearance has been so much approved of, that the Watermen's Steam Packet Company intend to augment their fleet by five new vessels of the same size and machinery of the same power, to be in readiness by Easter Monday next. Messrs. Ditchburn and Messrs. Penn have taken the contracts.—*Times.*

Marine Engines.—It may be said that Great Britain is the manufactory for the whole world for marine engines; at one factory alone (Messrs. Maudslay and Field), there are at the present moment going through their various stages of manufacture, engines of 3600 horse power in the gross, viz. the *Devastation*, a government steamer with 400 horse power, fitted with double cylinders, now in the Woolwich basin just ready for action. The *Thames* and *Medway*, each with 400 horse power beam engines belonging to the West India Mail Company; the *Thames* is nearly ready; the *Herculana* (sister boat to the Mongebello) with 200 horse power, double cylinders, nearly completed for the Neapolitan government; and the *Memnon* with 400 horse power double cylinders for the East India Company. All the above engines are now being fitted on board of the several vessels—besides the above, in the same factory there are now in progress four pair of 150 horse, one pair of 100 horse for the Danish Government, and a pair of 100 horse for the admiralty all with double cylinders, also two pair of 50 *annular* cylinder engines on Mr. Joseph Maudslay's last patent. In another place we have noticed engines for Egypt and the United States.

The Satellite.—A beautiful iron vessel built by Messrs. Ditchburn and Mair has been running the last two months between the Adelphi and Gravesend with great speed and regularity. She draws but little water, and frequently steams the distance from Blackwall and Gravesend in about an hour; she has a pair of 35 horse *steeple* engines arranged expressly for her, which are a beautiful specimen of Messrs. Miller, Ravenhill and Co.'s. workmanship, they occupy a very small space in the vessel and are fitted with expansive gear worked with great simplicity.

Steam Towing.—We learn that during the present fruit season a steamer will tow vessels between Malaga and Gibraltar. It is to be hoped that this system of towing in the sea will be extended.

The Chili.—We regret to learn that this steamer has been wrecked on the coast of the same name.

FOREIGN INTELLIGENCE.

The Mosaic Pavement at Salzburg.—*Munich, Sept.* 7.—Private accounts from Salzburg state that it is intended to remove the lately discovered Roman mosaics from their present position, and lay them down in another situation, where they may be protected from the influence of the weather. It is said that the place fixed on is the site of Mozart's monument. Besides the large mosaic pavement, the design of which consists only of architectural ornaments and foliage, two smaller pieces were discovered, which are equally devoid of pictorial representation. There are likewise considerable remains of the walls of the chamber to which these mosaics belonged. The paintings on these are similar to those found at Pompeii, consisting of flowers and tendrils of vines on a red ground. The mosaics, as well as the paintings, are evidently of the third or fourth century after Christ. One very striking peculiarity in the smaller mosaics is the frequent introduction of the sign of the cross, which it is scarcely possible to regard as a mere accidental ornament. At the depth of half a foot below the large mosaic pavement, is another of finer workmanship, which, as it is necessarily the more ancient, promises to be an object of still greater interest. The proprietor of the house must have had some motive in thus covering over the old pavement and raising the floor. If once the upper pavement were removed, there would be no great difficulty in uncovering the second.—*Allgemeine Zeitung.*

St. Petersburg, August 26.—300 workmen are now daily employed in rebuilding the Imperial palace in the Kremlin at Moscow, which was pulled down four years ago. The new building is made fire-proof, the very rafters being of iron, and no wood being employed except for the floors. This palace is to be heated by means of 250 metal pipes communicating with every part of the building, and proceeding from a furnace contained in the vaults below. The ornamental gilding alone costs 300,000 rubles.

The great hall of St. George of the winter palace, which had just been rebuilt, had given way, and all the splendid Italian paintings and vases which it contained been destroyed.—The loss is estimated at several millions of francs. No life was lost; and the remainder of the palace was intact. On the day before the accident a chapter of the Order of St. George was held in the hall which has fallen.

Venice.—A bridge is about to be constructed at Venice, intended to unite that city to the Continent, and to connect it with the railroad of Milan. The management of this gigantic undertaking has been conceded to the engineer, Antoine Busetto Pitich; the average expense is estimated at 4,830,000 livres Austrian. The bridge will also contain an aqueduct intended to supply the town with fresh water, which has hitherto been supplied in boats from the Continent; Venice being unprovided with wells and fountains, and having but very few cisterns.

The Improvement of the Seine.—A commission has been appointed by the Prefect of the Seine, to take into consideration a project for improving the navigation of the river within and below Paris. Part of the project consists in establishing this navigation on the left branch, running along one side of the Cité. Another plan attached to it is the construction on the centre of the Pont Neuf of a vast building, from which eight turbines, of the force of 4000 horse power,(?) would throw immense quantities of water into every quarter of Paris.

Russia.—A joint-stock company in England has obtained the Emperor's permission to make an iron railway from Moscow to St. Petersburgh, and will begin its operations perhaps this autumn, but certainly in the spring. Five years are allowed to complete the whole line, which will be 33 miles longer than the common road between Moscow and St. Petersburgh, because it is to pass through to Bybinsk, in the government of Yaroslaw, on the right bank of the Volga, because that town carries on the most extensive corn trade with St. Petersburgh. All the vessels laden with the produce of the south, which comes up the Volga to the north, must stop here.—*Hamburgh papers, Sept.* 10.

The Rhein and Mosel Zeitung of Sept. 4 states, that in the course of the operations in the Cathedral of Cologne for the restoration of the pictures of the Saviour and the Apostles Peter and John, the workmen have brought to light several colossal figures which have been obliterated with whitewash during the last century. It is to be hoped that these figures will be restored along with the others to their original state. The same journal mentions that the two pictures which had been wantonly injured at the exhibition in Cologne have been again hung up in their places, after having been removed for the purpose of repairing them. In spite of every inquiry, the person who committed the malicious act has not yet been discovered, nor is it possible to assign any imaginable ground for so wanton an outrage.

MISCELLANEA.

The Sun Fire-office Building.—The dispute between the city authorities and the Sun Fire-office, is at last terminated by the consent of the latter body to set back their building to the act of Parliament line, and to round the corner at the south-east of Bartholomew-lane. The Commissioners of Sewers will pay, as the value of the land thus appropriated to the public, such a sum as may be determined upon by Mr. Cockerell, the surveyor of the Sun Fire-office, and some surveyor to be appointed by themselves. The directors of the Sun Fire-office have, in the opinion of the citizens, acted most unwillingly and ungraciously, and it would have been much more creditable to these directors to have conceded to general convenience, what was never equitably theirs, than, by persisting in forming this projection, to have compelled the Commissioners of Sewers to appropriate public monies to an improvement in which the Sun Fire-office was really as much interested as the public themselves.—*Times*.

New Mode of Rating the Gas and Water Companies.—Some of the parishes in the eastern districts of the metropolis have lately been making a valuation survey of the length and bores of the various mains and branch services belonging to the Water Companies in their respective parishes, as also the length of the gas-pipes laid down, and all property belonging to them, for the purpose of rating them on a fair and equitable per centage, in the place of allowing the companies to compound for them, by the payment of a stipulated annual sum as heretofore, and which composition has been found in reality to be much beneath their actual value. The companies' profits, it is well known, being very considerable, their property has not been rated in a fair proportion to the general property of the parish. By the adoption of rating the companies after the survey, the parishes will derive a great annual increase of revenue, which will contribute much to relieve the parishioners in general, by adding to the parochial resources. The example is about to be followed by other parishes in the southern districts, who are making surveys for the same purpose, where the source of revenue, increased by rating, will be much more considerable, in consequence of the immense quantity of water and gas-pipes laid down in the southern districts by several companies in rivalry of each other.—*Times*.

Improved Locomotive.—Messrs. Coulthard, of Gateshead, engineers, have just completed a powerful locomotive engine, including all the modern improvements, with also, in one respect, a novelty in construction of great practical advantage. This consists in the rejection of what we may call the "cinder-chamber," so that the bars are exposed to the external atmosphere, and the ashes fall directly upon the ground. Thus, the bars being presented to the cold air on the outside, they do not waste away with that rapidity which is consequent upon the ordinary construction, and considerable economy is the result. The engine being built more for power than for speed, the works are placed chiefly on the outside, and are of peculiarly easy access for purposes of repair. Trial was made of her powers on Thursday week, in the presence of Mr Wood, under whose superintendence she was built, and other gentlemen, who were much gratified by her performances; and after remaining for experiment on the Brandling Junction Railway a few days from this time, she will be removed to the Clarence line, to commence her labours in good earnest.—*Tyne Mercury*.

The Strike at the New Houses of Parliament.—The strike of the two hundred masons is likely to be productive of much injury to the working men, as they could not have chosen a worse plea on which to strike, while they have put themselves in direct contact with government. All combinations are bad, and particularly where they are employed to repress industry for the benefit of idleness. Nothing can be more infamous than a system which fines men for working faster than their fellows. The masters will gain by this imprudence.

Sir William Burnett's patent process for the preservation of timber, canvass &c. is gaining ground with the public; it has already been adopted by the government authorities at the dock yards. For the service of the Portsmouth Dock Yard, there is now being made at Messrs. Fairbairn's, Mill Wall, a large iron tank, 51 feet long and 6 feet diameter, with air and force pumps for the purpose of impregnating timber and canvass with Sir William's solution—it is also to be applied for the preservation of upwards of 6000 yards of felt, and the deal casing to be used for clothing the steam boilers of H. M. War steamer the *Growler*, now having her engines put on board at Messrs. Seawards manufactory at Limehouse.

Hoax by a Bank Clerk.—Last month we transferred into our columns an extract from the *Literary Gazette*, giving a short account of a newly-discovered method of propulsion, by which a common garden or invalid chair could be propelled along a common road by a galvanic power at the rate of 40 miles an hour; and it was further stated that the young man who had discovered this new power daily travelled in his chair from St. Alban's to the Bank of England in half an hour—a distance of 22 miles! Great curiosity was naturally excited by the supposed discovery, and the young man, who is a Bank clerk, was questioned concerning it, both by the governor of the Bank, and also by Mr. Smee, the cashier, &c. He was invited by the latter, and by several other persons, to display the powers of his new machine, but made repeated excuses for delay; he first excused himself on the score of illness, and on being again pressed to exhibit the machine, he stated that he had driven it accidentally against a post, and shattered it to pieces. Upon being, however, more closely questioned, he at last confessed that the whole story was a hoax, and that no such machine had ever existed, save in the fertile imagination of the supposed inventor. This *denouement* was only made known on Thursday, and it has created a great sensation in the Bank of England. The motive of the youth for the above hoax cannot be accounted for. We are informed, however, that some such galvanic power does exist,(?) but that the expense is too great to allow of its being made use of.—*Times, Aug.* 28.

Projected Light on the Goodwin Sands.—The Lords of the Admiralty and the Board of the Trinity-house have finally arranged with Mr. W. Bush, the engineer, that the cast-iron caisson, which he has now nearly completed at Deal, shall on Wednesday, the 15th inst., be floated to its place on the north-east end of the Goodwin Sands. It will be remembered some weeks ago we noticed the progress of this undertaking, which is now about to be sunk and firmly fixed to the chalk rock which Mr. Bush calculates on finding about 30 feet below the surface of the sand. The caisson will then form a base upon which a lofty column of stone will be raised, surmounted with a light, and that from its position and general usefulness to all maritime counties, it will be called "The Light of all Nations," which will be inscribed on the column. This new Goodwin light is not only designed as a beacon to warn the mariner off these sands, which have been so fatal, but is also intended as a guide from the North Sea, through a swashway, hitherto, from its danger, impracticable. This channel is about half a mile wide, and leads into a capacious bay within the Goodwin, having from 30 to 40 feet water, and being sheltered from every quarter, ships will there ride in safety. A very large party are going out on the 15th to view the floating of the caisson, and the Government steamers are ordered to be in readiness. It is expected that his Grace the Duke of Wellington, who takes a lively interest in the undertaking, will be present on the occasion.—*Times, Sep.* 6.

Newly Recovered Land.—Since the opening of the new cut from Eau Brink to Lynn, which took place about 20 years ago, the old channel, which was very wide and spacious, by which the water of the Ouse and its tributary streams were formerly conveyed to Lynn, has been gradually silting up, and much of it has now become firm land, producing rich and flourishing herbage. A few days since a portion of this newly recovered land (containing about 900 acres), which is now embanked and fenced with live quickset fences, and divided into convenient pieces for occupation, was let by auction, at the Globe Inn, Lynn, and the annual rental obtained for it averages nearly 3*l.* per acre. Calculating upon this ratio, were an embankment of the Wash to take place, the annual value of the land which would be obtained by that undertaking we might reasonably estimate at not less than £500,000. At the last quarterly meeting of the Lynn town-council, Mr. F. Lane laid upon the table a copy of a memorial presented to the Commissioners of Woods and Forests, which memorial referred to the inclosure of the Great Level of the Wash, and was accompanied with a letter, stating that the application to Parliament upon that subject was intended to be renewed in the next session. —*Norfolk Times*.

London Bridge.—This bridge is to be closed for the purpose of repaving the road, which is to be done with Aberdeen Granite, not exceeding three inches in width, to be laid in parallel courses.

Windsor Home Park.—Great improvements are going on by order of Her Majesty. A very neat iron bridge has been erected over the Datchet road which has been covered with the Seyssel Asphalte. Other works in Asphalte have also been executed at the castle.

LIST OF NEW PATENTS.

GRANTED IN ENGLAND FROM 24TH AUGUST, TO 23RD SEPTEMBER, 1841.

Six Months allowed for Enrolment.

RICHARD WHITAKER, of Cambridge, machinist, for "*improvements in cutting the edges of books, and paper for other purposes; and in impressing ornaments, letters, and figures on the binding of books and on other surfaces.*"—Sealed September 4.

THEOPHILE ANTOINE WILLHELME COUNT OF HOMPESCH, of Mivart's Hotel, Brook-street, Middlesex, for "*improvements in obtaining oils and other products from bituminous matters, and in purifying or rectifying oils obtained from such matters.*"—September 4.

JOHN BOOT, of Quandron, Leicester, lace glove manufacturer, and JOHN KING, of Henor, lace-maker, for "*certain improvements in machinery or apparatus for manufacturing or producing figured or ornamented fabrics in ivory and bobbin-net lace machines.*"—September 4.

JOHN GRAFTON, of Cambridge, civil engineer, for "*an improved method of manufacturing gas.*"—September 4; two months.

MICHAEL COUPLAND, of Pond-yard, Southwark, millwright and engineer, for "*improvements in furnaces.*"—September 4.

GEORGE WILDES, of Coleman-street, merchant, for "*improvements in the manufacture of white lead.*" (Being a communication.)—September 4.

WILLIAM HILL DARKER, senior, and WILLIAM HILL DARKER, junior, both of Lambeth, engineers, and WILLIAM WOOD, of Wilton, carpet manufacturer, for "*certain improvements in looms for weaving.*"—September 4.

LOUIS LACHENAL, of Titchfield-street, Soho, mechanic, and ANTOINE VIEYRES, of No. 40, Pall-mall, watch-maker, for "*improvements in machinery for cutting cork.*"—September 4.

JOHN JUKES, of Lewisham, gentleman, for "*improvements in furnaces or fire-places.*"—September 6.

PIERRE PELLETAN, of St. Paul's Church-yard, professor of medicine, for "*improvements in propelling fluids and vessels.*"—September 6.

JOSEPH DREW, the younger, of Saint Peter's Port, for "*an improved method of cutting and rolling lozenges, and also of cutting gun-wads, wafers, and all other similar substances, by means of a certain machine designed by him, and constructed by divers metals and woods.*"—September 6.

LUKE HEBERT, of No. 12, Staple's-inn, London, for "*certain improvements in apparatus and metals used in the manufacture of gas for illumination: also improvements in the apparatus for burning the same.*" (Being a communication.)—September 8.

RICHARD ELSE, of Gray's-inn, Esq., for "*certain improvements in machinery or apparatus for forcing and raising water and other fluids.*"—September 8.

WILLIAM FAIRBAIRN, of Millwall, Poplar, engineer, for "*certain improvements in the construction and arrangement of steam engines.*"—September 8.

JOSEPH COOKE GRANT, of Stamford, ironmonger and agricultural implement maker, for "*improvements in horse rakes and hoes.*"—September 8.

NATHANIEL CARD, of Manchester, candle-wick-maker, for "*certain improvements in the manufacture of wicks for candles, lamps, or other similar purposes, and in the apparatus connected therewith.*"—September 8.

JAMES THORBURN, of Manchester, machinist, for "*certain improvements in machinery for producing knitted fabrics.*"—September 8.

MILES BERRY, of Chancery-lane, civil engineer, for "*a new or improved method or means of, and apparatus for, cleansing typographical characters or forms of type, after being used in printing.*" (Being a communication.)—September 8.

OGLETHORPE WAKELIN BARRATT, of Birmingham, metal-gilder, for "*certain improvements in the precipitation or deposition of metals.*"—September 8.

JOSEPH GARNETT, of Haslingden, dyer, and JOHN MASON, of Rochdale, machine maker, for "*certain improvements in machinery or apparatus employed in the manufacture of yarns and cloth, and are also in possession of certain improvements applicable to the same.*" (Being partly a communication.)—September 8.

EDWARD LOOS DE SCHELESTADT, engineer and chemist, and ETIENNE STERLINGNE, tanner, of Regent's-square, in the county of Middlesex, for "*certain new or improved machinery or apparatus and process for tanning skins or hides, and preparing or operating upon vegetable and other substances.*"—September 8.

GEORGE MANNERING, of Dover, plumber, and HENRY HARRISON, of Ashford, plumber, for "*certain improvements in the means of raising water and other liquids.*"—September 8.

ALPHONSE RENE LE MIRE DE NORMANDY, of Redcross-square, Cripplegate, doctor of medicine, for "*certain improvements in the manufacture of soap.*"—September 8.

WILLIAM CROSSKILL, of Beverley, iron-founder and engineer, for "*improvements in machinery for rolling and crushing land, and in machinery to be used in the culture of land.*"—September 9.

WILLIAM HICKLING BENNETT, of Ravensbourne Wood-mills, Deptford, gentleman, for "*improvements in machinery for cutting wood, and in apparatus connected therewith, part of which may be applied to other purposes.*"—September 9.

CHARLES LOUIS STANISLAS BARON HEURTELOUP, of Albany-street, Regent's-park, for "*an improved manufacture of continuous priming for, and improved mechanism for the application of the same to, certain descriptions of fire-arms.*"—September 9.

CONRAD FREDERICK STOLTMEYER, of Golden-terrace, Barnsbury-road, Islington, merchant, for "*certain improvements in obtaining and applying motive power by means of winds and waves, for propelling vessels on water, and driving other machinery.*"—September 17.

WILLIAM NEWTON, of Chancery-lane, civil engineer, for "*improved machinery for manufacturing felts or felted cloths.*"—September 20.

JOSEPH HULME, of Manchester, engineer, for "*certain improvements in machinery or apparatus for grinding, sharpening, or setting the teeth of cards, or other similar apparatus employed for carding or operating upon cotton, wool, or other fibrous substances.*"—September 20.

THOMAS HUCKVALE, of Over Norton, Oxford, farmer, for "*improvements in horse-hoes, and in apparatus for treating and dressing turnips, to preserve them from insects, and promote their growth.*"—September 20.

ALFRED ELAM, of Huddersfield, surgical instrument maker, for "*improvements in apparatus for instruments for the relief and cure of procedencia and prolapsus uteri.*"—September 20.

LUKE HEBERT, of Birmingham, for "*improvements in machinery for fulling woollen cloth.*" (Being a communication.)—September 20.

WILLIAM CHARLTON FORSTER, of Bartholomew Close, gentleman, for "*a material, or compound of material, not hitherto so used for preventing damp rising in walls, and for freeing walls from damp, which material, or compound of material, can be applied to other purposes.*"—September 20.

FRANCOIS MARIE AG. THE DEZ MAUREL, of Newington Terrace, Surrey, for "*an improved buckle.*" (Being a communication.)—September 20.

GEORGE SHILLBEER, of Milton-street, Euston-square, carriage builder, for "*improvements in the construction of hearses, mourning and other carriages.*"—September 20.

WILLIAM BUSH, of Deptford, engineer, for "*improvements in the means of, and in the apparatus for, building and working under water.*"—September 21.

COMTE MELANO DE CALCINA, of Nassau-street, Soho, for "*improvements in paving or covering roads, and other ways, or surfaces.*"—September 21.

EDWARD EMANUEL PERKINS, of Weston Hill, Norwood, gentleman, for "*improvements in the manufacture of soap.*"—September 21.

JOHN DUNCAN, of Great George-street, Westminster, gentleman, for "*improvements in machinery for driving piles.*"—September 21.

HENRY BESSEMER, of Baxted House, Saint Pancras, engineer, and CHARLES LOUIS SCHONBERG, of Sidmouth Place, Gray's Inn Lane Road, artist, for "*improvements in the manufacture of certain glass.*"—September 23.

GEORGE SCOTT, of Louth, miller, for "*certain improvements in flour mills.*"—September 23.

JAMES WHITELAW, engineer, of Glasgow, and JAMES STIRRATT, manufacturer, of Paisley, Renfrew, for "*improvements in rotary machines to be worked by water.*"—September 23.

TO CORRESPONDENTS.

Mr. Pilbrow.—*We shall be happy to lay before our readers any new facts he may bring forward in support of his peculiar form of Engine, and when he has got the steam up in the 50 horse engine now constructing on his principle, we shall feel much pleasure in recording the results.*

Mr. Barret and Mr. Brooks.—*We have been again called to account by these two gentlemen, for not publishing their communications; we can assure them that it is our desire to accommodate all our correspondents if possible, but on account of the numerous articles connected with the profession which demand immediate attention, we are obliged to defer controversial articles; we will however endeavour next month to accommodate both Mr. Barret and Mr. Brooks.*

Probably after three years more practice F. will say that we have been merciful.

Books received which must stand over for notice until next month—Elements of Perspective Drawing; Report on Boucherie's Process of Preserving Wood; Denton's Outline of a Method of Model Mapping; A Letter to the Shareholders of the Bristol and Exeter Railway, by W. Gravatt, C.E., F.R.S.; this letter discloses some suspicious circumstances, which we hope before our next publication appears, the parties concerned will be able to clear up.

We regret that we have not been able to find room for a very valuable report on the Improvement of Lough Erne, by Mr. Rhodes, E.C.

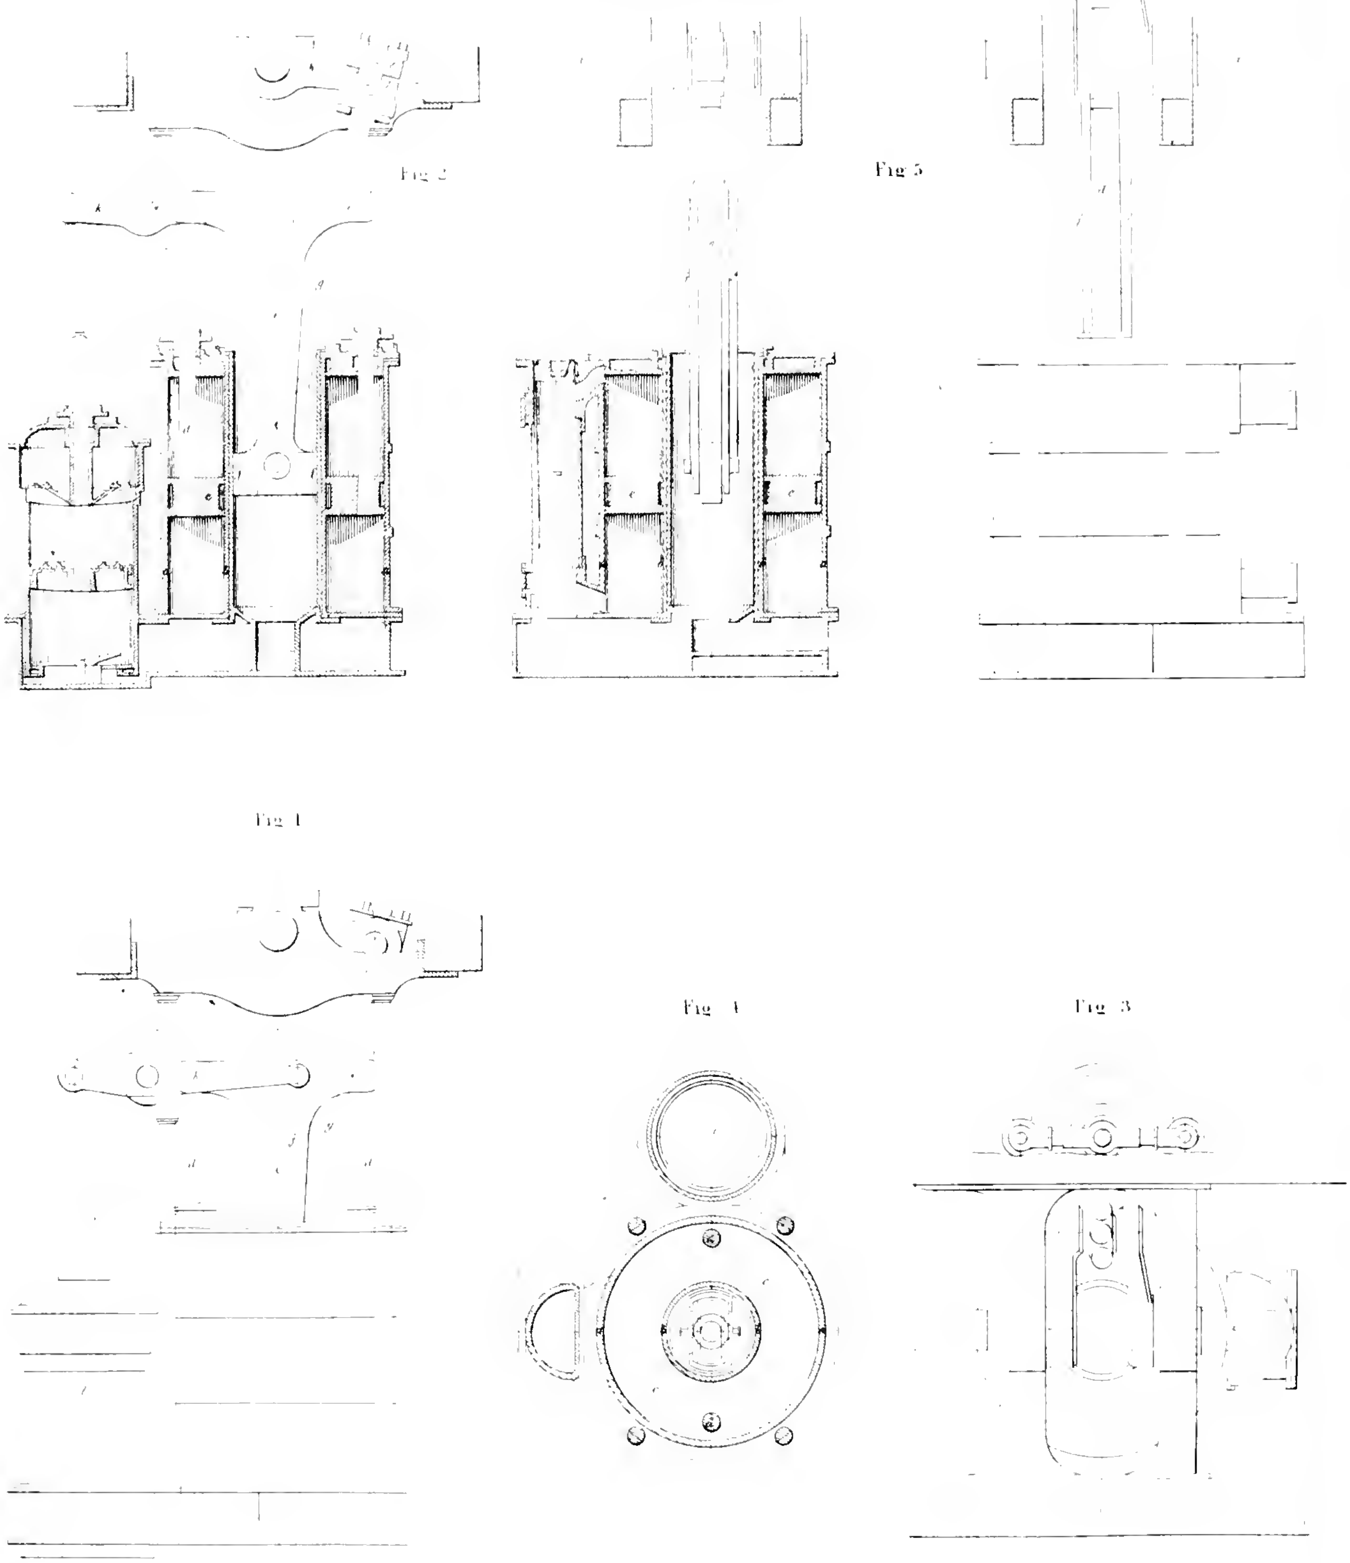
Communications are requested to be addressed to "The Editor of the Civil Engineer and Architect's Journal," *No. 11, Parliament Street, Westminster.*

Books for Review must be sent early in the month, communications on or before the 20th (if with drawings, earlier), and advertisements on or before the 25th instant.

Vols. I, II, and III, may be had, bound in cloth, price £1 each Volume.

Joseph Maudslay's Improved Marine Steam Engine

Patd. [illegible]



IMPROVEMENTS IN THE CONSTRUCTION OF MARINE STEAM ENGINES.

(With an Engraving, Plate VIII.)

Abstract of Specification of a Patent granted 16th March, 1841, to Joseph Maudslay, of the firm of Maudslay, Sons, and Field, Engineers, Lambeth.

These improvements relate to the arrangement of certain parts of steam engines of that kind, (usually termed direct action engines), whereof the centre of the cylinder is situated immediately beneath the axis of the cranks, and are assigned for the purpose of producing and applying a greater amount of steam power than has heretofore been available within a given space or area on ship board, and for the purpose of applying a greater length of stroke and connecting rod in a given height, than can be obtained (in a direct action engine) by any other means, and the lower end of the connecting rod guided without any lateral pressure on the piston or piston rods.

They consist in disposing the connecting rod in a space which is left vacant for its reception, (together with the requisite appurtenances of that rod) within the central part of the steam cylinder, and within the central part of the piston which works up and down in the said cylinder, the steam cylinder having for that purpose a small cylinder fixed concentrically within it, and the piston being a broad ring or annulus, which encompasses the said small cylinder, and fits into the annular cylindrical space which is left between the interior of the steam cylinder, and the exterior of the said small cylinder. The annular piston is moved alternately up and down in the said annular cylindrical space, by the force of steam acting therein, but which steam does not enter into the interior of the small cylinder, neither is any piston or part of the piston fitted therein, but the interior of the small cylinder is left open at top and vacant within, for the connecting rod and its requisite appurtenances to work in, with liberty for that rod to move up and down therein, and likewise with liberty when so moving, to incline as much as it requires to do, from a vertical position alternately on one side of the vertical and then on the contrary side thereof, in consequence of the upper end of the connecting rod accompanying the motion of the crank pin in its circular orbit (in the usual manner of connecting rods), whilst the lower end of the said rod moves alternately up and down in a vertical line, that line being at the central line or imaginary axis of the steam cylinder, and which axis would in ordinary steam engines be situated in the centre of the solid metal of the ordinary piston and piston rod, but according to my improvements in the arrangement and combination of the various parts, the said vertical line or imaginary axis of the steam cylinder, is situated in an open space which, as already stated, is left vacant for the purpose of receiving the connecting rod, together with its appurtenances within the central part of the steam cylinder, and within the central part of the annular piston, in consequence of the small cylinder being fixed concentrically within the interior of the steam cylinder, and in consequence of the cylinder cover, as well as the piston being each a broad ring or annulus, and each being suitably fitted to the annular cylindrical space between the two cylinders, but without covering or occupying the interior of the small cylinder.

These improvements will be more fully understood by a reference to the accompanying engraving, and the following description thereof, in which fig. 1 is an elevation of the said engine taken longitudinally, fig. 2 is a longitudinal vertical section corresponding to the side elevation fig. 1, fig. 3 is a horizontal plan of the upper part of the engine, and fig. 4 is a horizontal section of the cylinder thereof; fig. 5 is a transverse vertical elevation and section representing two such engines disposed side by side for combined action; one of the two engines in fig. 5 being represented in elevation, the other in section. The same letters of reference denote the same parts in all the figures.

The exterior or large cylinder is shown at *a a*, the interior and smaller cylinder concentric to it at *b b*, and an annular piston at *c c*, having two piston rods *d d*, working through stuffing boxes in the annular cover of the cylinders, the upper ends of which rods are affixed by keys to the T shaped cross head *e, e, e, e*, at the lower ends of which cross head there is a slider *f*, working within the inner cylinder, to this slider *f* one end of a connecting rod *g* is attached, the other end of the rod being attached to the crank pin of the crank *h*, on the propelling shaft.

From this arrangement it will be perceived that by the ascent and descent of the piston *c c*, the rods *d d*, will cause the cross head *e e*, to move perpendicularly up and down, and in so doing to raise and depress the slider *f*, with the connecting rod *g*, which rod will by that means be made to give rotary motion to the crank *h*, and thereby cause the paddle-wheel shaft *i* to revolve. The rods *j j*, connected to the slider *f*, will at the same time work the levers or beams *k k*, to which the rods of the air pump *l*, are attached.

Having fully described the invention, the patentee desires it to be understood that he does not claim the use of two concentric cylinders and an annular piston, but he claims as his invention the use of the space within the interior cylinder for the lower end of the connecting rod to work in, whereby the ultimate length of stroke and connecting rod within a given height is obtained, and the lower end of the connecting rod guided without any lateral pressure on the piston or piston rods.

CANDIDUS'S NOTE-BOOK.

FASCICULUS XXXII.

> " I must have liberty
> Withal, as large a charter as the winds,
> To blow on whom I please."

I. ONE of the prettiest little bits of street architecture about town that I know of is the front of a small house adjoining the Polytechnic Institute, in the upper part of Regent Street;—a very clever and artist like specimen of Italian, in which rustication of a more than usually finished and picturesque character has been very happily applied—of that kind which may be termed *mixed* rustication, both vermiculated rustics and moulded ones with plain faces being employed, —as has likewise been done in the new houses on the south side of Lowndes Square. The character thus produced is at once rich and sober. The archway forming the entrance to some livery stables, on one side, is not the least agreeable feature in the design, nor is it any compliment to it to say, that it is in infinitely better taste than the huge slice of architectural gingerbread which Nash clapped by way of frontispiece, against that mass of ugliness the Royal Mews at Pimlico. How that Nash did palm his Brummagem stuff upon old George the Fourth!—and took pretty good care to be paid for it in sterling cash —good and lawful money of the realm!

II. Because it does not happen to be as big, as tawdry, and as ugly as one of the Regent's Park Barracks—those genteel Union Workhouse affairs—no one has been able to discern any merit at all in the specimen above referred to. The Paddington or Paddy style—the horrible mushroom monstrosities which are now springing up in that district, and which are apparently directed by some Nash the second—some genius well qualified to be the successor of that mighty master, —are far more to John Bull's taste, and according to his notion of "genteel houses."

III. "Can you give me any sure general rule for my guidance by adhering to which I shall always be certain of attaining superior beauty in composition and design?"—Such was the question once put by an architect to a connoisseur of acknowledged taste, who thereupon replied: "My advice was asked the other day by a writer who wished me to inform him what rule he should attend to in order to raise himself in the literary world. My counsel to him was: be original if you can, be interesting if you are able. As I answered him, so now I answer you: display both invention and taste, and into whatever you do take care to put character and effect. I know of no other general rule; but if you can act up to that, I believe you will find it a sufficiently efficacious one." A plain answer to a very *simple* question!

IV. It is a wonder that Pugin has not shown up the range of Brummagem Gothic buildings in the Temple,—most trumpery and tasteless as to character, though, no doubt, not very trumpery—perhaps of most sterling merit, as to cost. Not a little strange, too, is it that he did not have a fling at that notable example of Civic Gothic the façade of Guildhall, which is such a perfect monstrosity that it deserves to be pulled down.

V. Besides giving Turner a tremendously heavy blow—one almost sufficient to demolish him, and put him quite *hors de combat*, the reviewer of the "Exhibitions," in Blackwood, deals a few home strokes at Stanfield, and also at our present English view-mania. "What," he asks, "must the inhabitants of all the tumbledown places on the Rhine and the Rhone think of us, our scenery, our buildings, and our taste, when they learn that representations of their beggarly edifices and their abominable outskirts form the chief ornaments of our Royal Exhibition?"—"Nor in respect to architecture," he afterwards observes, "are our views always in good taste. The low and the mean, the decayed and the poverty-stricken, are often thought to be the only picturesque, as if *picture* must indulge in vile associations. Let not art take *habitat* in "rotten rows," nor vainly imagine that the eye should seek delight where the foot would not willingly tread—the purlieus of misery and vice. All the pictorial charms of light and shade, and colour are to be found in subjects which shall not degrade them. There is no lack of architecture that elevates instead of depressing the mind, both by its grandeur of design, the work of genius, and by the associations it calls up. In a word, in every branch of art let what is low and mean be discarded, however it may tempt the artist under the idea of the picturesque."—To the above advice which is very much needed, might be added another wholesome caution namely, that in subjects more or less professedly architectural, the architecture itself should be treated as principal—as that in which the main interest lies, and not as too frequently happens, exhibited little more than nominally being nearly slurred over, while the value of the composition is made to depend upon accessories and casual circumstances—perhaps on *staffage* and figures, or some exaggerated contrast of light and shade, improbable if not impossible,—a pyebald medley of midday and midnight. As to architectural character, whether arising from the ensemble or the detail, that is not to be looked for in the "illustrations" annually manufactured to suit the taste of the million. We have views of Windsor Castle, wherein the building itself shows itself only as a mere speck in the landscape, the real view being that of trees and cattle, or figures in the foreground. In many cases, indeed, such mode of representing and "illustrating" buildings is not only highly convenient, but suitable and advantageous also, the things themselves being of no interest, or at all worth being shown. This may be affirmed of almost the greater part of topographical illustrations—views of the most insipid and common place houses, &c. imaginable, "of no value except to their owners."

VI. One might almost imagine that scarcely a building of any note had been erected in Germany within the last five and twenty years,—that Berlin, Potsdam, Munich, Dresden, Vienna, Hamburgh, &c. could not boast of a single new architectural feature of any merit, that Schinkel, Klenze, Gartner, Moller, Gutensohn, Ohlmuller, Semper, &c. had executed nothing—nothing at least deserving the attention of the English public. How else are we to explain the neglect which modern German architecture has experienced from those who set themselves up as luminaries of taste, to enlighten the public, and to "illustrate" by their pencils the *notabilia* of other countries?—Our consolation must be that perhaps we lose very little by such subjects as those above alluded to being passed by unnoticed by our manufacturers of views and "illustrations,"—things for the most part made up from slovenly, hurried sketches, which the engraver is left to make out as well as he can, and to dress up to the best of his ability. What such productions want in regard to truth and fidelity, is amply made up for by imagination and invention,—which have ever been reckoned among the more valuable qualities of art. Besides which there is one very great advantage attending the disregard of truth-telling accuracy, which is, that it does not forestal the gratification to be derived from viewing the buildings and places themselves, since they are generally found to be altogether different from their pretended representations. Thus when seen they make all the impression of perfect novelty, and produce double surprise—agreeable surprise at finding them greatly surpass expectation, and a queerish, indiscribable sort of surprise at finding out how much we have been all along *mist*-ified by owlish illustrators.

VII. After seeing to-day the works at the New Houses of Parliament I feel most amiably disposed towards Mrs. Wright of "awful conflagration" celebrity—whom I once, I believe, called a stupid old Jessabel worthy of the pillory, for had she by timely interference prevented the "accident," the splendid pile now rising to view would never have been reared. It was a mercy that the old "Houses" were burnt down when they were; since had the fire occurred during the "reign" of James—that is, the reign of James Wyatt "of execrable memory,"—we should have had some strange Gothicizings, such as those which now strike us with astonishment in some of the buildings still remaining in what was formerly the river front. The great fault of Mr. Barry's Gothic is that it puts us quite out of conceit with a good many other things, and with Windsor Castle among the rest; which I must confess falls greatly short of what I had been previously led to expect, there being very much in it that is exceedingly questionable as to taste. Not the least remarkable circumstance in Barry's edifices is that the inner courts—the quadrangle of the Speaker's residence, for instance, will be though less elaborate as carefully designed and finished as those parts which are exposed to public view; whereas the greater part of the exterior of the British Museum presents only a mass of plain brick wall, with naked windows. I admit that more attention is paid to design in the inner court of that edifice,—and wonderfully frigid it is—classically dull and Smirkish throughout. Poor Smirke! how greatly he is to be pitied!—and for the very reason that many may now envy him, to wit, because he has had so many opportunities of manifesting his imbecillity. Barry—Smirke, they are as far asunder as the two poles; or I might say the difference between them is that of the tropical and the frozen regions. As to Barry, I am afraid that his Houses of Parliament will sadly discomfort Welby Pugin, by giving the lie direct to his assertions

VIII. "One of the Ventilation Folks" has taken too much *au pied de la lettre*, the obviously quizzical remarks in which I indulged in regard to the excessive and *fussy* rout on the subject of ventilation, as if it was a perfectly new discovery, and as if people had been suffocating themselves for ages past, rich and poor alike, in palaces as well as in hovels, in the country as well as in towns, and inhaling pestilence at every breath, at least when within doors. Nothing as far as I can discover, did I say in favour of stinking alleys, and frowsy rooms; nor did I express any admiration for the *aroma* of a drain, though from what the "One" has said it might almost be fancied that I recommended it as "a cheap and elegant substitute" for attar of roses. My remarks went no further than a little banter on the overstrained necessity for far greater attention to ventilation than has hitherto been considered requisite, except for prisons, factories, and other buildings where people are densely pent up together. That the doctrine of the Ventilation Folks is somewhat overstrained can hardly, I think, be denied: for the plain reason that it proves rather too much, and that a great portion of the population in towns could hardly exist at all; nevertheless exist they do, and that, too, under circumstances which must frequently aggravate a thousandfold the mischiefs arising from insufficient ventilation.

If ventilation be of such exceeding importance as is insisted upon by its advocates, how terribly—nay fatally must those people blunder who take their daily airing in a carriage with the windows drawn up, and which is then nearly air-tight. Not less blundering is the practice of those who make it a point to secure an airy bedchamber, and then closet themselves within curtains drawn so closely around them, that they might as well sleep in a closet of the same dimensions as their bed. If "Ventilation" be quite in the right, Gentility must be confoundedly in the wrong; since what barbarians those must be who in order to gratify a little trumpery vanity, stow away and squeeze their "five hundred dear friends" together, till they might nearly as well be in the Black Hole at Calcutta! Why do not the Ventilation Folks call upon the legislature to make all such "At Homes" illegal assemblages, devised for the purpose of smothering her Majesty's loyal and fashionable subjects? I know not whether the Ventilation Folks are particularly musical, but if they are so at all, I presume that their chief and favourite instrument is the Æolian harp; at the same time I suspect that some of them have no particular dislike to playing the *trumpet*.

HINTS ON ARCHITECTURAL CRITICISM.—PART 2.

My last paper confined itself to a statement that architecture possessed the same claims to open criticism as her sister arts;—my present design is to enforce those claims more strongly. The attempt then was to deprive taste of its precarious nature, and so to shake prejudice, as to prepare the mind for further illustration in proof of that statement; the present effort consists in reconciling an apparent discrepancy between the claims of architecture and the other arts, by displaying the peculiar features in which her poetry is cast, and by showing that though the mind be effected in a more remote and delicate manner, and that though an emotion, or an idea induced by it, be neither so animated, nor so vivid as another art might produce, yet that its effects are not the less faithful, nor less the result of a principle (whilst the principle itself emanates from nature); and hence, that if there be such a principle to guide the architect towards the material of his fancy, then architecture may remodel herself, and criticism may unbend.

One peculiar distinction of architecture appears to be in its compelling us when viewing the composition, to assume a suggestive or comparing attitude, and this necessity is consequent upon there being little that is strictly imitative in its phisiognomy or shape. This power of suggestion varies in degree, in the choice of features, and in the manner of their disposal. Where there is an introduction and classification of natural figures, so as to intrude on the province of the sculptor, the suggestive power of the art is shown in its faintest degree, for the imagination is in that case assisted by the presence of a familiar object, and the senses being palpably impressed, the mind has less effort to arrive at the final conception and emotion. The suggestive power in this case however still belongs to architecture, because it forms a feature in the whole, and because the architect exercises a discretionary power in the adaptation; but the features themselves are not so strictly suggestive as architectural features usually are

The strictly suggestive character is, where the object has no counterpart in nature, but where, from a certain attitude or proportion in the figure, assisted by relative position, the mind is left to suggest to itself an object in nature, expressive of some ideal quality, to which the figure might claim a point or two of resemblance.

In the comparison between the figure which has no counterpart in nature, and that which the imagination furnishes, there is extreme delicacy of perception requisite to detect a similitude; for, in exercising this power of comparison, we but transpose the elements of wit, since the strength of wit which consists in its delicacy is but the perception of a certain resemblance between two things, not essentially similar, but alike only in those features of which the idea takes cognizance. Two ideas in this case present themselves, and the relation found in those ideas, after the test of comparison, is essentially the product of wit. The relish which the mind has for this ingenious activity, the natural bias there is apparent in most of us, to indulge in this harmless intricacy of thought,—the pleasure too which we experience in detecting the force of an allusion, all imply an innate power in the mind to perceive a possible harmony or relationship between two separate and distinct things. It is in fact a self creative power, which for the time the mind exercises, by which out of apparently inapt materials, it shapes a perfect idea. Applying this to architecture, we may at once perceive the origin of the claim, which its inanimate features have upon us. Further to examine into the principle which moves us, we may perceive, that in the comparison of wit, however varied the play of fancy, or however apportioned the strength of perception may be, the ideas placed in juxtaposition, are not seen directly in the attribute of an object, but in that which is mostly associated with that attribute,—viz. the attitude or position by which we judge of the mind or intention. It is the external sign which wit first embraces, and not the inward evidence, and hence it is we comprehend the force of the ludicrous, (which is in truth the force of unexpressed wit) from figure, attitude, &c., our idea of pleasure arising from conflicting associations,—that is, from certain real or declared properties of the object, or of the mind through the object being seen connected with associations, which we perceive totally at variance with those naturally connected with them. It is upon this ground that we smile at the large head of a dwarf, or at the affectation of delicacy in a fat person, or laugh at the threatening attitude of a little slender man: therefore the pleasure of comparison is the pleasure of attitude; and inasmuch as this pleasure may be carried from wit to poetry, a definition of the poetry of attitude is necessary to assist in supporting the poetry of architecture.

The attitude of an object affects us then because we observe certain dispositions of the mind when exhibited, are frequently associated with certain attitudes, which, when unstudied appear natural, until from frequent observation that the same attitude is an index to the same disposition of the mind, we identify that attitude with it. It is this which has given personification to still life, and peopled nature with living beauty and grandeur. It is this same principle which has associated the willow with grief, and the oak with stubborn dignity;—which has detected modesty in a flower, or discovered wanton beauty in moving foliage. It is in truth the principle of life to the art of the poet, and it is by this that the poet is understood. The spectator of nature admits this in his own emotions, as he watches those objects which surround him, for he sees the graphic power of scenic poetry to consist in its picture of attitudes. The poet admits its influence still more delicately when he allows an attitude to invisible things. It was a consciousness of the poetry of attitude, that induced the lines:

> "'Tis sweet to listen as the night winds creep
> From leaf to leaf."

For whilst the ear is made sensible of the approach of the winds, the eye also may observe their furtive melancholy progress. It is thus then that attitude engages us, but attitude is not always significant of a collected state of mind;—there is often a carelessness about it which induces a different emotion from that attitude, which directly expresses an idea: it being always borne in mind that the object is for a time the personification of feeling and of will. A similar kind of effect is produced on the mind in such a case, only very faintly,—there being no definable idea connected therewith. It is very frequently the case in architecture that we feel the truth of this, as we revel amidst the smaller attractions of a composition, where we perceive about its minutiæ, attitudes, which we think beautiful, without knowing why. This innocent perplexity of thought which assails the mind, leaving it only when it has bewildered it, is the very secret of all the interest created: the reason being tempted into innumerable petty defeats, from each of which it arises to encounter a fresh one, as the several parts of beauty appear to seduce it on. It is here that criticism is disarmed,—criticism taking cognizance only of the position and extent of such attraction; and, it is because criticism is disarmed at this point, that architecture often exhibits such redundancy of beauty, which sickens the fancy and the taste. Attitude however has its carelessness, in a nearer approach than this to individual beauty, that is, where there is a more definite proportion traceable through its parts, though the same perplexity of the mind may be preserved; and it is in this state of attitude that we discover the beautiful in architecture, and by this are enabled to depict its ideal of grace or of grandeur. Byron beautifully illustrates this thought in his description of Dudù:

> Few angles were there in her form, 'tis true,
> Thinner she might have been and yet scarce lose;
> Yet, after all, 'twould puzzle to say where
> It would not spoil some separate charm to pare.
> She looked ————————
> The mortal and the marble still at strife,
> And timidly expanding into life.

Admiration of women in general, springs from the same subtle and exquisite cause: our ideas moving like the movements of sense amidst the same perplexities, becoming as we gaze, like the lovely cause, an elegant deceit For to admire woman requires not that we be absorbed by her mind, or her acquirements, since to appreciate either, we must turn to the cold test of a balance, or a criticism: nor do we descend to the base notion that she is the mere adjunct of pleasure, since poetry, the very element of her charms must then decay. No!—we seek her as a riddle,—we love her as an enigma,—we chase her through the follies of her course as a lovely inconsistency,—as a fanciful light we would snatch at and grasp. Our vanity tempts us to seize this for ourselves, which nothing seems to arrest, and to hug this creature of caresses, if only to rob nature of her dearest child.

Our ideas of grace and grandeur in architecture becoming then often those of attitude, as do those of the beautiful and sublime in nature,—grace, which we identify with no particular proportion when discovered in nature, becomes at once in attitude a lovely perplexity,—a creature of careless, yet correct shape, which, at a motion however slight, would take another form of elegance, as beautiful as she herself would be unconscious. Grandeur differs from grace, inasmuch as the energetic differs from the wanton, so that grandeur is always the creature of comparison, whose colossal form suggesting powers, contrasts itself with familiar trifles.

The principle which affects us has already been shown, but looking at this in a simpler and more homely guise, we may say that it is the poetry of attitude, which is the poetry of arrangement;—that is displays itself in domestic taste, and gives to the taste of a woman, that elegance and beauty so peculiarly her own. It is because her mind can engage itself in such gentle and beautiful comparisons,—because her perception of things is but a perception of their poetry,—because (which is a consequence) she allows nothing, and admits nothing around her, but such as can echo to her sensitively graceful mind, that her abode is replete with harmony, and beauty, and love.

Such is a feeble definition of the poetry of attitude, which is universal throughout nature, whether exhibited in her minuteness or her vastness, and such is a scanty description of that subtle faculty which extracts from her ever varying flowers, that honey which it hives for the nourishment of art.

Laboured as such reasoning may appear, inapplicable as such abstract considerations may be thought to the practical requirements of art, there is nevertheless in such an analysis, the exposure of poetry in its germ. There is, in testing our sensations by the varieties of nature, that secret spring opened into activity, which enriches the productions of art, and causes beauty, grace and grandeur, to start from the inanimate stone. There is, in generalizing our views, a liberality given to the mind, which deducing out of its observations, the true principles which affect it, begets an intuitive confidence in its own powers, to conceive and embody for the eye, its ever beauteous—ever endless creations. The deduction from the argument is, that if nature be the poet's laboratory, and if attitude prove to the mind one of her most operative principles, then, the degree of poetry in architecture bears a ratio (as far as attitude is concerned) to her power over attitude. It has already been shown by inference that she has this display of attitude, and that she embraces the same materials of beauty, which we see in external nature, therefore, as children of nature, we assert the poetry of our art. We know too that she has the same scenic effects from the lights and shadows she distributes; for when, as in the cathedral, these fall softly on surrounding objects, or when the eye sinks wearied from its awful wanderings amidst vastness and obscurity, to repose amidst beauties which peep from the dimest perspective, chords of joy swept by attitude vibrate on to entrance the senses.

So much for the principle which moves us, and so much for the argument in favour of architecture and her claims to criticism: yet, it must be borne in mind, that no more is attempted than to show a principle;—all illustration being consequent upon, and not connected with it:—the present attempt being solely to establish a claim to criticism, and not to dilate upon what it would be premature to consider, when attitude itself is merely subsidiary.

Space prevents further pursuance of a subject which would lead us away from attitude, to proportion, the questionable nature of which it was designed to sketch. Not wishing however to intrude further before the reader, the conclusion is reserved. However humbly these hints are delivered, or however feebly they may have been conceived, the writer knows that nature is adequate to the profoundest investigations, supplying as she does to every art the truest and the wisest rules, and that the more closely we adhere to her unchangeable maxims, the more dignified do we rise as artists, and as lovers of truth. He knows also that unless an art be capable of charming the senses, or of enriching, or of delighting the imagination, and can support its claims to such power, it is only a mockery of commendation to say that its compositions are governed by the most exact rules, and hence it is only a mockery to criticize:—"*ars enim, cùm à naturà profecta sit, nisi naturam moveat ac delectet, nihil sane egrisse videtur*:"—Cic. de oratore.

FREDERICK EAST.

October, 1841.

ENGINEERING WORKS OF THE ANCIENTS, No. 10.

THE present paper, which will be devoted to the Latin authors, will conclude this series, which, although far from being complete, is extensive enough to show that much may be done to illustrate the antiquities of engineering. C. J. Cæsar is the first author who comes before us, and in him we find nothing except an allusion to the mining skill of the Gauls, and an account, in Book 4, ch. 15, of the bridge he threw over the Rhine. In Sallust we find absolutely nothing. From Livy the gleanings are but few, an allusion to the works of the Tarquins in the first book; in the ninth book a statement that Appius Claudius Censor executed the Claudian aqueduct and Appian way; in book 39, a similar mention of C. Flaminius; in the 100th book, which is lost, there was an account of the drainage of the Pontine marshes. Quintus Curtius, in his 4th Book, ch. 2, has a long account of the siege of Tyre, and in Book 5, ch. 2, a description of Babylon. From Paterculus we have not been able to gain any thing, and Vitruvius we have left to the architects.

PLINY.

Pliny the Elder, who died A.D. 79, is to us one of the most interesting writers, for including in his work every department of the organic and inorganic world, we could scarcely fail to discover something of his value. We had occasion, however, last month to refer, in the review of Mr. Aikin's work, to some of Pliny's remarks on bricks, so that we are precluded from now giving them; the mining portion, we have also felt it necessary to exclude

BUILDINGS IN EARTHQUAKE COUNTRIES.

Pliny Book 2, ch. 82, recommends several modes of construction as calculated to resist the effects of earthquakes; he says that in some cases deep wells are advantageous, as they allow the dangerous gases to escape; that in some towns where there are many underground sewers, earthquakes are less felt; and that building on piles is extremely effective, as was to be observed in Naples, where the most solid part of the town is that which has suffered most. Brick walls, he also thinks, are less injured than others.

TUSCANS—ISTHMUS, &c.

In the 3rd Book, ch. 16, our author says that the Tuscans were the first to begin the canal system of the Po, by improving the Sagis. In Book 4, ch. 4, it is mentioned that King Demetrius, and the Emperors Julius Cæsar, Caius and Domitius Nero tried to cut a canal through the isthmus of Corinth but failed. In Book 31, ch. 3, is given a long treatise on wells, and chap. 6, on conduits.

INVENTORS.

Euryalus and Hyperbius, two brethren at Athens, caused the first brick and tile kilns, yea and houses thereof to be made in Greece. Gellius is of opinion that Doxius, the son of Cælus, invented the first houses that were made of earth and clay, taking his patterns from swallows and martens' nests. Cingra the son of Agriopa, first devised tiling and slating houses, as also found out the brass mines, both in the island of Cyprus, he also invented pincers, hammers, levers, and the anvil. Danaus sank the first wells in Greece at Argos. Cadmus at Thebes found out stone quarries first. Thraso was the first builder of town walls, towers and fortresses, according to some, but according to others the Cyclops and Tyrinthians. Lydus, the Scythian, or Delas the Phrygian, taught the art of casting and melting brass, and of tempering it, and the Chalypes or the Cyclops invented the forge and furnace for brass. Erichthonius or Æacus discovered the silver mines of Attica, and Cadmus, the Phenician, the gold mines of Mount Pangæus, and the mode of working and melting that metal, although by some it is attributed to Thoas and Æaclis in Panchaia, or to Sol the son of Ocean. Midacritus was the first who brought lead (query tin) from the island Cassiteris. The iron-smith's forge was first invented by the Cyclops. Coræbus, an Athenian, taught the art of casting earthen vessels in moulds. The weaver's spindle was invented by Closter, son of Arachne; the potter's wheel by Anacharsis the Scythian, or Hyperbios the Corinthian; carpentry, and carpenter's tools, as the saw, chipaxe, plane, hatchet, plumb-line, augre, gimlet, as also glue by Dedalus; and the rule and square, the level, the lathe and the key by Theodore the Samian. Pyrodes, son of Cilix, found out the way of striking fire from flints, and Prometheus the means of keeping it in a wick of the *ferula* or giant fennel stalk. Instruments of warfare and vessels of war owed their origin to many hands, but to the Syrians is attributed the catapult, to the Phenicians the balista, and to Epeus at Troy the ram. (Book 7, chap. 56.)

METALS.

In the 33rd book Pliny begins his discourse on metals, minerals and mining, this is continued in the 34th.

CEMENTS, BRICKS, &c.

It is in the 35th book that our author discusses the subject of pottery, He says that a means had been found out to make a strong kind of mortar or cement with the broken sherds of potters, if the same be ground into powder and tempered with lime, this is called Signina, and durable pavements are made in the same way. Puzzolana is next described, and other earths used for hydraulic cements as those of Cyzicum, Cassandria, Gnidos, Aulis, the Nile, &c. Afterwards came the several kinds of mud walls, pisee work, rubble, &c., and the several forms of bricks.

The 35th Book is descriptive of stones, marbles, &c., where it is said that Ethiopian and Indian sand was used in cutting marble. This Book also treats upon limes, mortars and pavements.

In thus concluding our labours on this subject, we trust that we may indulge a hope that we have not laboured in vain; it was our endeavour to show that engineering was no art or science of to-day, but one of the remotest antiquity, long practised and long honoured, and if in so doing we have in degree vindicated the claims of the engineering profession to distinction, we shall consider our exertions fully repaid. We may say with truth, that however trifling the result, they have cost us much research, long time, and the perusal of many volumes, which, as they rarely come under the student's inspection, so has he little time to devote to their perusal.

A NEW SAFETY VALVE.

SIR—If you consider the following worthy of insertion, you would much oblige by giving it a corner in your valuable Journal. It being well known that a compound bar of steel and brass will, on account of their different rates of expansion, assume a curved form on the application of heat, which property I propose to apply to a new safety-valve by the following means:—I would place such a compound bar in a curved form into a cylinder open at each end, having four arms radiating to its centre through which passes a rod fixed to the cylinder, and which carries at the other end a circular plate moving steam tight, of a fixed plate perforated with two or three holes for the escape of steam. Then the bar being set, so that the apertures in the fixed plate shall be covered at the proper working pressure of the steam, then if the temperature should by any means be raised, the bar will immediately cause the rod to turn and open the valve.

There are many mechanical details that are not mentioned, wishing only to set forth the principle.

I am, Sir,
&c. &c.

18th Oct.

FUNNEL.

Vienna.—"The Austrian government," says a letter from Vienna of the 16th of September, "has formed the gigantic plan of building at the eastern extremity of this capital, on ground which is wholly unproductive, a new town, capable of containing 50.000 inhabitants, and which is to be provided at the outset with all the requisite great public buildings, such as churches, residence of the governor, court of justice, exchange, theatres, museum, &c. This town is to be called "Ferdinand tadt." The plans are already made by the Chevalier Forster, architect of the Court, who before he submits them to the government, intends to communicate them to the principal academies of the fine arts in Europe, with a request to give their opinion."

MR. STEVENSON'S IMPROVEMENTS ON LEVELLING INSTRUMENTS.

Sir—In the minutes of the Institution of Civil Engineers which were published in last month's Journal, there was a notice of my improvements on levelling instruments; but that notice was not correctly given, and strangely enough omitted all mention of *two* of these improvements. I have therefore as a favour to request that you will give the following correct account of these improvements a place in your Journal, which may be considered to be the present acknowledged organ of the profession.

Levelling Staff.—The improvements on the levelling staff is as follows: the first is the introduction into the staff with sliding vane of an adjusting screw with clamp, by which, after the vane has been brought within $\frac{1}{4}$ or $\frac{1}{8}$ inch of being correct (which is readily done with the hand), the vane is firmly clamped, and the final adjustment up or down is at once made with the screw. A similar plan, I have since been informed by Mr. Manby, Secretary to the Institution of Civil Engineers, was used by Capt. Lloyd (Roy. Soc. Trans.), and also by Mr. Bunt, while prosecuting their scientific researches; but Capt. Lloyd's staff was only 6 ft. long, and Mr. Bunt's 9 ft., being too short for engineering use. The application of this arrangement to engineering purposes I have found of great utility. The above adjusting apparatus is for the vane when on the lower half of the rod, which is 12½ ft. long. But when the level line (*i. e.* the optical axis of the telescope produced) is above the lower half of the staff, the vane is as in all rods with sliding vanes, first clamped at the top of the upper half of the staff, which is then pushed or slid along the face of the lower half, until the vane is within $\frac{1}{4}$ or $\frac{1}{8}$ inch of being correct, when the *upper half of the rod* is clamped and finally adjusted up or down by a clamp and screw apparatus fixed at the back of the lower half. By this plan, although the vane may be far out of reach, the adjusting apparatus never moves, being a fixture and within reach of the hand, thus obviating the necessity of having a long adjusting wire fork for working a capstan-headed vane screw, which, although perfectly suitable for Mr. Bunt's *optimum* levelling would of course not answer the long rods used by engineers. The next improvement is *the combinations in one rod of all the advantages of the sliding vane staff, with vernier readings for accurate work, and the self-reading staff for rough work.* This is effected by having the back of the rod graduated to feet and decimals by means of inlaid bone figures which are read through the telescope level. In this way I have not lost sight of Mr. Gravatt's ingenious contrivance of self reading. In making a section where it is necessary, in order to carry forward a correct result, to be careful only with the first and last sights after and before moving the instrument, the intermediate sights are read off the back of the staff by the telescope. The above instrument, which is 12½ feet long, and may be said to consist of a sliding vane staff and a self-reading staff, is, by the contrivance of a late friend of mine, packed up in a box 3½ feet long and 4 inches square!

Level.—The first improvement in the level is the fixture to the telescope tube of a *circular level sluggish in its motions*, instead of the comparatively delicate cross bubble of Mr. Gravatt's level.

The last improvement is the introduction of a *ball and socket joint* between the head and legs of the instrument, so as to have a motion intermediate in fineness between that of the parallel plate screws and that of the legs. Before the introduction of the parallel plate screws, I understand that levels had a ball and socket motion instead of the screws. The present improvement consists in *restoring* the ball and socket for the *rough setting*, and at the same time *retaining* the parallel plate screws for the *final adjustment.* The clumsiness of the present arrangement consists in the instrument being at all dependent on the setting of the legs. With the instrument thus improved, the surveyor is made quite independent of the level of the ground where he sets the legs of his instrument, and may place them without regard to the inclination of the telescope to the horizon. Looking first to the circular level, and releasing the clamp of the ball and socket, he with one hand moves the head of the instrument till the bubble is in the centre of the circle, an operation which is done almost instantaneously. The socket screw is then clamped, and the telescope bubble is brought to the *absolute* level by a slight touch of the parallel plate screws. In this way the legs of the instrument need never be moved after the instrument has been placed on the ground, and the parallel plate screws have almost nothing to do, advantages which all who are accustomed to levelling will fully appreciate. I may mention that the price of altering my old level to the new form was 1*l.*, but I have no doubt that in future the charge may be less. That the above improvements are well worthy the attention of the profession I am fully assured, else I should not have brought them forward. My own experience on hundreds of occasions, as well as that of others, has placed any thing like doubt completely aside, and with the ball and socket joint I have been enabled on very many occasions lately to take in sights with one setting of the instrument, that would otherwise have required two, owing to very irregular and precipitous rocks, which did not afford sufficiently level rests for the legs to allow the bubble to be brought right.

I remain, Sir,
Your obedient servant,
THOMAS STEVENSON.

Little Ross Island Light House Works, Kirkcudbright.
Oct. 11, 1841.

ON THE ECONOMY OF FUEL IN LOCOMOTIVES CONSEQUENT TO EXPANSION AS PRODUCED BY THE COVER OF THE SLIDE VALVE.

Sir—The confidence of anonymous writers is sometimes exceedingly amusing. For reasons best known to themselves they seem to put but little value on the idea that they themselves may perhaps be labouring under misapprehension; and such is singularly the case of a gentleman signing himself M., the author of a letter in your October number, containing some strictures on a paper of mine in your August number, on the subject which is the title of this letter. This gentleman, Mr. M., having discovered, he says, some errors in my calculations, hopes you will allow him to point them out for the benefit of your readers; and he begins by premising that although some formulæ of mine, which he points out, are correct, yet in two of them there are expressions which are identical, and which, he says, might perhaps be better expressed, now whether or not these expressions are identical, any schoolboy can find out, and whether or not they are identical, I hope Mr. M. will have the generosity to allow me to suppose them better stated in the form I have adopted. Mr. M. now proceeds to state that the value of (*s*) (*s* being the area of the piston) is incorrect, and that it is impossible to deduce the area of the piston from the length of the stroke cover and lead of the slide, and ratio of the greatest to the least pressure of the cylinder, without knowing how much steam is generated in the boiler. If Mr. M. would have the goodness to read over again a part of my paper, he would find it there stated that in the mode of expansion virtually adopted in locomotives, the cylinders are enlarged so as to consume the same quantity of steam, (which is just the whole steam that the boiler can produce); and this is the only way in which the question of advantage from expansion can be treated; now if Mr. M. would consider for a little he would see that what I am about with the equation,

$$s\left(a' - \frac{(2\,d - b)\,t}{p}\right) = 2\,d \times 1$$ is finding what area the piston must have so that the steam may be cut off at (a'), and yet the same constant quantity of it consumed, and he would see that so far from being able to give (*s*) any value we please, it can on the contrary have only one definite and particular value, which is assigned by this equation, and so far from $2\,d \times 1$ being an arbitrary quantity, it is the very quantity that properly represents the quantity of steam produced by the boiler, or which is the same thing in the question under consideration, the volume that the cylinder would have if no expansion took place.

Mr. M. in the next paragraph leads me to doubt if he understands the mode of analysis it is necessary to follow in estimating the work performed by an engine working expansively, for the expression $\frac{a'\,p}{x} - t$ does not express the effective working pressure during the expansion, and only at that part of expansion where the piston is at a distance (x) from the beginning of the stroke; and how he has discovered that this gives the effective working pressure 3 or 4 lb. per square inch too much he does not mention, and I am unable to find out. Mr. M. mentions that I make no allowance either for the diminution of temperature of the steam during the expansion, or the waste space which has to be filled with steam. Perhaps Mr. M. for the benefit of your readers will be kind enough to tell us how much the temperature of the steam will be reduced in the hot climate of a locomotive's smoke box? Would Mr. M. seriously propose to introduce into this analysis the slight modification necessary for the waste space filled by the steam; which waste space varies in all locomotives, and will yet be reduced to almost nothing? Again, Mr. M. states that the effect during the part of the stroke from the opening of the eduction port the termination of the stroke, must not be neglected on account of the small opening of the port during that period, and that the pressure of the steam is previously very little reduced by expansion. Mr. M. ought to have told us what degree of expansion he alludes to, as that altogether decides the extent of diminution of pressure by expansion, and when he considers that at this part of the stroke the motion of the piston is very slow, and the motion of the valve very quick, he will be able to see that the contemplated effect of this part of the stroke is considerable. Mr. M. next states that the effect of the compression of the educted steam is so small that it might be disregarded. I am sorry to see Mr. M. make such a remark, after having read the last paragraph of my paper, as the effect of this compression is altogether dependent on the extent of the cover and the lead.

Mr. M. in his concluding paragraphs has got into a sad maze, he supposes that I put the initial pressure of the steam in atmospheres equal to the area of the piston, and founding upon this most wonderful equation some beautiful deductions, he states that "these results show the manifest absurdity of the supposition." If Mr. M. would substitute for the letter (*s*) the figure (5), he would immediately be relieved from a multitude of his difficulties, and you are able to say whether the letter or the figure is in my paper. With the assistance of these remarks, perhaps Mr. M. will find out that the paper which he states requires "revision and correction" virtually less requires either than his own letter.

And I am, your obedient servant,

J. G. LAWRIE.

Cartsdyke Foundry, Greenock,
October 6, 1841.

SIR—I regret exceedingly that any expressions contained in my letter concerning Mr. Lawrie's communication on the Economy of Fuel in Locomotives consequent to Expansion as produced by the cover of the Slide-valve, and which you favoured with insertion in your Journal for this month, should have given that gentleman offence, as I perceive by his letter, which you were kind enough to send me for perusal, to have been the case. I therefore take the earliest opportunity of assuring him, through the medium of your columns, that such was perfectly unintentional, and also of acknowledging two errors into which I had fallen, though not altogether by my own fault, as I think I shall now show. In the first place I objected unjustly to his equation

$$s\left[a' - \frac{(2d-b)t}{p}\right] = 2d \times 1;$$

in which he merely stated (*s*) to be the area of the piston, having inadvertently omitted to mention at the same time that the area of piston required to use the same quantity of steam without expansion was considered as unity, so that (*s*) is not the absolute, but the relative area of the piston, or the ratio of its area when the steam is cut off after the piston has travelled a distance (a') to what it would be if the steam were not cut off at all; and I think Mr. Lawrie will allow that any other reader would be liable to be led into the same mistake as myself through this oversight on his part.

The second error which I have to acknowledge is the having attributed to Mr. Lawrie the absurd hypothesis that the safety valve be so loaded that (*p*) is equal to (*s*) (which he would have seen to be so printed in the Journal, if he had taken the trouble to refer to it before writing his letter), whereas I ought to have supposed it to be a misprint, as in fact it is, and I now see clearly that the (*s*) was intended by Mr. Lawrie for a (5).

I shall now endeavour to convince Mr. Lawrie that the rest of my remarks were not thrown out without due consideration.

First then, although a school boy might have been able to find out that the two expressions alluded to in the first part of my former communication were identical, if the problem had been proposed to him, yet I should very much doubt whether he would see it at a glance, without having any previous suspicion of the fact; but, having discovered it in the course of my investigation (for which discovery, however, I beg to be understood to claim no particular merit), I thought it would be useful to communicate it to your readers, since it saves the trouble of calculating the same quantity twice over by two different methods.

I have now to return to the equation already quoted above, in the second member of which the factor (1) expresses the area of the piston when there is no expansion, and (*s*) its area when the steam is cut off at (a'), the same quantity of steam being admitted during the stroke in both cases; and with this explanation I acknowledge the correctness of the above equation, except inasmuch as the waste space at the end of the cylinder, which has to be filled with steam as well as the length (a') of the cylinder, has been omitted in the account (and this Mr. Lawrie must excuse me from admitting to be *reduced to almost nothing*), and also inasmuch as the pressures (*p*) and (*t*) are used instead of the corresponding densities of the steam. The Count de Pambour, in his *Treatise on Locomotive Engines*, and *Theory of the Steam Engine*, assumes this waste space to be equal to $\frac{1}{20}$ of the contents of the cylinder within the limits of the stroke of the piston, and I believe this estimate to be, in all cases, rather below than above the truth. Besides, where is the necessity or advantage of neglecting that quantity, when there is no difficulty in taking account of it, at least by approximation? Its actual value may be employed, when known, otherwise by using an approximation such as $\frac{1}{20}$ a more correct result would be obtained than by omitting it altogether. The above equation, corrected for the waste space, and with the substitution of the densities (δ) and (δ') for the pressures (*p*) and (*t*) respectively, becomes

$$s\left[a' - \frac{(2d-b)}{\delta}\delta' + w\frac{\delta-\delta'}{\delta}\right] = 1 \times \left[2d + w\frac{\delta-\delta'}{\delta}\right],$$

whence

$$s = \frac{2d\,\delta + w(\delta-\delta')}{a'\,\delta - (2d-b)\,\delta' + w(\delta-\delta')};$$

where (w) expresses the length of a portion of the cylinder equal to the waste space at either end of it.

In order to show that the corrections which I have introduced, although not greatly affecting the result, amount notwithstanding to something appreciable, I shall presently apply them to one of the examples at the end of Mr. Lawrie's former communication; but it will be necessary first to make a further correction in the latter, which I shall do as soon as I have replied to the remaining paragraphs of his present letter.

With regard to my understanding the mode of analysis it is necessary to follow in estimating the work performed by an engine working expansively, I am sorry the want of perspicuity in my former letter was such as to create a doubt in Mr. Lawrie's mind, and I trust I shall now succeed in dispelling it; indeed the doubt has arisen from his assigning a more extended signification to an expression, which I used in common with himself, than the said expression had any right to bear, or was originally intended to bear by either of us. When I said that he found the *effective working pressure* during the expansion to be equal to $\frac{a'p}{x} - t$, I did not mean the *mean effective working pressure*, nor could I mean that that quantity, which so evidently varies with the value given to (x), could be supposed constant during the whole of the expansion, but precisely what Mr. Lawrie himself meant, viz., that it was the general expression of the *effective working pressure* during expansion, the particular value of which at any given instant would be found by substituting for (x) its value for the position of the piston at the given instant. This is, however, merely a misconception on the part of Mr. Lawrie, who no doubt thought my objection rested on the supposed difference which I have just explained away, whereas the real point at issue is whether the constant term (*t*) in the above expression faithfully represents the negative part of the effect, or the resistance of the waste steam on the back of the piston, or not. Now (*t*), as I stated in my former communication, is used by Mr. Lawrie to express the *lowest* pressure of the waste steam in the cylinder, which probably scarcely exceeds the pressure of the atmosphere, and he has likewise used it for the *mean* resistance of the waste steam, that is, the resistance due to the blast pipe added to the pressure of the atmosphere, during the whole of the portion (*b*) of the stroke. Now, according to the Count de Pambour's experiments, with the mean evaporation of locomotive boilers, and the size of orifice of the blast pipe commonly adopted, the mean resistance due to the blast pipe, when the velocity of the engine is 20 miles an hour, is 3½ lb. per square inch of the piston. In the description of Robert Stephenson's patent locomotive engine in the new edition of Tredgold on the Steam Engine, page 451, it is stated that that resistance is "6 lb. per square inch when running at the usual rate of 25 or 28 miles an hour," and that at greater velocities it "has been found to increase to double that amount, and even more." I think I am therefore fully borne out in the opinion that Mr. Lawrie's calculation makes the effective working pressure (I should have added, on the average) 3 or 4 lb. per square inch too much, if not more.

With respect to the diminution of temperature consequent on expansion, Mr. Lawrie must surely be aware of the possibility of reducing the temperature of elastic fluids, by sudden dilatation, many degrees below that of the surrounding bodies; but, since he wishes me to tell him how much the temperature will be reduced in the hot climate of a locomotive's smoke-box, I answer that, when the time given for expansion is excessively short, as it is in locomotives, this reduction is not sensibly affected by the climate, but depends on the primitive pressure and degree of expansion of the steam, and that in his 3rd example, where the steam is (supposed to be) cut off at 5·2 inches from the commencement of the stroke, the diminution of temperature would, with that expansion, amount to about 80 degrees; but this is much greater than it would be in reality, on the hypotheses made by Mr. Lawrie, because the values found by him for *(a')* and *(b)* are so much too small as to exaggerate the expansion enormously; as an instance of which, in the example just quoted, these valves ought to be 0·7726 and 0·9259 respectively, instead of 0·2884 and 0·7, and the steam would consequently be cut off at 13·9 inches, instead of 5·2, from the commencement of the stroke. This error, which runs through all 4 examples, and thus vitiates all the deductions, arose from Mr. Lawrie inadvertently changing the unity from the radius of the eccentric to the width of the port, in applying his formulæ.

Mr. Lawrie says that, when I objected to the omission of the effect of the steam during the part of the stroke from the opening of the eduction port to the termination of the stroke, I ought to have told you what degree of expansion I alluded to, as that altogether decides the extent of diminution of pressure by expansion. This is sufficient reason for not neglecting the quantity in question; for if there is any degree of expansion for which it ought not to be neglected, the only way to be sure of not doing so in that particular case is to include it in the general formula. However, I will take Mr. Lawrie's 2nd example, where the lead (on the steam side) is $\frac{1}{6}$ of the breadth of the port, and the cover (also on the steam side), $\frac{1}{2}$ breadth of port. Mr. Lawrie assumes that the valve has no cover on the eduction side of the port, which I think he will not find to be exactly the case; Mr. R. Stephenson allows $\frac{1}{16}$ inch on each side, and the ports are only 1 inch wide, which makes the cover on the eduction as well as the steam side of the port, $\frac{1}{16}$ of its width. It is obvious that this arrangement causes the eduction to commence later, by which means the pressure of the steam is not reduced so low at the end of the working stroke as it would otherwise be. It is, however, with the conditions assumed by Mr. Lawrie that I have calculated, at a great cost of time and labour, what the diminution of pressure would be in this example, from the opening of the eduction passage to the end of the stroke. I have supposed the initial pressure (before expansion) to be 5 atmospheres or 73·53 lb. per square inch, and the total area of the port $\frac{1}{10}$ that of the piston, and I have purposely made the reduction of pressure come to more, rather than less, than it would really amount to.

The radius of the eccentric, or $\frac{1}{2}$ the travel of the valve, which is called unity in the formulæ for calculating *(a')* *(b)* and *(c')*, is equal to the width of the port + the cover $= \frac{3}{2}$ width of port, whence the width of port $= \frac{2}{3}$, and $l = \frac{1}{9}$, $c = \frac{1}{3}$. With the aid of these values we find $a' = 0{\cdot}8482$, $b = 0{\cdot}9479$. Neglecting the waste space, the pressure is reduced by expansion to 65·07 lb. The eduction lead = the lead + the cover on the steam side $= \frac{2}{3}$ width of port, which is the extent of opening to eduction at the end of the stroke; and the crank is 26° 23′ 16″ from the dead centre when the port begins to open. This I have divided into intervals of 1°, and have computed the discharge of steam during each interval, supposing it due to the difference between the pressure *at the beginning of the interval* and the pressure of the atmosphere. This calculation is consequently very long, but I believe there is no formula yet discovered which gives the discharge during the whole time at once. I found in this manner that the pressure would be reduced at the end of the stroke to 52·87 lb., or 38·16 lb. above the atmosphere, which gives a mean pressure during the eduction lead of at least 44·26 lb. per square inch, or distributed through the whole length of the stroke, 2·31 lb. This, I think, Mr. Lawrie will not call *inconsiderable*; while the effect of compression would certainly not surpass, if equal, 0·4 lb. per square inch through the stroke, which I consider rather to be neglected than the former.

I shall conclude my letter with showing, as I stated above, that the corrections I introduced into the value of *(s)* are not altogether to be neglected, and for that I shall apply them to the example chosen above. By Mr. Lawrie's formula, we have

$$s = \frac{5}{4{\cdot}211 - 1 + 0{\cdot}9179} = 1{\cdot}1936.$$

By the corrected formula, making $2\,d = 1$, $\delta = 1$, $\delta = 4{\cdot}3557$, $w = 0{\cdot}05$, we have

$$s = \frac{4{\cdot}3557 + 0{\cdot}1683}{3{\cdot}703 - 0{\cdot}0521 + 0{\cdot}1683} = 1{\cdot}1872.$$

The difference is certainly not very considerable, being only about $\frac{5}{9}$ per cent. on the required area: but why should even that correction be omitted, when it can be applied without any difficulty and with scarcely any additional trouble?

I am, Sir, your obedient servant,

M.

October 14, 1841.

CROSBY-PLACE, BISHOPSGATE STREET.

The committee appointed to superintend the restoration of this most interesting specimen of ancient domestic architecture appear to have brought their labours nearly to a close, and an inspection of the result of those labours will secure the praise of every lover of our architectural antiquities. It is highly gratifying to witness the timely preservation of a building which is "the only example of any magnitude of the halls and places of our forefathers in the metropolis, the numerous other buildings of this nature which once graced the city having fallen victims to the great fire, or the no less destructive hand of innovation. The reparation appears to have been carried forward as far as is desirable until the particular use to which the hall is to be hereafter applied shall be ascertained; and most fervently do we hope that it may be such as shall best accord with its present beauty and its past history. The new materials and workmanship harmonize so thoroughly with the original, as to render it impossible, except on the minutest inspection, to distinguish between the new and the old. The matchless beauty of the roof in the hall has been effectually preserved. This unique specimen of timber-work is remarkable for the skilful omission of ties and hammer-beams. It is divided into eight principal compartments in length, and four in breadth, the points of intersection being ornamented with light and graceful pendants, pierced with small niches, each pendant forming the centre of four arches, so that from whatever point it is viewed the eye is presented with a series of arches of elegant construction. The principal timbers are richly decorated with bosses of foliage, and "spring from octangular corbels of stone." It is remarked that the low pointed arch, approaching to an ellipse, is admirably calculated for the dissemination of sound. "The shafted oriel," notwithstanding all the rough usage to which it has been exposed, has recovered its pristine beauty, and, as well as the other windows, is "richly dight" with the stained glass armorial bearings of the former proprietors, and of the various companies and individuals of whose munificence the hall itself will be the lasting memorial. From some sources, of which we are ignorant, the council chamber and throne-room have been restored to a state of great beauty; not, indeed, on the same scale of magnificence as the hall, to which alone the public subscriptions have been devoted, but yet in a style perfectly in keeping with the age and character of the structure. When Crosby-place shall be transferred to the hands of its next possessors, these rooms will probably receive all those rich decorations which will enable them to vie with the splendour of a hall. It is, however, from its historical associations that Crosby-place must ever derive its greatest value and interest. In the reign of Edward IV., it was the magnificent home of Sir John Crosby, its reputed builder, who was here probably honoured with the presence of that Monarch whose cause had been so greatly strengthened by the zeal and prudence of his princely host. It is well known to have been afterwards the abode of Richard III.; Shakspeare has immortalized the fact, so that "Richard, Shakspeare, and Crosby-place, must ever be identified." Here Sir Bartholomew Read, Mayor of London, entertained a solemn embassy from Maximilian, Emperor of Germany, of which Lord Cassimir, Marquis of Brandenburg, his cousin, accompanied with a bishop, an earl, and a great number of gentlemen well-appareled, was principal embassador, which were triumphantly received in London, and were lodged at Crosby-place." Sir Thomas More, the witty and unfortunate author of the *Utopia*, when in favour, occupied Crosby-place, and afterwards sold it to "his dearest friend" Bouvisi, the Lucca merchant. In 1594, it was purchased by "the rich Spencer," who died possessed of nearly a million of money, and was an ancestor of the present Marquis of Northampton. Here he entertained no less a personage than the Duke of Sully, the Ambassador of Henry IV. of France. Among the sub-tenants in the early part of the 17th century, we find a name immortalized by Ben Jonson's most beautiful epitaph, "Sidney's sister, Pembroke's mother," and William Russell, probably a scion of the noble house of Bedford. In the disastrous period of the civil wars it was used as a prison for the Royalists; and in 1662, the Reverend Thomas Watson was the first ejected minister who officiated in the hall: he converted it into a Presbyterian meeting-house. He was followed by Stephen Charnock, Dr. Grosvenor, a pupil of Benjamin Keach, and Edmund Calamy, jun. The congregation continued to meet here till 1769, when it was dispersed, a farewell sermon being preached on the occasion by Mr. Jones, the predecessor of Dr. Collyer, at Peckham. The hall, as every one knows, became subsequently a common warehouse, and fell rapidly into a state of ruinous decay, from which degradation it has now, at length, been recovered. Thus, for nearly four centuries, has this beautiful structure remained, the witness of decent hospitality, of boisterous mirth, and of merry wassail; at one time its "rich embowed roof" and arras-covered walls echoing the sweet music that arose from the minstrels' gallery; those walls then denuded of their costly draperies, and resounding with the groans and oaths of the Cavaliers, and once again consecrated by the solemn psalms and hymns of the Presbyterians; and now, rescued from the dust and noise and bustle of the packer's warehouse, it silently waits to witness the mysterious future, and again to see "one generation passing away, and another coming."—*Correspondent of the Times.*

LIFE OF ST. ETHELWOLD.

By HYDE CLARKE, Esq., F.L.S.

THE end of the tenth century is famous in English history for the great extension of the Benedictine order, and of monastic buildings, effected by St. Dunstan, Archbishop of Canterbury, and his two coadjutors, St. Oswald, Archbishop of York, and St. Ethelwold, Bishop of Winchester. These were men of remarkable ability, forming a constellation of talent, which might well affect the monkish writers with admiration, and arrest the attention of the historian. Under their direction King Edgar lavished the wealth of his kingdom on the Benedictines, and he was able to boast of having erected fifty monasteries, many of which flourished in splendour for above 600 years, and became the germs of some of our finest monuments. The reign of Edgar indeed, forms an epoch in our architectural history, and as to St. Ethelwold was committed the direction of the material part of this revolution, it cannot be uninteresting to architects to contemplate the deeds of this ornament of their profession, of whom it is to be regretted that no modern memoir has yet been written.

Ethelwold was born towards the end of the reign of Edward 1st, surnamed the Elder, between the years 910-20, in the imperial city of Winchester, then the metropolis, and was the son of opulent, respectable, and pious parents, his birth, according to the legends, being preceded by omens of his subsequent greatness. St. Swithin and Daniel, Bishops of Winchester, were also natives of the city, as was Ethelwold's after colleague, St. Oswald. Having at an early age shown most pious dispositions, Ethelwold attracted the notice of the illustrious King Athelstan, in whose palace he, with Dunstan, for some time lived, and by whom he was afterwards placed under the care of St. Alfege the Bald, Bishop of Winchester, uncle of St. Dunstan. Having attained the proper age, and having previously received the minor orders, he was consecrated priest by St. Alfege, in the cathedral church at Winchester, at the same time with St. Dunstan, and it is supposed about the year 936 or 937. Besides Dunstan and Ethelwold, there was another priest ordained, who was named Athelstan, and who afterwards relapsed into a bad life, and Bishop Alfege is said on this occasion to have prognosticated the several careers of the young men. Ethelwold soon after retired to Glastonbury, and put himself under the care of his friend Dunstan, who had introduced into that house the rule of St. Benedict. Here Ethelwold afterwards became Dean, and must have been present, and no doubt co-operated, at the period when St. Dunstan was engaged in rebuilding the monastery.

At Glastonbury Ethelwold greatly distinguished himself, not only by his scholastic acquirements, and by the skill with which he taught grammar and prosody, but by his great industry, labouring with his own hands, and even cooking and performing menial offices. Being seized with an ardent desire of acquiring knowledge, the dean had intended to travel on the continent, but was prevented from carrying his design into execution by the Queen-mother Edgiva. This princess was the daughter of Sigeline, a Kentish earl, and mother of King Edmund 1st, and the reigning King Edred, whom she advised not to allow such a man as Ethelwold, whose wisdom and acquirements she highly praised, to leave his kingdom. The king, pleased with hearing such a character of Ethelwold, took great interest in him, and at the persuasion of the Queen-mother, gave him an estate at Abingdon, with the charge to restore an ancient monastery, then greatly dilapidated, consisting of a wretched building, and only possessing 10 manses. This event is generally said to have taken place in 954, but according to Ingulf and the Croyland charters, it was six years before, namely in 948. With the consent of his abbot Dunstan, and no doubt by his influence, Ethelwold went to Abingdon with Osgar, Feldbert, Friwegar of Glastonbury, Ordbert of Winchester, and Edric of London, and soon collected a body of monks, of whom he, by the king's wish, was ordained Abbot, and he then set himself to work, by head and hand, to carry out the task imposed upon him. From the king he obtained large estates at Abingdon, and a grant from the treasury, and he found in the queen-mother a liberal benefactress. From the king Ethelwold obtained a charter of ample privileges, which he himself appears to have illuminated. On a certain day the king came to the monastery, laid the foundations himself, and measured them out, giving directions also how the works should be prosecuted. At the banquet given in honour of this occasion, Ethelwold is represented by his biographers as having begun his career of miracles, by a prodigy much better suited to the taste of those times than of these, having furnished to the numerous Northumbrian guests an inexhaustible supply of wine from one jar. It appears to have been the practice in these days to board the workmen, and one of the legends relates that the monk who had the charge of supplying the workmen with provisions was named Alfstan, and that he performed his duties most laboriously and assiduously, not only cooking and serving out the provisions, but himself lighting the fire, drawing water, and cleaning the dishes. Abbot Ethelwold, seeing him one day engaged in performing his accustomed duties, begged him to dip his naked hand in the caldron, and to reach a piece of meat, which Alfstan did without scalding his hand, a proof of the religious purity of himself and the abbot, and of their unrefined manners. Among Ethelwold's gifts to Abingdon, most of them the work of his own hand, were a gold sacramental cup of great weight, three crosses of pure silver and gold, lost in the troubles of Stephen's reign, and candlesticks, censors and other vessels for the service of the church of pure silver, and some adorned with precious stones. Many of these were afterwards carried off by a Norman monk of Jumieges. At the request of King Edgar, Abbot Ethelwold also made a silver altar table of the weight of three hundred pounds, and which long remained admirable for the delicacy of its workmanship. He also made two bells with his own hands, and put them in the belfry with two larger ones, which had been made by St. Dunstan. Another of Ethelwold's works was a kind of chime consisting of a wheel full of bells, called the golden wheel, on account of its being gilt, and which was used on high festivals. Abbot Ethelwold was famous for preserving the sanctity of manners of his flock, but he seems to have been by no means illiberal as to matters of eating and drinking, his allowances to the monks being so bountiful as to become matters of proverb. As a ruler of the monastery Ethelwold acquired the highest reputation, and formed a school for singing and reading the service, to which persons from all parts of England resorted. Being greatly desirous of securing uniformity in the mode of performing the service he sent to Corby in France, then famous in this respect, and obtained some skilful monks as instructors. He also sent one of his monks, named Osgar, to the Benedictine Abbey of Fleury to study the rules of the order in that school. This Osgar, there is reason to believe is the one who succeeded our Abbot at Abingdon. Ethelwold exerted himself to a great degree for the advancement of his house, for which he obtained more than six hundred cassates of land, and charters from Edred and Edgar. One of his chief works at Abingdon was a cut which he made from the river Isis to supply the abbey with water, and also to work a mill, which he built. While digging for this canal the excavators found in the sand near the monastery of St. Helen, an iron cross, which Cessa, Viceroy of Wessex, and founder of the old abbey, had caused to be laid in the tomb on his breast. This cross was translated to the abbey, and became famous under the name of the Black Rood or Cross, upon which no one could take a false oath under pain of death, for it was believed to be partly made out of one of the nails of the cross, and sent by Constantine the Great or some of his British followers to England. It is further related that the monks having sometimes attempted to adorn this cross with gold or silver, as fast as they put it on one day it fell off and dissolved on the next. Abbot Ethelwold's zeal for his monastery was great, working even with his own hands, and having as his biographer states, attracted the especial despite of the devil, had on one occasion a heavy beam thrown at him by the great enemy, which knocked him into a pit and broke several of his ribs, and if it had not been for the pit the Abbot would have been crushed to pieces. As it was he soon recovered. Under his government the house prospered in sanctity, and a young boy, who was a favourite of the monks, had on his death-bed a beatific vision of the glories of heaven.

The time was now arrived when the talents of Ethelwold were to shine in a still more extensive sphere, the unfortunate King Edwin, pursued by the monks, had lost the greater part of his dominions, which had rebelled to his brother Edgar, and in 959 this patron of the monastic order obtained by the death of his brother the undivided rule of the whole empire. In 958 Edgar had granted a charter to Abingdon, and in 960 at Dunstan's request he chose our Abbot to undertake the work of the restoration of Evesham, who went there, restored the monks and appointed Oswald Abbot. Of Ethelwold's subsequent government at Abingdon, we have nothing more to relate than that having made that abbey one of the great schools of learning and piety, it became the nursery, whence the new monasteries of King

Edgar were supplied with pastors. A prayer for the prosperity of Abingdon remains as a monument of Ethelwold's love for that institution, and as a testimonial of his scholarship.

In 963 Brithelm, Bishop of Winchester, having died, Ethelwold was appointed to succeed him, and thus became bishop of his native city, which as before said was then the metropolis of the country. On St. Andrew's eve in this year which fell on a Sunday, Ethelwold was consecrated by Archbishop Dunstan, and immediately entered on his labours, finding his cathedral greatly needing repair, and what affected him more his canons of irregular life. In 964 we find Bishop Ethelwold's signature to three charters of Worcester Abbey, and it was in the same year that he was engaged in the restoration of Chertsey monastery in Surrey, sending to Abingdon for thirteen monks of whom Ordbert, a fellow townsman of the Bishop's, and originally of Glastonbury monastery, was appointed Abbot. In 965 we find the Bishop busy with the reform of the two monasteries at Winchester, in which he had great difficulties to contend with. Only three of the canons, Edsy, Wulsy and Wilstan could be induced to put on the cowl, the others retired, and were replaced with monks from Abingdon. Some of the displaced canons attempted to revenge their disgrace by giving the bishop a poisoned cup, but he soon recovered from the consequences. The result of these discussions was the holding of the two celebrated councils of Winchester and of Calne, at the first of which the cause was given against the seculars by a miraculous voice from a crucifix, and at the latter, on Dunstan appealing to God, the floor sank down and the adversaries of the monks were precipitated among the ruins, Dunstan and his friends remaining safe. In the preparation for this second miracle it is more than probable that Bishop Ethelwold was concerned.

Ethelwold was now high in power, holding one of the chief episcopal dignities, a minister, confident and confessor of the king, he took a great part in public events. Ethelwold is described with some prejudice by Sharon Turner as a man bred up by Dunstan himself, and of a temper to execute all his schemes. Dunstan was about the same age as Ethelwold, if anything rather younger, and although associates in their youth, and at Glastonbury, it could not with justice be said either by Florence of Worcester, or Adelard, that Ethelwold was brought up by Dunstan. Oswald, was like St. Dunstan, of high connexions, a native of Winchester, and partly educated there, and these two with Ethelwold formed a cabinet, which however obnoxious it might be for some of its schemes, yet it is not to be denied that it greatly promoted the prosperity of the country. Edgar and his ministry greatly patronized foreigners and trade, delivered the country from the scourge of wolves, reformed the coin, improved the navy, and the administration of justice. To return to the immediate exertions of Ethelwold, we learn that he rebuilt and re-established the Abbey of Benedictine Nuns at Winchester, and placed over it, Etheldritha, who had been his nurse. He also rebuilt the other two Benedictine monasteries. In 966 the site of the monastery of Medhamstead was bought by Ethelwold, and a magnificent abbey built, which was named by him Peterborough. According to Hugh Whyte, the Bishop was warned of God in the night that he should go to the Midland English or Mercians and repair the monastery of St. Peter, and that taking his journey into those parts he came to Oundle, supposing that to be the place, but was warned a second time, that he should follow the course of the river, he came to Medhamstead, and here the Lord appeared to him a third time and directed him by a singular omen, how he should proceed. Having cleared the site of the church, which he found used as a receptacle for herds of cattle, he returned to Winchester to make preparations for the restoration of the monastery. When having put up fervent prayers to God to incline the hearts of King Edgar and his queen and his court, to contribute their assistance to this work, he was overheard by the queen, who thenceforth solicited the king for its reparation, and he accordingly patronized the undertaking. Ethelwold among other measures purchased the fourth part of Whittleseamere, and many other endowments. In this same year he signed a charter for Croyland Abbey, and for the abbey of Hyde, at Winchester, and at London in the end of the same year, he united with the archbishops and bishops in a deed threatening the censures of the church on any disturbers of Croyland.

In 968 the Bishop attached his signature to two charters of Wilton Abbey, and it was most probably about this time that he received at that convent the vows of St. Wiltrude or Wulftrude, the mother of St. Edith. In 969, the distinguished scholar Alfric who was a pupil of Ethelwold's, was appointed Abbot of St Alban's. In 970 the Bishop translated the relics of St. Swithin from the churchyard of Winchester to the cathedral. In this same year although much occupied with his disputes with the monks at Winchester, Ethelwold was appointed by the king to restore the convent of Ely, and having obtained the Isle of Ely free of regal jurisdiction, he dismissed the priests, gave orders for repairing the church, and established therein a convent of monks. Brithnoth, who had been prior of Winchester, was appointed Abbot, and was succeeded at Winchester by Leo the provost. Brithnoth who was consecrated by Dunstan and Ethelwold, was afterwards unfortunately assassinated by order of the Queen Dowager Elfrida for refusing to comply with her passions. For Ely the Bishop obtained many grants of land, and he was a subscribing witness to two of its charters. In this year Ethelwold succeeded in completing Peterborough, and King Edgar being desirous to see it went thither, with the Archbishops Dunstan and Oswald, and attended by most of the nobility and clergy of England, who all approved and applauded both the place and the work. It was Ethelwold's happiness also to discover some very ancient charters bestowing great privileges on the place. It is to be remarked that at this time the prelate was constantly engaged travelling about, superintending the works, and examining the convents. During one of these journies it is related that performing mass in a country parish, the priest whose duty it was to take care of the sacred oil, having left the vessel behind him on the road, went back to find it, and to his surprise not only found it safe, but marvellously replenished.

In 971 the Bishop attached his signature to two charters for Ely, and the next year he prevailed upon Edulf, chancellor of King Edgar, instead of going to Rome, to labour in the restoration of St. Peter's church at Peterborough. Edulf approving of this advice, accompanied the king to Burgh, offered all his wealth to the monastery, assumed the monk's habit, and became first abbot of Peterborough, which he afterwards left for the archiepiscopal seal of York. In 973 Ethelwold subscribed the charters of Ramsey and Thorney. In the succeeding year the Bishop was at Wilton, signed one of the charters, and received the vows of St. Edith, natural daughter of King Edgar and St. Wulftrude. The Bishop used to visit Wilton from time to time, and on one occasion reproved St. Edith for wearing splendid garments, not being aware that she had haircloth next the skin. Edith replied that the Almighty looked not to the garment, but to the soul, and that he would as well receive her with splendid robes as in the attire of poverty. The Bishop in this year (974) translated the relics of St. Withburga and other saints into the new church at Ely. This same year Ethelwold was applied to to use his influence with the king respecting the foundation of St. Neot's in Huntingdonshire, which was begun by Earl Alric and his countess Ethelfleda. Ethelwold also consecrated the church and took it under his protection, sending monks from Ely and Thorney.

In 975 a charter was obtained for Winchester by the Bishop and subscribed by him, and shortly afterwards King Edgar died. During the reign of this prince Ethelwold also signed charters for Westminster, Rochester, Ramsey and York. Dunstan and Ethelwold immediately crowned Edward the Second, surnamed the Martyr, as King, but they soon found in the Queen Dowager Elfrida a powerful antagonist, bent upon their ruin. One of the results of these discussions was as before mentioned, the holding of the councils of Winchester and Calne, and the country was distracted both with civil and religious broils.—In 978 Elfrida proceeding to greater extremities, murdered the king, who was succeeded by Ethelred, surnamed the Unready. This prince was crowned on the Sunday fortnight after Easter, in 979, at Kingston, by Dunstan, Oswald, Ethelwold, and nine other prelates.

In 980 Ethelwold completed one of his great works, the cathedral of Winchester, which he rebuilt from the ground, obliging the monks themselves to assist with their own hands in the work. It is related that one of them named Guth, being at the top of a high scaffold at work fell down, but by the protecting influence of our saint, received no injury, climbing up again and resuming his labours, as if nothing had happened. In this year Ethelwold added to the cathedral the crypts or vaults under the east end of the church, and the walls, pillars, and groining of which remain in much the same state in which he left them, and are executed in a firm and bold, though simple and unadorned manner that gives no contemptible idea of Saxon art. A weather cock and organ are enumerated among his performances, and he enriched the church with the shrines of St. Swithin, Birin, Brinstan, St. Alfege and St. Edburg, when a farther rededication took place with great splendour, in the presence of King Ethelred, Archbishop Dunstan, and eight bishops. In 981 the Bishop of Winchester signed the charter for Tavistock, and ordained Elsy as Abbot of Ely.

It was in this year that the Danes attacked and plundered Southampton, and put Winchester itself in peril, and in the next year our prelate buried Alderman Ethelmer. In 983 Ethelwold visited Dunstan at Canterbury, and that saint foretold to him his approaching death. In 984 we find his last public act in his attestation to the charter of Shaftesbury, and in that year being taken ill at Beddington, in the county of Surrey, he died there on the 1st of August 984, his death being it is said accompanied with miraculous circumstances, his body having all the freshness of life, and his face the rosy hue of that of a young boy. His body was transported with great pomp to Winchester, and he was buried in the cathedral, but in what part is uncertain.

As an ecclesiastic Ethelwold has received the unbounded admiration of the monkish writers, but from every one his conduct during the famine at Winchester, leaving all other things out of consideration, entitles him to universal praise. During that severe famine he caused all the church plate to be sold in order to purchase provisions for the poor, remarking that the church, if reduced to poverty, might be again enriched, but that if the poor were starved, it was not in the power of man to recall them to life. His life is said to have been of a most hermit-like character, devoting himself to labour and study. Of his miracles besides those already alluded to, many are mentioned, particularly of the arms of a thievish monk being suddenly bound down to his side, of the Bishop's being found by the monk Theodoric overcome with fatigue, and sleeping over his book, how the monk sat down in the bishop's seat, was frightened by a horrible vision, and temporarily blinded for his temerity, how another monk Leofred, under similar circumstances, found that the candle had fallen on the book without even greasing it.

Ethelwold is represented as active in person, of acute genius, and of extremely retentive memory. We know that he patronized and practised every liberal art, and we have Alfric's testimony that he was one of the great restorers of learning in that age. Of his writings we have no specimen, except the prayer for the prosperity of Abingdon, but of his scholarship we can entertain no doubt, his zeal for the advancement of learning causing him throughout his life to teach personally, and he was consequently the instructor of many of the most distinguished characters of the age, both in civil and religious life. As an illuminator he is said to have had great skill, and his love for music showed itself in the foundation of the school at Abingdon. As an architect he is said, like his successor William of Wykeham, to have been a great builder both of churches and divers works, both while abbot and bishop, and we may note his mechanical skill in the donations he made to Abingdon. Besides the canal at Abingdon, he was also the designer of a similar work at Winchester, the benefit of which, says the historian of Winchester, is still felt by the inhabitants. They experiencing great inconveniences from the want of water, which then only flowed in one current at the eastern end of the city, St. Ethelwold made different canals, one of which begins near the village of Worthy, and thus distributed the water, at great toil and expense throughout the greater part of the city. He is also said to have been the builder of what is call St. Swithin's chapel at Winchester.

For a character so distinguished in all time the greatest admiration has been felt, and we have his life from the pens of two cotemporaries and pupils, Alfric, monk of Abingdon, and Wolstan, chanter of Winchester. It was in 996 that Alfhelm of Wallingford, being attacked with blindness, was directed by a vision to the tomb of Ethelwold and to Wolstan, who also had a vision of the saint, and on Christmas eve of that year, the body of the saint was enshrined. The offices in his honour are to be found in the Acta Sanctorum for the 1st of August, with two hymns in his honour, one of which is a curious specimen of the alliterative form adopted in Latin. The episcopal chair of this eminent man long remained an object of veneration and popular awe, it being believed that those, who, while they sat in it, instead of attending to the divine office, gave way to sloth and drowsiness, were punished with terrific sights and painful visions. A representation of St. Ethelwold is said to exist in the west window at Winchester.

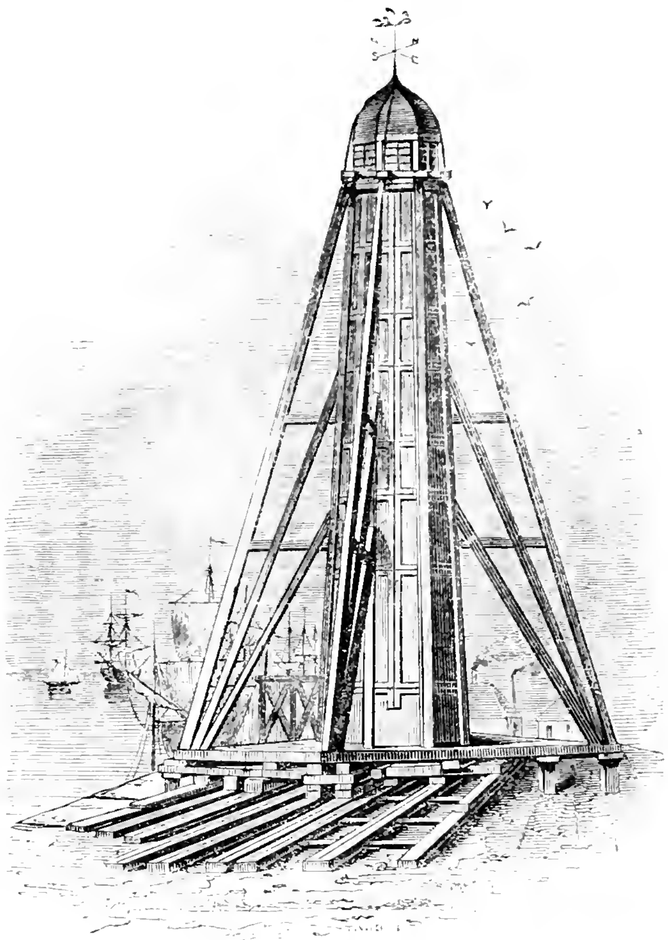
Ramsgate.—We understand that a survey is in progress for the purpose of ascertaining the practicability of a plan for forming a harbour of refuge capable of containing a fleet of men-of-war, or merchantmen of the largest class. It is well known that the Goodwin and Brake Sands afford considerable shelter to this part of the coast, and if the additional works necessary for forming this bay into a harbour of refuge can be made at a comparatively moderate expense, it will be one of the grandest and most valuable undertakings of these modern and wonder-working times. The survey is being made under the direction of Sir John Rennie, by Mr Hamilton H. Fulton.—*Kent Herald.*

SUNDERLAND LIGHT HOUSE.



In the Journal for September last, we gave a short account of an unusual occurrence, the removal of a Light-house, which we are happy now to announce has been firmly set upon its new foundation. The above engraving is a view of the light-house taken during its progress by Mr. Nicholson, of Newcastle. The removal from the North Pier was commenced on the 2nd August, and transplanted to the eastern extremity of the pier, a distance of 500 feet, and placed upon its new foundation on the 30th September last, and all the work will be completely finished by the 2nd instant, the whole period occupied being only two months.

The following is the plan submitted by Mr. Murray to the commissioners of the River Wear in May last, when it was under their consideration to pull down and re-erect the light-house on its new site:—"The masonry was to be cut through near its foundation, and whole timbers were to be inserted, one after another, through the building, and extending seven feet beyond it. Above and at right angles to them another tier of timber was to be inserted in like manner, so as to make the cradle or base a square of 20 feet; and this cradle was to be supported upon bearers, with about 250 wheels of six inches diameter, and was to traverse on six lines of railway to be laid on the new pier for that purpose. The shaft of the light-house was to be tied together with bands, and its eight sides supported with timber braces from the cradle upwards to the cornice. The cradle was to be drawn and pushed forward by powerful screws along the railway above mentioned, on the principle of Morton's patent slip for the repairing of vessels." The project was approved of, and the necessary arrangements made for carrying it into effect; the only deviation from its plan being, that during the progress of the work a windlass and ropes, worked by 30 men, were substituted for the screws. Not a crack nor appearance of settlement is to be found in the building.

We have been favoured with the following communication from Mr. Murray, by which it will be seen that the under-setting of the foundations are perfected.

SIR—In reply to your communication respecting the removal of the light-house on the north side of the harbour, I have to state that since it has been brought to its new site I have drawn out the timbers upon which it was conveyed, and the base on its southern side has been underset with two pillars of solid masonry. I am proceeding to do the same on its northern side preparatory to striking the supporting braces of timber, which probably may occupy another fortnight.

The light-house was erected in the year 1803, by the late Mr. Pickernell, then engineer to the harbour commissioners. It is wholly composed of stone; its form is octagonal, 15 feet in breadth across its base, 62 feet in height from the surface of the pier to the top of the cornice, where it is 9 feet in breadth across, and the top of the dome is 16 feet above the cornice, making a total height of 78 feet; and its calculated weight including the cradle and supporting timbers is 320 tons.

I am, Sir, your obedient servant,

JOHN MURRAY.

Sunderland, October 18, 1841.

It affords us much pleasure in offering our congratulations, with which we are sure all the profession will join, to Mr. Murray for the very successful issue of the bold experiment.

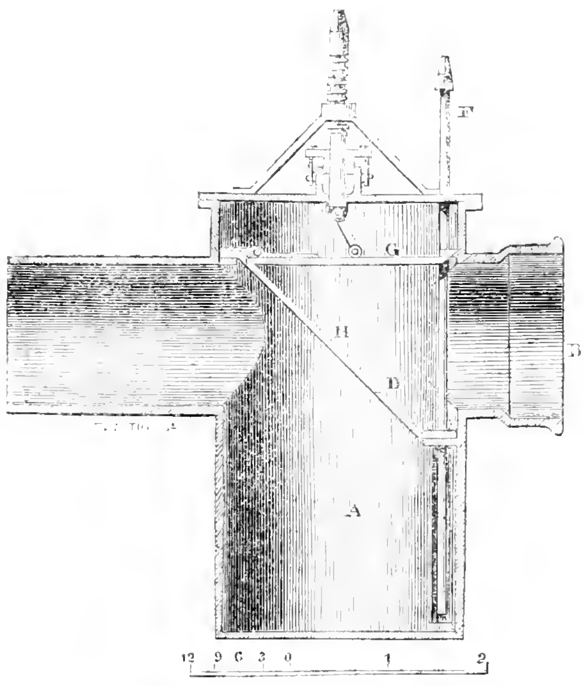
NEW SYPHON GAS VALVES.

SIR—I beg to forward you herewith a drawing with description of two Syphon-valves for the use of Gas Companies, which I have intended to answer the double purpose of syphon (or receiver) and regulating valve, and I flatter myself I have succeeded in my object. The cost of either valve and syphon united, will be considerably less than the common slide valve alone. Knowing it to be a subject of interest to many of the readers of your highly esteemed Journal, I have for some time had this subject under consideration, and I now place the result in your hands, by an early insertion of which you will oblige.

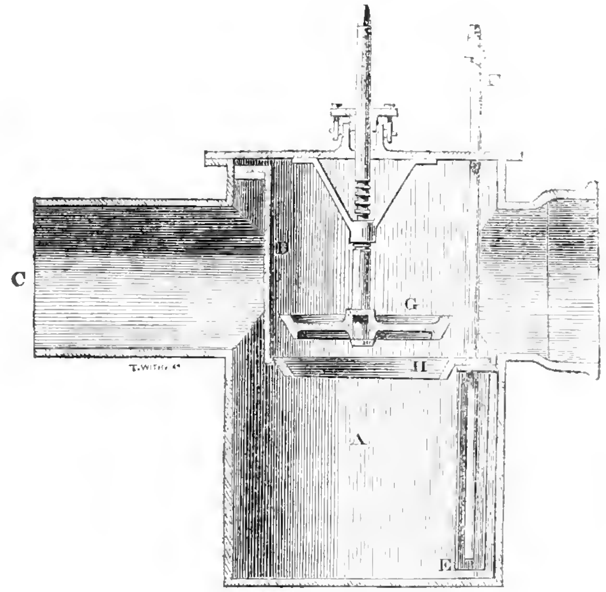
Sir, your very obedient servant,

THOS. HENRY NIMMO.

Chartered Gas Company,
Westminster Station,



A, cylinder to receive condensation, &c. from mains.
B, the inlet to be jointed into spigot of pipe.
C, the outlet to be jointed into socket of pipe.
D, division plate directing the inlet from the outlet, and bolted to the cylinder.
E, the tube to convey condensation, &c. from main into cylinder.
F, is a smaller tube placed within E, through which this condensation is drawn off.
G, the valve.
H, the valve-seat.



NOTE.—The supply of gas will be regulated in the same manner as other valves.

October 15, 1841.

IMPROVED RAIL AND CHAIR FOR RAILWAYS.

SIR—Having been practically engaged in the construction of railways for some years, my attention, about three years since, was directed to the designing a rail that should overcome several of the disadvantages, if not failures of the then, as well as the one still used, of intermediately supported rails.

My observations were then, and are now, with regard to that description of rails at present used. *First*, that the greatest strength of the rails is not in the direction of the force which they are intended to bear.

Secondly, that there is invariably considerable attrition between the rail and chair, and between the joints of the rails, and from which a portion of the useless noise so much complained of on Railways arises.

Thirdly, the fixing of the rails is subject to failure, by the loosening of the key or wedge that is used to fix them in the chair from the attrition consequent upon the imperfect connection between two hard surfaces, or from the wooden wedge having greater force to sustain than it is able without being compressed.

Fourthly, from the great force required to roll the irregular forms of the present rails, the same are very frequently flawed or fractured by the force applied to change the metal to the form so widely different from the bar converted, or otherwise in cooling from the sudden difference in bulk of metal after the rails are rolled.

From the preceding observations I designed, and have practically proved the following rail, which I shall feel grateful for the indulgence of making it public through the medium of your valuable and widely-circulated Journal. I respectfully submit it to the consideration of the profession, that it claims the following advantages.—First, the equal strength to resist or bear the weight or force of the transit of carriages with one-tenth less metal than intermediately supported rails now in use.

Secondly, requiring less power to roll the metal, and there being much less possibility of the rails being fractured by the process of rolling.

Thirdly, the greater security in fixing the rails in the supports, particularly at the joints.

Fourthly, the simplicity and strength of the supports added to the security of the rail, lessening the attrition, and being constructed with as little or less metal than the supports generally used. It will be admitted according to theory and practice, by a perfect cylinder rolling on a perfectly horizontal plane, the weight of the cylinder is received in vertical pressure on the surface of the plane. But as the wheels used on railways are not portions of cylinders but are portions or frustra of two cones with their bases opposite, formed by an axle (whose centre is the axis of the cones) at the distance of the gauge of the rails; although the surface of the rails should be perfect planes, the pressure or weight and force of the vehicles, and their contents transmitted from the surface of the wheels on to the rails, will not be vertical but at right angles to the head or surface of the wheels (which are portions of two cones), consequently the resistance to the force from the wheels ought to be in the direction the force is received from the surface of the wheels, and the strength and support for the wheels of railway carriages ought to be laterally as well as vertically. In the common intermediately supported rail, this is endeavoured to be obtained laterally by the flange of the rail, and vertically by the depth of the rail, assisted a little by placing the chairs declining a little inwards, but which is entirely at the mercy of the workmen employed to lay the rails.

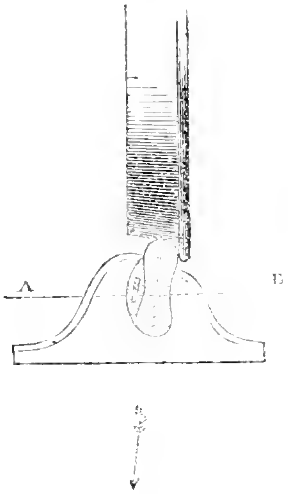

Fig. 3.

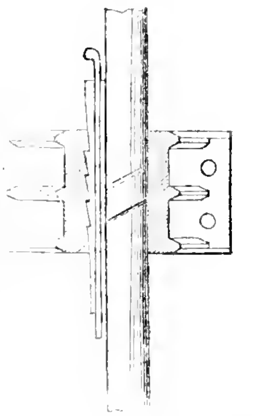

Fig. 4

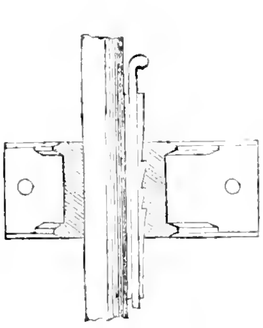
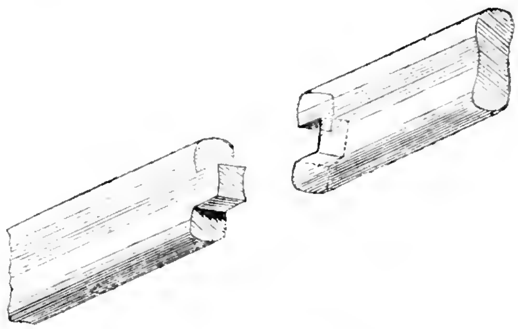


From the preceding axioms, I will endeavour to show, that my design is practically on the right principle for intermediately supported rails, in as clear and concise a manner as I possibly can, by reference to the diagrams.

Figs. 1, and 2, are elevations of two chairs, with portions of wheels thereon, and section of rails. Figs. 3, and 4, are two chairs cut off at the line A B in fig. 1, shewing the juncture of two rails in the wide chair, fig. 3. Fig, 5, is a perspective elevation of the rail, shewing the tongue joint. Figs. 6, and 7, are diagrams of two barrels, the railway wheels are supposed to be portions thereof. The one fig. 6, is supported by two half-inch boards four inches wide, placed at right angles to the bearing surface of the barrels. The other, fig. 7, sup-

Fig. 5.



ported by one-tenth more wood in the shape and position of the common rail: this is suggested as a cheap and easy practical experiment to test the principle of the rail.

Fig. 6.

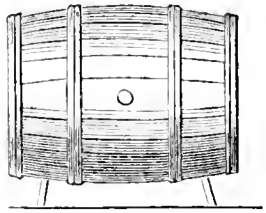


Fig. 7.

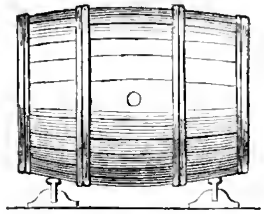

With regard to the rail being equal in strength with one-tenth less metal, arises from its being placed so as to receive the direction of the force or weight from the surface of the wheels in the direction of the greatest strength of the rail, and from its impracticability to bend outwards without rising upwards, so long as the weight or force is not more than the rail will bear without flexure, and the tendency of the wheels to thrust outwards, will of course prevent its bending inwards. In the rolling metal in the several forms they are now used on railways, the force or power required is in the proportion of the several angles that are to be formed, and the departure of the form from the previous section of the metal, and the forming of internal angles, is not only the cause of the rails being fractured by the greater force required for internal angles, but from the sudden difference in bulk of metal on its cooling, consequently a rail that has no internal angles, and the form, but the slightest departure from the section of the metal converted will require less power or force to roll it, and there will be less liability to fracture.

The security of fixing the rail in the chair consists in avoiding the attrition of two hard surfaces of equal density, by introducing a piece of metal more malleable than the rail or chair between them, and by securing the rail with a wood wedge, prevented from coming out by means of an iron key being driven into the centre of it, causing the wood to fill the ratchets in the chair as shown in figs. 3 & 4, and the wood having the greatest pressure downwards on the rails, as shewn in figs. 1 and 2, keeps the rail securely from rising, and the wood receives but little or no pressure from any weight transmitted from the surface of the wheels as shewn in figs. 1 and 2, and is therefore not liable to failure. The security at the juncture of two rails consists in their being kept firmly down in the chairs by the manner of their jointure by a tongue joint, as shown in fig. 5, are prevented from rising one above the other, and the noise is prevented by introducing a piece of thin cast lead between the meeting of the two rails, and by the chair being made of greater width as shewn in fig. 3. The chairs are without any internal angles, and consequently are not weakened, nor do they require additional metal to counterpoise against it, and their being no outward pressure by the rail, the chair does not require to be cast so heavy as those used to resist the outward pressure of the vertical rail. In conclusion, on this design I have only to add, I have full sized models of the above rail and chairs, and should it meet with the approval of the profession, I shall be happy to undertake the laying of the permanent way on any line of railway.

And am, Sir,
With much respect,
Your obedient servant,
W. B.

PROPOSED IMPROVEMENTS IN RAILWAY CARRIAGES FOR THE PREVENTION OF ACCIDENTS

Sir—In conversation with a friend on the late Brighton Railway accident, I have been informed, and believe the fact is, that from the generality of accidents on railways affecting the passengers on the first carriage behind the tender, (the engineer or engineers lives being considered of little value) a luggage van is placed behind the tender, or between the tender and first passenger-carriage, and the company do it as a great preventive of danger to the lives of the passengers, and as to the engineers, it is better for them to be in danger of their lives to make them vigilent and careful; all this may be very good for railway companies to soothe the public, but it can never be necessary to make engine-men careful by placing their lives in jeopardy beyond what can be absolutely avoided or eased, and I most respectfully submit it to the public, that as the engineers in the tender, and passengers in the first carriage behind the tender are subject to greater risk of their lives than the passengers in the second carriage behind the tender, and those at greater risk than the passengers in the third carriage and so on, the risk decreasing in the ratio to the distance of the carriage from the engine, the cause ought to be solved, or at least an attempt made to render the tender safer, and the first carriage as safe as the fifth one is now, and not let it rest by placing even a luggage van, to say nothing of passengers luggage in the van, in a situation of such imminent risk.

As a strenuous advocate for rendering travelling by railway the *ne plus ultra* for safety, I propose for consideration a few suggestions for the prevention of accidents on the following grounds.

The carriages are now all provided with elastic concussion receivers of equal elasticity, although it must be quite evident the elasticity is not acted on equally. To illustrate this we will suppose the elasticity of each carriage equals 1, and all the carriages are close on their concussion receivers; and we will suppose each elastic receiver to have already given way a length equal to one foot.

A train of carriages are started down an inclined plane, and at their arriving at their maximum velocity, an obstruction is met with, and the engine is stopped; the result will be that the tender comes with a force that the elasticity of 1 in 1 foot is completely overcome, and a concussion is the result between the tender and the engine to such an extent as to throw the men off or out of the tender, and the tender being stopped, the first carriage adjoining thereto receives a concussion on it, although the elasticity between the tender and engine had allowed the same to be eased one foot, and consequently with the elasticity between the first carriage and the tender of 1 in one foot, the first carriage is eased by the elasticity of one in two feet, but this proves to be insufficient and so does the elasticity or the easing received by the second carriage which is equal to 1 in 3 feet, but the elasticity received by the third carriage, proves in some cases sufficient to overcome to a very great extent, the concussion caused by the obstruction met with. As an improvement, I propose that the elasticity between the engine and tender should be increased to the greatest extent possible, say five feet, and the receivers of the concussions be kept close to each other, that is the drawboys or connecting chains should be just long enough to keep the receivers close, this would give the luggage van behind the tender, the safety the sixth carriage, and the first passenger-carriage the safety, the seventh one now enjoys. Trusting my motive in forwarding the preceding remarks, being for the safety of railway travelling, will be a sufficient plea for requesting it a place in your columns.

I am, Sir,
Your very obedient servant.
W. B.

ANONYMOUS ARCHITECTS.

Sir—I should feel obliged to any of your correspondents who would supply some information relative to the Market Cross at Shepton Mallet, which I understand is a new structure, and a handsome one of its kind. I could further wish to ascertain who was the architect of the building occupied by the "Society of Arts," at Birmingham, his name not being mentioned in Drake's "Picture" of that town, although the structure itself is there spoken of as "one of the most striking edifices" in the whole place. Surely local "Guides" might afford some information as to the authorship of modern buildings—which could be ascertained on the spot without any very great difficulty; or are we to suppose that the public have not the slightest curiosity whatever as to such trivial matters, and care no more who was the architect that designed, than who were the masons and labourers employed upon a public edifice.

In the case of a paltry building, the concealment of the architect's name may be an act of great kindness towards him; but it is somewhat preposterous to speak of one as "a splendid edifice"—"a truly elegant piece of architecture;" or in other terms of very high praise, and yet treat the author of the design as if he were a mere nobody, whose name was not worth recording at all,—not so much as that of an organ builder, for artists of the last description come in far more frequently for some share of notice.

Such being the case, it becomes a question whether its architect's name ought not invariably to be inscribed on every building making any pretensions to design;—I do not mean that it should be conspicuously placed so as to attract notice, but inscribed quite unobtrusively somewhere on the level of the eye, where if sought it could at once be found out,—in fact just as the name of an artist is attached at the bottom of an engraving; and if no objection be made to this last practice as savouring of presumption or conceit, hardly could there be any scruple as to adopting a similar practice in regard to buildings. In some few instances it might be altogether superfluous,—for example in the New Houses of Parliament, and the Royal Exchange, it being already matter of notoriety throughout the kingdom, that Barry is the architect of the one, and Tite of the other. But there are many works —and those not without merit, of which owing to there being no architect's name attached to the structures themselves, it is very difficult to ascertain by whom they were designed. However should I be mistaken at least in regard to the two above-mentioned—the information I ask for, can be furnished me in your next number.

I remain, &c.
Z.

DREDGE'S SUSPENSION BRIDGE.

Sir—I have been accidentally prevented from seeing your Journal of September last until now, or I should sooner have availed myself of your kind permission to reply to Mr. Dredge's communication. I do not know whether it is a part of Mr. Dredge's *patent right* to be exempt from criticism, but if such be the case, it ought in fairness to have been announced to the public at the same time that the invention was made known; as this, however, has never, I believe, been done, it is hard to account for the expression of "injured innocence" with which Mr. D. has seasoned his letter, unless, indeed, he is to be regarded as a sort of privileged character, whose inventions are not to be subject to animadversion like those of other individuals. Neither was I before aware that the truth of a mathematical demonstration was, in any degree dependent upon the name of its author, but as Mr. D. seems to think otherwise, I now give my name, in order that he may no longer suffer from the intellectual trammels which it would seem I have most unwittingly imposed upon him. It is much to be wished that Mr. Dredge, at the same time that he made known my having misconceived the construction of his bridge, had, at least for the benefit of your readers, if not of myself (who it appears am undeserving of such a favour, because I have omitted my name) stated in distinct terms, what are the peculiar features which distinguish his patent bridge. I should thus have been enabled to form an opinion of the merits or demerits which it may possess, without incurring the danger of a second "great mistake;" but as the case now stands, I do not see how I can enter upon the discussion with justice to myself or your readers, as it might very possibly happen that I should not be writing about Mr. D.'s bridge, but something quite different. The drawings which appeared in your Journal (Vol. III. page 193), it must I think be allowed, are calculated to convey the impression that the suspension rods are arranged in parallel though inclined positions, especially Fig. 3, at least they do not appear to be *tangents* to the curve which Mr. D. *seems* to assert, and no one could suppose, of course, that they are arranged without any order or method whatever. I think, therefore, that the inspection of the drawings alluded to, would necessarily lead to the conclusion that the rods were parallel. If, however, I have fallen into an error upon this point, which, however, Mr. D. does not distinctly assert, it will follow that such of my remarks as are founded on the supposition of the rods being parallel, will immediately fall to the ground as inapplicable to Mr. D.'s bridge, and I am quite willing to allow him the full benefit of this, claiming, however, at the same time for myself, the privilege of examining his bridge *de novo*, when I know what it is; and he may rest assured that should I discover any merits which were not before apparent, I shall at once freely acknowledge them.

I remain, Sir,
October 11. Your obedient servant,
George F. Fordham.

ON THE FORMS AND PROPORTIONS OF STEAM-VESSELS.

Sir—A former paper on this subject, which you were so good as to give a place in your columns, having occasioned the observations of your correspondent A. M., before proceeding further, his letter demands my attention. I think his objections to the method adopted for ascertaining the comparative resistance of the simple forms of vessels on which the calculations were founded, arises principally from his having overlooked the effect of what has commonly been called the "minus pressure," that is, the loss of pressure abaft, occasioned by the water's not closing in immediately on the vessels' after body, on account of the rapidity of her motion. This effect of motion is equivalent to an increase of pressure on the bow, and when the velocity is such that the water will not close in on the *lowest* part of the immersed body, the case becomes one of simple hydraulic pressure increased by motion. Besides the loss of pressure occasioned by the absolute absence of water behind the moving body, it has always been found that there is a great reduction in this respect before such a velocity has been attained as would prevent the closing of the water behind. This is occasioned by the *rarefaction* of the water, or its being mixed with a large portion of air, or leaving intervals of unoccupied space in the wake of the vessel, and though these effects are of course diminished, (as it was my intention to notice as I proceeded with the subject) by the proper modification of form in the after body of a vessel, I believe that in the simple forms which I have supposed, moving at such velocities as are acquired by large steamers at the present day, the result of these two sources of resistance would be such, that the sections would rest very nearly on the merits of their respective hydraulic pressures. It is the difficulty of estimating the exact influence of these two effects, which has caused all experiments hitherto made, as far as I can ascertain, to prove defective in their results, and apparently to contradict themselves at different velocities. Sir Isaac Newton assigned twice the pressure given by M. Bomit, and though he shewed his own results to be defective, they long remained the best data on which calculations on this subject could be founded. The experiments of the London Society for the Improvement of Naval Architecture, did not afford the means of establishing any certain law for estimating these resistances, and the velocities at which their trials were made being comparatively low, I do not think I am altogether unauthorised in adopting this mode of calculation for high velocities and simple forms. Some experiments detailed by Dr. Hutton, on the motion of bodies in air tend to support this view, as they show that resistance increases in a larger ratio than the square of the velocity even in an elastic fluid, and the deviation from this ratio becomes greater and greater as the velocities are increased, a result most probably arising by decrease of pressure on the hinder part of the body, caused by the rarefaction of the air as the speed is increased.

After this explanation, I proceed briefly to notice the two points of carriage of fuel, and action of the paddles as compared in vessels of the different proportions supposed. If two such vessels required each 400 tons of coal for her voyage, equal to about 16,000 cubic feet of water, the vessel 200 feet long by 40 beam, would have her draught of water increased 2 feet by this additional load, while the other, 200 feet by 30, would suffer an increase of draught of 2 ft. 8 in. We here see that the narrower vessel has the disadvantage in several respects, she has a greater depth in proportion of her body immersed, and suffers consequently an increase of hydraulic pressure. In consequence of the coal occupying a greater depth, on account of her smaller amount of beam, than in the other vessel, her centre of gravity is more raised in proportion, brought nearer to her axis of rotation, if it was before below it, and raised further above it, if in the first instance it was already so, as I believe most frequently is the case. In either case one great source, though perhaps not the principal one, of her stability or power of resisting a rolling motion is diminished; she is rendered less able to carry sail, which may sometimes prove the only resource for safety and less able to resist the stroke of the sea abeam, the latter being very commonly supposed among nautical men to be the cause of the President's foundering. Again, by leaving a smaller depth of the hull vacant for buoyancy above water, her power to rise over a sea is diminished, and she will consequently be wetter and pitch deeper in proportion to her increased load than the wider vessel. And lastly, (supposing her a vessel of the usual form) by bringing her full lines more in contact with the water, her speed must suffer a most serious diminution. Again, as regards the action of the paddle-wheels, supposing the paddles of these two vessels to be of equal diameter, and the floats having the same dip at their respective draughts of 15 and 20 feet. The narrow vessel again suffers a disadvantage as compared with the other; for her paddles being sunk deeper, the floats enter the water at a smaller angle to the horizon, and leave it at a greater, and thus the effective action is diminished and the backwater increased. This defect being severely felt in narrow vessels, different means have been tried to counteract it. The mean dip of the paddles has been reduced by raising the wheels higher on the hull, but this method has the disadvantage of making the paddles fly light when the fuel is reduced, the weather wheel frequently hardly dipping; the heavy pedestals for the paddle shaft must also be raised with it, and thus the centre of gravity must also rise, and the tendency to roll be increased, and if the hull be built higher out of the water in the same proportion, an unnecessarily large surface is exposed to the sideway action of the water and wind, and the rolling tendency still further augmented;—besides the engines working more rapidly increase the consumption of fuel without a proportionate increase of speed. The various descriptions of feathering paddles seem most applicable to narrow deep vessels, as it is in such when deeply laden that the oblique action of the floats is most felt; but even here I believe the additional power requisite to overcome their friction is generally considered to counterbalance the gain of power; and the floats being all constantly vertical present a much larger surface to the direct action of a head or following sea, and in such case become additional impediments to speed. The reefing paddle seems most likely to answer the end proposed, but may it not be a question whether the increased speed of the engines, when the wheels are reduced in diameter, does not cause some increase in the consumption of fuel? which would certainly be avoided in a great measure by building vessels of such proportions as would render any such contrivances needless. Feeling the great advantage of experimental evidence in support of expressed opinions, it was my intention to have illustrated these remarks by a few simple experiments, bearing solely on the points they refer to, but on consideration, so many difficulties appeared to oppose the probability of obtaining any data sufficiently accurate by such means as I could command, that this design was unavoidably abandoned. It is to be hoped that the experiments now proceeding under the auspices of the British Association, of the further prosecution of which I was not aware when I entered on this topic, will tend to clear away the difficulties which have hitherto attended the application of theory to this interesting subject, and advance naval architecture to a station somewhat more on a parallel with the present state of the other practical sciences.

I am, Sir, your's, &c.

H. P. H.

COUNT DE PAMBOUR IN REPLY TO MR. PARKES.

Sir—In a paper written by me and inserted in your number for September last: *On the Momentum proposed by Mr. Josiah Parkes, as a measure of the mechanical effect of locomotive engines*, the following passage occurs: "The author tells us that he is more accustomed to handle the hammer than the pen." I have since perceived that I had, there, by mistake, attributed to the paper of Mr. Parkes, *on boilers and steam engines*, a sentence which I had read in the very useful work of Mr. Armstrong, *on the boilers of steam engines*, preface, page xi, Weale, 1839. The two works having come to me at the same time, and being precisely on the same subject, I had made the error of ascribing to the one, what in reality belongs to the other. This point is however without the least importance, having no reference to the arguments presented in my paper, and I correct it only for the sake of accuracy.

Since the publication of the paper above alluded to, Mr. Parkes has printed in several periodicals, a letter in which he accuses me of having misrepresented his sentiments, in my refutation of his strictures against me. I had thought, first, that if my paper itself were put under the eyes of the persons who had read Mr. Parkes's letter, it would, by the full references contained in it, show sufficiently that I had not misrepresented the sentiments of Mr. Parkes; and I had, in consequence, only asked of the editors of the periodicals in which Mr. Parkes's letter had been published, to insert that paper as an answer. But this request having been refused by the *Literary Gazette*, and a mutilated part only of the letter which I had sent with the paper, having appeared in the *Mining Journal*, with the omission of what I considered the most important passages, it becomes necessary for me to make a different answer. Therefore, I beg you to insert in your next publication, the following paper, as a reply to Mr. Parkes's allegations.

I remain, Sir,

Your very obedient servant,

G. De Pambour.

October 18, 1841.

Supplementary paper, *On the Momentum proposed by Mr. Josiah Parkes, as a measure of the Mechanical effect of Locomotive engines.* By the Count de Pambour.

In a former paper, inserted in the Civil Engineer and Architect's Journal, for September last, we have proved that all the strictures presented by Mr. Parkes, in his paper: *On steam boilers and steam engines*, inserted in the *Transactions of the Institution of Civil Engineers*, vol. iii., against some of the experiments of our *Treatise on Locomotive Engines*, are entirely founded upon errors of his own; and, besides, that his *momentum* or intended "standard" of the mechanical effect of locomotive engines, which he proposes to substitute in place of every other research on the same subject, leads him to conclusions and results altogether faulty.

However, as in a letter inserted by Mr. Parkes in several periodicals (*Literary Gazette*, September 18th, *Mining Journal*, same date, *Civil Engineer and Architect's Journal* for October), he complains that in answering his strictures, we have misrepresented his sentiments, we shall now add a few more observations, to show that we have not misrepresented the sentiments of Mr. Parkes; and, besides, that it is not upon sentiments, but upon facts, that we can establish clearly *that the whole of the calculations and tables of Mr. Parkes are erroneous*, and, as every one of his conclusions and strictures are founded upon the numbers obtained in his tables, *that every one of his conclusions and strictures are equally erroneous.*

For that purpose we shall resume, in the same order, all the articles of our former paper, quoting more particularly the facts, or the expressions of Mr. Parkes, upon which is grounded our refutation.

1st. We have said that, to calculate the mean pressure of the steam in the cylinder of each of the engines submitted by us to experiment, Mr. Parkes uses the *average* velocity of the whole trip between Liverpool and Manchester. This fact cannot be denied, and is made quite evident by looking at his table viii. column 10, table xiii. col. 9, table xvi. col. 2, in which the velocities are headed, *mean velocity of the engines per hour*, and are in fact the average velocities of our experiments, given page 175 of the *Treatise on Locomotive Engines*, 1st edition, and page 253, 2nd edition; with the exception only of the cases in which Mr. Parkes has increased the velocities, from a pretended correction of his own, of which we shall speak in a moment.

Now, in recurring to our former paper, same article, it will be seen that such mode of calculating the pressure in the cylinder, from the *average* or *mean* velocity of the whole trip, is altogether faulty: because it gives only the pressure which would have taken place, if the whole trip had been performed at a *uniform* velocity. But the velocity varied considerably in the different portions of the trip, according to the more or less inclination of the part of road traversed by the engine, as may be seen in our detailed table of those experiments (pages 225 to 234, 1st edition, and pages 389 to 394, 2nd edition of the *Treatise on Locomotive Engines*). And in taking account, *as ought to be done*, of the time during which each partial velocity has been continued, we have proved, in our former paper, that the *real* mean pressure in the cylinder, is very different from the pressure given in Mr. Parkes's calculation. We can, therefore, safely conclude that the pressures, and correspondent volumes, of the steam in the cylinder, presented by Mr. Parkes as the results of his computation, are altogether faulty.

2nd. We have shown a first error, which Mr. Parkes introduces, as a fundamental basis, in all his calculations, and which has nothing to do with his *sentiments*. But he does not stop there. We have said that, moreover, he increases almost all the velocities nearly $\frac{1}{6}$; and to be assured of this, it again suffices to compare, in his paper, table viii. col. 10, table xiii. col. 9, table xvi. col. 2, with our own table page 175, 1st edition, and page 253, 2nd edition, of the *Treatise on Locomotive Engines*. It will be found that the velocity of *Vulcan*, in experiment VI. (table viii. of Mr. Parkes), is increased from 22·99 to 26·90 miles per hour, that of *Vesta*, in experiment V, from 27·23 to 31·60 miles per hour, that of *Atlas*, in experiment III, from 15·53 to 18·15 miles per hour, that of *Atlas* in experiment IV. from 20·59 to 24·07 miles per hour, that of *Leeds*, in experiment VIII, from 21·99 to 26·70 miles per hour, that of *Fury*, in experiment IX, from 18·63 to 21·79 miles per hour, and that of *Fury*, in experiment X, from 21·99 to 23·00 miles per hour. So that, out of ten experiments extracted from our work, seven have been made entirely false by this alleged correction to the *observed* velocities; and this is worse than if the whole of them had been falsified in the same manner, as it would, at least, have left the same proportion between the results. Mr. Parkes makes the same addition to the *observed* velocities, and therefore introduces the same error, in calculating the experiments of Mr. E. Woods, with the *Hecla*, since we find (page 112):

"Mean velocity during the trip...... 29·47 miles per hour.
"*Difference for gradients* .... 1·46 „

"Mean velocity on a level .... 30·93.

Mr. Parkes falls into this error, because, in speaking of *fuel*, it is said, in our *Treatise on Locomotive Engines* (page 324, 1st edition, and page 311, 2nd edition), that when the engines ascend without help one of the two inclined planes of the Liverpool and Manchester Railway, the surplus of work, thence resulting for them, equals, on an average, the conveying of their load to about $\frac{1}{6}$ more distance; that is to say that the engine will, in that case, consume as much *fuel* as if it had conveyed an equal load to a distance greater by $\frac{1}{6}$, on a level. And the *critic* thence logically concludes (page 86) that the *velocity* must be by so much increased, without perceiving that this correction refers only to the *work* done, and, as a consequence, to the corresponding consumption of fuel, but not to the *velocity*, which would suppose, not only that the load has been conveyed to $\frac{1}{6}$ more distance, but, besides, that it has been conveyed there *in the same time*.

Respecting this mistake, we have also proved that the error of Mr. Parkes has the double consequence of increasing the pretended effect produced, and lowering the pretended pressure of the steam in the cylinder; so that the proportion between the power applied and the effect produced is made doubly erroneous, and introduced so in his tables.

All this is certainly undeniable, and rests upon tables and facts only, not upon sentiments, and when we say that the *whole* of the calculations and tables of Mr. Parkes are grounded upon those mistakes, it cannot be denied either, in looking only at table viii. col. 10, table ix. col. 19, table xiii. col. 9, table xiv. col. 3, table xvi. col. 2. It will be there seen that *every other column is depending upon the alleged velocity of the engines.* Therefore, we are right when we conclude that the volume and pressure of the steam consumed by the engines (table ix. col. 26, 29), the horse power produced per cubic foot of water vaporized, or the quantity of water and coke employed to produce one horse power (table x. col. 44, 45, 49, &c.), the *momenta* generated per second (table xiii. col. 11, 12, table xiv. col. 9, 10, 11), and finally all the consequences derived from the comparison of the results obtained in those tables, about the alleged inaccuracy of the experiments, or the respective effects of locomotive and fixed engines, are in every way erroneous.

To show, by a particular example, the fallacy of the results to which Mr. Parkes has been led by this wholesale and faulty way of calculating, with a wrongly averaged and greatly exaggerated velocity, without taking account of the gravity, or of any of the other resistances really encountered by the engines, we refer to the two experiments of *Fury*, of which Mr. Parkes says (page 128), "a reference to the *Fury* (previously adverted to as giving anomalous results) exhibits that engine as having performed more work at 23 than at 21$\frac{3}{4}$ miles per hour, by the ratio of 24 to 19; it is therefore with certainty we may conclude one or both of those experiments to be erroneous." We have shown that this consequence presented by the *critic* with such certainty, proceeds only from his having neglected to consider that one of the experiments was made from Manchester to Liverpool, and the other, on the contrary, from Liverpool to Manchester. But, on account of the general rising of the road from Manchester towards Liverpool, the gravity opposes more resistance in that direction than in the other. So that, although the load of the engine was lighter in the first trip, still there was more work required of the engine, to convey that load to the other end of the line. In fact, in making the calculation as it ought to be, that is to say in taking account of the gravity *overlooked by Mr. Parkes*, it is found that, in the trip made from Manchester to Liverpool, the work done by the engine amounted to conveying 1964 tons to one mile, or 65·5 tons to 30 miles, on a level, and in the other trip, to 1837 tons to one mile, or 60·6 tons to 30 miles, on a level. Therefore the engine ought to have employed more time in performing the first trip than the second, which, concurrently with the other errors of computation of Mr. Parkes, had led him to conclude with "certainty" these experiments to be erroneous.

3rd. Mr. Parkes (pages 82, 83) says, "the pressure deduced from the sum of the resistances, given in column 29, for M. de Pambour's experiments I. to X, is composed, 1st of the friction of the engine without load, which includes the resistance opposed to it as a carriage, in common with the train; 2ndly, of the additional friction brought upon the engine by the load; 3rdly, of the resistance of the load at 8 lb. per ton. According to the author, these three items include all the resistance overcome by the steam, excepting that occasioned by the blast, in excess over the atmosphere. The amount of the latter should, therefore, be ascertainable by comparing the whole force exerted by the steam on the piston, with the force assigned as requisite to overcome the aforesaid three, out of the four component parts of the total resistance. The difference between these pressures should represent the precise amount of the counter elasticity of the steam in the blast-pipe." So, it is clear, as we have said in our former paper, that Mr. Parkes calculates the pressure owing to the blast-pipe, merely by taking the difference between the valuation of the divers resistances and *his own* result of the pressure of the steam in the cylinder. Now, we have already proved that this last result, obtained by Mr. Parkes as representing the pressure in the cylinder, is altogether erroneous. Therefore his supputation of the pressure in the blast-pipe must equally be so. But, besides, it is evident that such a mode of proceeding, by merely taking the difference between two assumed quantities, to establish the value of a third unknown, could never give, for this one, a value sufficiently certain to make it the test of experiments and *facts*; since every thing neglected in the calculation, like water lost by *priming*, resistance of the air, gravity, &c. would necessarily pass to the account of the pressure due to the blast-pipe, and falsify it. Consequently, if, by this calculation, Mr. Parkes is led to very inaccurate results, he ought not to be astonished, and we are not certainly.

4th. Mr. Parkes (pages 98, 99), in speaking of our two experiments made with the engine *Leeds*, says: "the author also has informed us that in the two experiments, the pressure in the boiler was precisely the same, and the regulator opened to the same degree. The power applied in the two cases was, consequently, precisely equal, and equal weights of water as steam passed through the cylinders in equal times; whence it results that the effects should have been similar. The expenditure of power was, however, greater by more than a third in the second than in the first case, to produce like effects, for we see that the effective horse power required 85·43 lb. of water as steam in the second and only 60·94 lb. in the first." And (page 100), "if, as asserted, the pressure in the boiler were precisely the same, and the regulator opened to the same degree in the second as in the first experiment, equal power must have been generated and expended in the same time, though at the higher velocity, the lighter load was moved through a greater space in that time. Had M. de Pambour reduced his data to the terms of value in these tables, he must inevitably have discovered the numerous errors of fact, and deduction, which are now brought to light."

So, it is clear that we did not misrepresent the sentiments of Mr. Parkes when, in our former paper, we said that he concluded against the accuracy of the experiments, because in the two cases cited, the useful effects of the engine had not been the same. But we have proved, in that paper, that in spite of an equality of pressure in the boiler and of opening of the regulator, there is always more loss supported by the engine, in overcoming its friction, the resistance of the air, &c., at a great than at a small velocity. Therefore, the useful effect produced, or *effective horse power* ought not to be *similar* in the two cases; and the "numerous errors of fact, and deduction, which are now brought to light," by the *Critic* and his tables, are nothing but a new misconception.

5th. We have said that Mr. Parkes submits the two same experiments, and the other experiments afterwards, to the test of a new principle, which consists merely in his making a confusion between the vaporizations effected in traversing the same distance and the vaporizations effected during the same time. This will be proved by the following passage, in which it will be seen that Mr. Parkes quotes our words relative to the vaporization *for the same distance*, and afterwards applies them to the vaporization *in the same time.* We have marked in *italics* the words which make this misreasoning quite evident. He says (page 99), "in his *Treatise on Locomotive Engines*, (pages 310, 312), M. de Pambour states a near parallel to these two experiments, by supposing a case of the same engine, with the same pressure in the boiler, travelling *the same distance* with two different loads. *The distance travelled being the same*, the number of turns of the wheel, and consequently of strokes of the piston, or cylinders of steam expended will be the same in the two cases.... So the mass or weight of steam expended will be in each case in the ratio of the pressure in the cylinder.... Now the author has given us the resistances on the piston which amount in the first case to 38·43 lb., and in the second to 23·93 lb. per square inch; and yet he assumes an equal expenditure of water as steam, *in equal times*, in the two cases.... To be consistent, however, with his own rule, above quoted, viz. that the weight of water consumed as steam are to each other as the resistances on the piston, it is obvious that if, in the first case, 3026 lb. of steam passed through the cylinders *in an hour*, 2166 lb. only would have been expended in the second case." And (page 101), "But we have already seen that if the quantity of water were correctly taken in the first case, a less quantity must have been consumed in the second, as the load upon the pistons of the engine in the two experiments deduced from their velocity and assigned resistances, differed in the ratio of 38·43 to 23·93; *and the water as steam consumed, in equal times, must necessarily have varied in the same ratio*, or as 3026 lb. to 2166 lb. It would be fruitless to pursue this analysis further, and vain to attempt the rectification of errors,—a task which properly belongs to the author."

We see that the passage quoted from our work establishes distinctly that when an engine draws two different loads over the same ground, the quantity of water vaporized, *for the same distance*, must be in proportion to the total pressures of the steam in the cylinder. But Mr. Parkes concludes from it, that the quantities of water vaporized, *in the same time*, must be in the ratio of the pressures. But we have proved, in our former paper, that those two consequences are precisely contrary to each other. Therefore the principle alleged by Mr. Parkes, and which he uses afterwards throughout his paper, to "test" the accuracy of the experiments, rests merely upon a new mistake of his own, which consists, as we have said, in making a confusion between the vaporization *for the same distance*, and the vaporization *for the same time.* So that there is no occasion to "attempt the rectification of errors" discovered by the application of this *new* principle.

6th. Mr. Parkes comparing the locomotive with the fixed engines, says, (page 90), "Thus the fixed non-condensing engine is the most economical of the two; but if Mr. de Pambour's data are correct, we must abandon all preconceived opinions, and all belief in the accuracy of pre-ascertained results on the non-condensing engine; we must reverse our engineering creed, and acknowledge the fixed non-condensing engine, with its simple atmospheric resistance, to be far inferior, in economy of steam, to the locomotive, with its plus atmospheric resistance." And (page 98), "for it is utterly impossible that the locomotive should accomplish an equal effect, with $\frac{1}{4}$ less steam than the condensing engine. To go over this ground again would be a mere repetition of arguments previously used."

By these passages it is fully established that Mr. Parkes would, as we have said in our former paper, conclude against the accuracy of the experiments, because a locomotive engine cannot possibly produce a useful effect equal to that of a high pressure non-condensing, or to that of a condensing engine. But we have proved that the case may occur; and Mr. Parkes concedes it himself (pages 156, 157), in saying of a sort of locomotive engine under his charge, "the consumption of steam per effective horse power, per hour, has been shown to be 120 lb. for the fixed non-condensing engine, and for the locomotive under review 112·54 lb., which proves the latter to have been the most economical of the two, at nearly the same absolute pressures. This is a new, and perhaps, an unexpected result." Therefore Mr. Parkes's first objection was good for nothing. But, besides, it must be borne in mind that the velocities used by Mr. Parkes, to calculate the effects of the locomotive engines, being nearly all considerably increased, as has been proved above, he must necessarily arrive at exaggerated results for the effects which he supposes to have been produced by those engines. Therefore this new argument against the accuracy of the experiments, is again the result of his own errors of reasoning and calculations.

7th. To prove that the same unfounded arguments have been urged by Mr. Parkes, and with the same results, against every other engineer who has published experiments on locomotive engines, we need only quote the following passages.

Respecting the experiments of Mr. *Robert Stephenson*, Mr. Parkes says (page 105), "They contain within themselves abundant proofs of error in the quantities assigned to the consumption of water as steam.... Now, if the evaporative data are correct, it would appear by the ratio which the volume of steam consumed bears to that of the water which produced it ($\frac{1}{20}$th being deducted for waste), that the absolute pressure upon the pistons in this case amounted to 81·95 lb. per square inch; but there was only 50 lb. in the boiler! If, therefore, 77 cubic feet of water passed through the cylinders in an hour, in the shape of *pure* steam, the blast-pressure or counter-effort above the atmosphere, was 34·41 lb. instead of $2\frac{1}{2}$ lb. per square inch on the pistons." And (page 106), "Experiment XII. In this case I have assumed an equal evaporation in the same time as in the foregoing experiment; and if $\frac{2}{7}$ were deducted for waste, the blast-pressure would be less than nothing—or a vacuum; for, with the subtraction of $\frac{1}{4}$ for waste, as in the table, the absolute pressure amounts only to 11·10 lb., whilst the resistance required 10 lb. per square inch; and if, contrary to demonstration, it be considered possible that the 77 cubic feet of water were converted into pure steam, and that this quantity passed through the cylinders in the hour, the blast-pressure would equal the whole force required to balance the assigned resistance; for the absolute pressure on the pistons would have amounted to 20·70 lb. per square inch, whilst the sum of ascertained resistance was only 10 lb."

Respecting *Dr. Lardner's* experiments, Mr. Parkes says, (page 110), "It appears, from the tenth conclusion, that the author considers his experiments, so far as they have gone, as giving results in very near accordance. It cannot fail to be remarked that the term discordance would seem to be much more appropriate than accordance to the indications of the last column in the table. But no fair average can be struck from such irregular results; and (page 118), "If the resistance assigned by Dr. Lardner as opposed to the motion of the train be correct, the efficiency of the steam in the locomotive is more than double that obtained by the best condensing engines, more than treble that derived from stationary non-condensing engines, and equal to the performance of a Cornish expansive engine doing a 50 million duty with a bushel of coals."

Respecting the experiments of Mr. *Nicholas Wood*, Mr. Parkes says, (page 129), "The *North Star* affords a sequence of six experiments at velocities varying from $18\frac{1}{2}$ to $38\frac{1}{2}$ miles per hour, but the sequence of results is so irregular as to indicate error in two of them, which I have accordingly marked and rejected, for it is certain that a greater measurable effect must accrue from the expenditure of equal power at 25 than at 30, and at $31\frac{1}{2}$ than at 34 miles per hour; yet the reverse appears on the face of the experiments. It is also equally impossible that a greater momentum should have been generated by a like consumption of force at 34 than at 25 miles per hour."

Respecting the experiments of Mr. *Edward Woods*, with the *Hecla*, Mr. Parkes says, (page 117), "On turning to the tables, and examining the results of this experiment (case 2), it will be apparent:

"1. That a duty has been performed of double the amount effected by the condensing engine, with an equal expenditure of power (column 15).

"2. That the absolute force impressed upon the pistons, as determined by the relative volumes of water and steam was 30·95 lb. per square inch, whereas the tractive effort requisite to overcome the assigned resistance, amounted to 39·28 lb. per square inch, exclusive of the force equivalent to the friction of the loaded engine and blast pressure (cols. 29, 30).

"3. That the power required of the engine to balance the tractive effort alone was $151\frac{1}{2}$ horses, whilst the absolute power furnished by the steam to move the engine, to neutralize the blast resistance, and to overcome the load, amounted only to $119\frac{1}{2}$ horses (columns 33, 34).

"4. That the water expended as steam per horse power per hour, was 37·89 lb. for the tractive effort or duty only (column 42), whereas the condensing engine consumes 70 lb. per effective horse power.

"5. That compared with a fixed non-condensing engine at equal pressure, the locomotive, though labouring against the heavy counter pressure of the blast, from which the other is free, is assumed to have performed equal work, with less than one-half the expenditure of power.

"Such are the incredible results arising out of data purporting to be fairly and necessarily deduced from impeachable experiments."

Therefore we were quite justified to say in our former paper, that it was remarkable that in applying his pretended verifications to all the experiments published on locomotive engines by different engineers, Mr. Parkes had found that the conditions to which he proposed to subject those experiments were not verified in them, and that such a result ought to have put him on his guard against the soundness of his own arguments. But, besides, we have proved that Mr. Parkes has used, in all his calculations, velocities which are erroneously averaged and greatly exaggerated; that he has taken no account of the gravity on the different inclinations of the road; that he has neglected the friction of the engines, the resistance of the air, &c.; that he has calculated erroneously the pressure and volume of the steam in the cylinder, as well as the pressure due to the blast-pipe; that he has tested the experiments by a false principle, grounded upon his confusion of the vaporization for the same distance with the vaporization in the same time; and we shall see very soon that in calculating what he calls the *momentum* generated by the engines, he has wrongly considered the whole weight of the train as raised up in the air by the engine, instead of being dragged or rolled along the rails; all points established upon the very *tables* and *words* of Mr. Parkes, so that he cannot say that his sentiments have been misrepresented; consequently, we were justified also in adding that he heaps errors on errors, combining and complicating them unawares, till he arrives at a point where he does not produce a single result that is not erroneous.

8th. After having shown the material errors and general misreasoning which pervades the whole of the strictures of Mr. Parkes against our researches and those of others, we come to the *Critic's* own conception, that is to the calculation of the mechanical effect of locomotive engines, by what he calls the *momentum* generated. He says, (page 128), "Column 2 exhibits the momentum, or product of the mass, in tons, of the engine, tender and train, multiplied into its velocity in feet per second; and the sums thus represent the respective mechanical effect produced per second by each engine." And (page 130), "Four means are derived from these results. Mean 1. informs us, 1st, That when the velocity is increased in the ratio of 1·52 to 1, an increased consumption of power is required for the production of equal mechanical effects, or of equal momenta, in the ratio of 1·43 to 1, being somewhat less than in the direct ratio of the velocities. 2nd. That power is expended in the ratio of 2·43 to 1, or in about that of the square of the velocities to produce equal gross commercial results. 3rd. That power is expended in the ratio of 3·11 to 1, or in not much less than that of the cubes of the velocities, to realize equal useful commercial results."

So, in our former paper, we have properly cited Mr. Parkes, and therefore our conclusion is correct, that what he calls *momentum* is nothing more or less than the common useful effect (weight of engine included), as explained in every work upon that subject; with the exception that, here it is wrongly calculated; and to be convinced that it is wrongly calculated, it suffices to give a glance at table XVI., page 143, of Mr. Parkes's paper. There we see that the *Atlas*, in experiment I, produced a *momentum* equal to 206·90 tons, gross load of the engine (column 5), multiplied by 14·263 feet per second, mean velocity of the engines per second (column 9), equal to 2951·01 tons moved one foot per second (column 11). This *momentum* or *mechanical effect*, reduced in pounds, is equal to 6,610,262 lb. moved one foot per second, or to 396,615,744 lb. moved one foot per minute. Now, if we observe that a horse power is expressed by 33,000 lb. moved one foot per minute, we shall see that the *momentum* produced by the *Atlas*, in that experiment was equal to

$$\frac{296,615,744}{33,000} = 12,019 \text{ horses.}$$

Experiment II. exhibits a momentum equal to 12,504 horses, experiment III. a momentum equal to 5,862 horses, and so of the others. The *North Star* alone produced a *momentum* or *mechanical effect*, equal to 21,668 horses. These extraordinary results proceed from Mr. Parkes taking erroneously the total weight in tons, for the resistance moved, as if the whole train were *carried up in the air by the engine;* whereas the true resistance overcome in rolling the train along the rails, is only at the rate of about 6 lb. per ton of weight; besides the friction of the engine, the gravity, the resistance of the air, &c., neglected by Mr. Parkes.

Certainly, then, we were quite right to say that calculations like these do not tend to the progress of science, but that they would rather lead it back to its first rudiments; and if we have added, besides, that Mr. Parkes *has not made one experiment on locomotive engines*, it is a fact that can easily be verified in looking at his table XVI., from which he has drawn his *momenta*. In column I. of that table, the name of every one of the experimenters is given, and there is not one experiment in the name of Mr. Parkes. So that a man so fertile in strictures against the experiments of others, has not made a single one, himself.

I must now say a few words on the letter of Mr. Parkes, lately inserted in several periodicals, in support of his former strictures against my experiments on locomotive engines. It would seem from that letter, that I have attacked Mr. Parkes, but mere dates will easily settle that point. The attacks of Mr. Parkes against me will be found in his paper, *On Steam-boilers and Steam-engines*, inserted in the *Transactions of the Institution of Civil Engineers*, vol. III., with the date, London, 1839, given (page 162) at the end of the paper. In this writing I am attacked almost without interruption, from page 77 to the end. The alleged inaccuracy of my experiments is presented under all possible forms, as the necessary consequence of the results obtained by Mr. Parkes in his tables. It was then incumbent upon me to protest against any conclusions drawn from these tables, and to prove that they are, as well as the reasonings of the *Critic*, an uninterrupted series of mistakes. Therefore I published an answer in the introduction to the second edition of my *Treatise on Locomotive Engines*, Weale, 1840, and afterwards printed it again with more details and full references, in the *Civil Engineer and Architect's Journal*, September 1841. This date, and the whole subject of the paper itself, show sufficiently that it is but an answer to the unfounded strictures of Mr. Parkes.

Now that I have established that, in my refutation of the criticisms of Mr. Parkes, I have not misrepresented his sentiments, it would be very easy, and completely justifiable, to add some observations upon the expressions used by Mr. Parkes in his letter, to support by words what he could not support by arguments. But, as it is my decided intention to keep distinct from any discussion foreign to the scientific question, I shall abstain from presenting any remark on the subject, begging only the persons who want to form a precise judgment of this controversy, to read the letter of Mr. Parkes again, after having perused this paper, and then to make their own observations.

G. De Pambour.

GREAT WESTERN STEAM SHIP COMPANY.

The question about the legality of the Great Western Steam Ship Company carrying on a marine engine factory has now been decided, the supporters of such an absurd plan have at last been compelled to come forward and concur in their own defeat, a circumstance not to be regretted, when it is considered with how much pertinacity they stuck to their bantling, and how determined they were in their endeavours to foist it upon the unwilling shareholders. As it is, a great loss must be incurred in the disposal of the property, independently of the waste which must have been caused by the maintenance of the establishment, and the victimized shareholders remain without any remedy against those who have so grossly abused their trust. When individuals embarked their property in the Great Western Steam Ship Company, marine engineers especially, they never contemplated that the funds of the Company were to be applied to any purpose but the legitimate one of engaging in the carrying trade, they did not expect that their money was to be wasted in rivalry against themselves, or that the company was to go to the expense of hazardous experiments. Yet scarcely had one ship been launched, before the directors, who had barely capital enough to fit out another ship, set up a large building yard and an engine factory, intended for executing machinery on the greatest scale. The result it wanted but little sagacity to foresee; it was a sad destruction of the Company's prospects, and a serious injury to their revenue, for while these experiments have been going on, the North American and West Indian Mail Companies have launched each half-a-dozen steamers, and have set them to work. Where, however, is the Mammoth? she has not even her hull finished, and when she will be launched no one can tell. As to the propriety of any company, except one with a fleet of vessels, like the General Steam Navigation Company, engaging in ship-building or engineering, it is preposterous, and still more so where there is only a paltry amount of capital available for the purpose.

The next question is whether it is at all proper for a joint-stock company to engage in such a business as marine engineering, and we have no hesitation in saying that no company is justified in undertaking any thing of the kind. We think it more necessary to dwell upon this point, as some ambitious individuals are endeavouring to form a separate company for the purpose of carrying on the rejected steam factory, which will as certainly prove a loss to its new proprietors as it has to the Great Western Company. There is no rule laid down which applies more clearly to this case than that which governs the constitution of joint-stock companies; it is expressly defined that a joint-stock company can only safely engage in such pursuits as are beyond the capital or credit of a private individual, and that any company, endeavouring to compete with private enterprise in its own proper sphere, must sustain a loss. Now, surely, with regard to steam ship building, it cannot be said that there is any call for a company to engage in it, as the private parties who now carry it on have proved themselves fully competent, having, during the present year, supplied not only the English government, but other governments with steam frigates, and having turned out of their yards a fleet of first-class vessels for the North American and West Indian stations. There is no call for a company, every one is satisfied with the present system, and the Great Western Steam Ship Company, or the Steam Ship Factory Company, must lose largely in a ridiculous contest with a small capital against the Maudslays, Sewards, Millers, Lairds, Napiers, and Acramans, of the great steam ports. We therefore conjure the Bristolians to beware of the snare which a few ambitious men are getting ready for their downfall.

Malta.—It has been determined by the Admiralty to erect at Malta a biscuit baking apparatus on the plan of Mr. T. T. Grant; it will be situated over the galley arches. We have heard also that a dock is forthwith to be constructed in the dock-yard there, on a site pointed out by Captain Brandreth, and for that purpose a contract has been made in Catanea for stone of an admirable quality, equal to granite, but in reality lava, which is to be delivered on the spot, ready worked for use, at 2*s*. 9*d*. only the cubic foot.

SMOKE NUISANCE IN LARGE TOWNS.

At a Court of Common Council held at Guildhall, London, on the 11th October last, Mr. Anderton presented a Report of the Committee appointed to inquire into the nuisance arising from smoke of manufactories and steam engines, &c., and the best means of obviating the same.

The following is the document referred to:—

To the Right Hon. the Lord Mayor, Aldermen, and Commons of the City of London, in Common Council assembled.

We, whose names are hereunto subscribed, your committee for general purposes, to whom on the 29th day of October last it was referred to inquire into the annoyance and nuisance to which the inhabitants of this city are subject from the smoke of manufactories and steam-engines, and also from steam-boats on the river Thames, and the best means of obviating the same, and to report thereon to this Court, do certify, that with a view of collecting every information upon the subject we directed advertisements to be issued, intimating the nature of the reference to us, and expressing our desire to receive any suggestions in writing as to the best means to be adopted for remedying the inconveniences complained of, and in consequence thereof we were favoured with communications from upwards of 41 parties, suggesting a variety of modes for that purpose, and for the better information of this hon. court we have classed and arranged the same under the following heads:—

1. Parties tendering general advice.
2. Methods for the combustion of coal and the prevention of smoke, by the introduction of fresh or undecomposed air into the furnaces.
3. Methods for the purpose of coking or charring the coal in furnaces, such furnaces forming part of the ordinary furnace of steam-boilers, coppers, &c.
4. By the introduction of a jet of steam, in conjunction with a jet of air, into the furnace of steam-boilers.
5. By the use of anthracite, Welch coal (either Langannoch or Merthyr), or coke.
6. By compressed fuel.
7. Parties possessing plans, but at present unexplained.
8. General complaints, but no remedy proposed.

Class 1.
General Advice by Papers, Books, &c.

The papers and communications of Mr. Charles Hood (No. 17), Dr. Reid (No. 33), Mr. C. W. Williams, presented by Mr. Henry Dircks (No. 41), are of too valuable a character to be curtailed (particularly the latter). The whole subject is handled in a manner that would, if put fairly in practice, completely do away with the smoke, and be attended with highly beneficial results to the proprietors of steam-engines, manufactories, and others using coals in large quantities; it will be needless here to refer to any particular point, as the whole are included, by the methods to be considered, as they present themselves in the following classes:—

Class 2.
Methods for the Combustion of Coal and the Prevention of Smoke by the Introduction of Fresh Air into Furnaces.

Mr. W. Hazelden (No. 15) writes a favourable report of a furnace patented by a Mr. Andrew Kurtz, and of which patent he has a share; he further states that a saving of 22 per cent. in fuel has been effected by the use of this patent. Their terms are liberal, and they are willing to allow any engineer appointed by the committee to examine and report upon the same.

John Bewley (No. 5 b), on the same patent, writes that the plan is simple and easy of application to the great majority of steam-engines; that he is agent for this patent, and shall be happy to show the plan in operation to any person conversant with such matters, and give them the opportunity of testing the same to their entire satisfaction.

This patent, we believe, consists of a series of hollow fire-bars forming an inclined plane, the highest end being next the bridge; through these bars air is admitted from thence through small openings in the bridge. This air, mixing with the gases from the fuel, forms an explosive mixture which readily fires; thus doing away with smoke, &c.

Samuel Hall (No. 18) is the patentee of a plan much of the same nature. His method is to place a quantity of pipes in the flue between the boiler and the chimney. Air is admitted through those pipes, thence it passes in flues or tubes to perforations in or near the bridge. The office of the tubes (placed in the chimney throat) is to intercept and return a portion of the heat (which would be lost up the chimney) to the fire, and to warm the air admitted for the purpose of forming an explosive mixture with the gases.

Mr. Samuel Hall thus writes—

"If you will select a stationary engine, and one on board a tolerably large steam-boat on the banks of the Thames, for the application of my apparatus, I will furnish it and put it up to the engines at my own expense, to be paid for at a moderate price (to be previously agreed on) if it answers the purpose; but if not, to be taken away also at my own expense, and the success or non-success of the process to be left to your decision."

Numerous testimonials accompany this communication.

R. F. Forester (No. 11) is a testimonial of more recent date (in favour of the foregoing), and since the advertisement has been put in by our directions.

Henry Dircks (No. 41)—This communication is principally in explanation of a patent by C. W. Williams, of Liverpool, which is for the admission of fresh air through small orifices placed in the flame bed behind the bridge, stating that by the use of this apparatus, the air (forming the explosive mixture with the gases) will be more divided and mix more readily, and the combustion will be more perfect. He at the same time uses a perforated plate, or a series of tubes in the ash-pit beneath the fire bars, thus insuring a more perfect and economical combustion of the coke or charred coal on the bars, and by this process the Newcastle coals possess every advantage of the Anthracite, Langannoch, and other Welch coals.

A variety of testimonials in favour of the process from the most eminent chemists accompany the communication.

Class 3.
By the method of coking or charring the coal in furnaces, forming part of the ordinary furnace of steam-engines, &c.

John Chanter (No. 5 a) is the patentee of a number of plans for the purpose just described.

His combination, as he now describes it, is as follows:—To the front of the common boilers now in use, he places an "auxiliary boiler," which is connected to the principal boiler by both water and steam pipes, thus insuring a circulation of the water. Under this supplementary boiler he places the fire bars, laying them lowest at the back end (the inclination being six or eight inches to the foot) beneath these fire-bars he places a plate of iron, which he terms a "deflector;" this is for the purpose of warming the air (feeding the fire on the bars) by reverberation. At the lower end of this furnace a common furnace is constructed, which receives the coke or charred coal in an incandescent state from the upper bars.

Thus when coal is thrown into the upper furnace, the smoke, in its passage to the chimney, has to pass downwards over the clear burning fire on the bottom bars.

Acraman and Co. (No. 1).—This communication is a letter to Mr. Chanter on the last subject, and on the utility of such patent when applied to marine engines. Also a list of questions submitted by them to Mr. Thompson, resident engineer, at Liverpool, for the British and North American steam-boats, all of which are answered in a very satisfactory manner by the latter gentleman.

R. Thompson (No. 36).—This is a letter from this gentleman to Messrs. Acraman & Co., of Bristol, containing a favourable report on the application of Mr. Chanter's plan to the Enterprise steamer, of Glasgow.

Earl of Dartmouth (No. 7).—This communication is in favour of a plan of Mr. Hall, of Leeds, and is the only notice of this principle. This we believe is the plan adopted:—A division is formed longitudinally or otherwise in the fire-place, thus forming two furnaces, which are fired alternately, the smoke and gases arising from the fresh fuel in one furnace is destroyed by passing over the bright fire of the other. The noble Earl states that he has applied the apparatus to some boilers in Staffordshire, and it causes them to consume nearly the whole of the smoke.

J. Juckes (No. 19) is the patentee of a plan for consuming of smoke, and saving of fuel. The method he uses is as follows:—

"In the centre of a common fire-place he places an apparatus which receives the coal from a hopper, the coals so placed are introduced into the furnace beneath the fire, instead of being thrown in from above and upon the coals under combustion in the usual manner; by this plan, the gases (arising from the fresh fuel) are destroyed by passing upwards through the coke or charred coal under combustion.

When the coal so admitted becomes caked, the feeder is again lowered, and a free vent or passage is formed for the admission of fresh air into and through the burning fuel. The patentee is willing to give reference or information.

R. Rodda (No. 30) is the patentee of a plan for the consumption of smoke and saving of fuel. His method is to divide the furnace into two parts, the fresh coals are put in the first division to coke, and are then thrust back into the second division; the gases arising from the fresh coal pass through lateral openings into the second division, where they are destroyed by the bright fire. A stream of fresh air is admitted joining the smoke in the passage, thus rendering it more fit for explosion.

A list of testimonials from the houses of Messrs. Barclay, Perkins, & Co., Messrs. Truman, Hanbury, & Co., and others, accompany the communication.

Class 4.

By the introduction of a jet of steam, in conjunction with a jet of air, into the furnace of steam boilers.

W. Bell (No. 3).—This communication is in favour of a plan patented by Mr. Ivison, of the Castle Silk Mills, Edinburgh. The method he uses is to admit a portion of steam through a small pipe into a finely perforated fan branch placed in the furnace, whilst at the same time openings are made into or near the bridge. Through these openings fresh air is admitted, which air and steam mingling with the gases arising from the fuel under combustion, forms an explosive mixture which readily fires, thus destroying the smoke.

A report from the Manchester police accompanies this communication.

Mr. English (No. 9) is the editor of the *Mining Journal, Mining Review*, &c. In his communication he directs attention to notices of Ivison's and other patents contained in the above works, most of which have been described in the present papers.

W. Greaves (No. 13) also notices Ivison's patent, he being agent in Newcastle for the said patent. He further advises the use of coals known by the name of Leaze's Main, which, in conjunction with the said patent, produce but little smoke.

W. Smith (No. 34) writes that Ivison's patent has been applied to an engine belonging to the police-office, Aberdeen: the smoke is in a great measure consumed, and that a saving of coal is effected.

Class 5.

By the use of Anthracite Welch coal (either Langannoch or Merthyr) or Coke.

All the communications which are classed under this head show that fuel of the above description can be procured in any quantity, is perfectly free from smoke, and would be found as economical as the Newcastle or other descriptions of coal.

Class 6.

By the use of compressed Fuel.

Thomas Oram (No. 26).—This communication states, that the patentee has a method of preparing the compressed fuel, which will emit but little smoke, has a greater power of heat than the best coals, and of a much lower price to the consumer. A sample of the fuel accompanied the communication, a portion of the same has been burnt, and we find but little smoke emitted, but without analysis it would be difficult to form an opinion.

Class 7.

Parties possessing plans, but at present unexplained.

Dez Maurel (No. 6).—Of this we cannot do better than give the following translation:—

"Invention of an apparatus to prevent chimnies taking fire, exempts them from cleaning or sweeping, and which does not allow any soot to escape from the top.

"The inventor proposes to make the following demonstration:—There will be constructed, at the expense of the committee, a chimney, of which the tower is to be 20 feet high, and made of wood. The part nearest the fire shall be tarred in order to demonstrate the impossibility of its taking fire; and the upper part shall be whitened, in order to be assured of the nullity of action of the smoke destroyed by the apparatus.

"In the fire are burnt pit-coal, wood shavings, oil, and essence of turpentine, and after this the apparatus shall be taken away, and in less than half an hour the white part of the tower will be entirely coloured. The apparatus (of which the price is very moderate) is of long duration, and requires but one minute to clean it."

Mr. Eugene de Varoe (No. 8).—This memorial showeth that he hath invented an apparatus by which the soot or carbonic portion of smoke is destroyed, and the gaseous portion rendered harmless; it is easy of adaptation; chimney-sweepers are rendered unnecessary; an impossibility of overheated flues; would render the atmosphere of London as pure and serene as the cities of the continent, and would give an additional security to life and property. Has performed experiments before men of science, and would feel honoured by the commands of the Court of Common Council to perform such experiments as would demonstrate the utility of the invention.

W. H. Griesbach (No 14) showeth, that if 50*l.* be placed at his disposal (in consideration of his time and expences), and the use of a steamer, he has no doubt of removing the nuisance complained of. The expense of the experiment to be borne by the parties interested. In the event of success, a sum of money (the amount previously determined) to be paid to him; and further, did he not receive an answer to his communication, dated the —— day of ——, he should leave for the continent in a few days.

W. Miller (No. 22) showeth, that he has discovered a method of preparing coal by a simple process, which has the desired effect, and should be happy to submit some coals thus prepared, at any time, in London.

John Parsons (No. 28) showeth, that he has invented a plan, by which the nuisance complained of may be got rid of, as also the inconvenience arising from smoky chimnies of houses in general. That his plans have been tested, and found perfect; and he would be glad to explain to any person appointed by the committee.

Reddell Brothers, (No. 31) show that they are in possession of a plan by which the object could be gained; that it is very simple and self-evident upon explanation, and they would be happy to give such explanation to any person appointed by us. The plan would meet with the cordial support of the fire insurance companies and of the public generally.

John Williams (No. 38) showeth, that he has tried different experimeuts, and at last succeeded in finding one perfect, which would completely do away with the nuisance complained of; and, if allowed a little time, he intends publishing a treatise on the subject, the profits of which he purposes giving to some institution in the part of the country where he resides.

W. Wood (No. 40) showeth, that he has invented a plan which would have the desired effect, is easy of application, and, in the case of stationary engines, would be much cheaper than the methods used at present. He would be happy to show his plans to any person appointed by us at a few days' notice.

R. J. Brinley (No. 4 a) refers to an article in the 7th volume of *Chambers' Edinburgh Journal*, in which there is a thing detailed calculated to effect the object required, and would be happy to lend us the volume in question.

Class 8.

General Complaints, but no remedy proposed.

S. Ansell (No. 2) complaining chiefly of the annoyance arising from the ropes of the Birmingham railway at the Euston station, and the Blackwall railway, through the eastern part of the metropolis.

Misokapnos (No. 21), complaining of the deficiency in height of the chimney belonging to Messrs. Calvert's brewery.

At the same time your Committee feel we should not do justice to the several parties if we did not annex the whole of their plans and communications to this report, and to state, after a careful perusal of the same, that it appears to us to be highly desirable that the nuisance arising from the smoke of steam-engines and manufactories should be abated, and that we have no doubt a remedy may be found which will remove the annoyance complained of, and be attended with economy to the owners of steam-engines and manufactories generally; and under this conviction we recommend this hon. court to present petitions to both Houses of Parliament, complaining of such nuisance and annoyance, and praying that a law may be passed to prevent a continuance of the same.

And we are further of opinion that this Report should be printed, and copies thereof sent to the members of the legislature and of this hon. court, to the authorities of Birmingham, Sheffield, Glasgow, and all the other large manufacturing towns likely to be affected by smoke from steam-engines; and also to the principal engineers and scientific institutions of the metropolis: and we recommend the same accordingly.

All which we submit to the judgment of this hon. court.

Dated this 15th day of September, 1841.

The report was then ordered to be printed and circulated, and taken into consideration on a future day.

After the transaction of some further business, the Court adjourned.

ENCROACHMENT OF THE SEA AT DOVER.

Tuesday Evening, 19th October.

DURING the last three or four days the very boisterous weather which all along the south-eastern coast has more or less been detrimental to the shipping interest, has done considerable damage at Dover, carrying away an immense quantity of beach, and undermining a number of boat-houses and other small buildings which had for a number of years past bid defiance to the fury of the waves. In the bay, which to a considerable extent was sheltered from the wind and tide by the projection of the pier, several boat-houses opposite the Royal York Hotel have been washed down. For several days past, during the time of high water, the waves have come rolling into the bay in such awful grandeur as is rarely witnessed on this coast, carrying back with them the shingle to so great an extent that the sea now washes in 10 or 15 feet nearer the Marine-parade and Waterloo-crescent than it formerly did. The greatest destruction of property, however, has been to the westward of the Stonehead. Here, where the beach used formerly to accumulate in great quantities, and passing hence to the mouth of the harbour, whereby a free ingress and egress to vessels was prevented scarcely a pebble is to be seen—a phenomenon never before witnessed by the oldest inhabitant.

What can be the cause of this extraordinary circumstance, is difficult, perhaps, to determine, although the most probable conjecture is, that the enormous fall of chalk at the Round Down Cliff, about twelve months since, has stopped the progress of the shingle beyond it, in travelling to the eastward, as it used to do. But some persons, who have paid considerable attention to the subject, conclude that it arises from the large quantity of beach used in the construction of the sea-wall between this town and Folkestone. The circumstance, however, from whatever cause it may arise, is a subject for deep regret, as the presence of the beach was a great preservative to the town, while its absence has been the sole cause of the late destruction of property.

We have not been able to ascertain the amount of the damage sustained in this part of the town, but as the buildings belonged principally to boatmen and the humbler classes of society, they are of a serious nature; whilst future gales threaten more extensive destruction, unless something be done to check the raging waves. Further onward is the Bullock rock, on which is built Archcliff Fort, the residence of Colonel Munro, R. A., the commandant of the garrison. The base of this rock we perceive has also been undermined to a very great extent by the washing of the sea, and as there are several large clefts in various parts of it, there is every reason to fear that a portion of it will soon give way. The houses beyond this rock have been by the late gales placed in imminent danger. The platform on which they were built, and which extended several feet in front, has nearly all been carried into the sea, and some of the smaller buildings, one of which was the residence of a poor family, have been pulled down to prevent the materials being washed into the sea, and to make a road to the other houses. The platform leading to the entrance of the tunnel under Shakspeare Cliff, which was many feet in width, has also disappeared, with the exception of a narrow slip; but as a second tunnel is yet to be excavated, we do not apprehend that it will be of any loss to the South Eastern Railway Company. One thing, however, is now quite certain—the company will not be able to make the railroad in this place stand, without going to the e pense of erecting a wall to defend it from the encroachment of the sea; and this, it appears to us, would be advisable before the Dover terminus of the tunnel be commenced, if the materials for the construction of the same can be obtained. The whole of the beach, as we before observed, having been carried away, nothing now remains to prevent the sea washing against that vast and stupendous cliff which Shakspeare has immortalized, and we perceive that even here also the raging surf seems fully bent upon destruction. A large quantity of several thousand tons' weight fell into the sea on Sunday last, near the mouth of the railway tunnel, and many other huge masses may be seen at a distance tottering over an excavated base. A walk, therefore, beneath this cliff may now be considered as extremely dangerous.

The attention of many of the inhabitants of Dover is now turned towards the object of preventing the sea making any further encroachments on the town, and for this purpose a deputation of them yesterday morning waited on Mr. Jenkinson, the Deputy Lieutenant Governor of Dover Castle, to ascertain if any assistance could be rendered by the Harbour Commissioners. The deputation was received by Mr. Jenkinson with every mark of respect, and he informed them that everything that he, as a Harbour Commissioner, could do should be done, and that he would immediately communicate with His Grace the Duke of Wellington on the subject.

A STEAM BOAT OF A NEW CONSTRUCTION.

(Abridged from the *New York Herald*, August 7.)

THE new steam boat, the *Germ*, is arrived in our waters, and has made an experimental trip off the Battery. Lieutenant Hunter, the inventor of this boat, and Captain Hosken, of the Great Western, took a trip in her yesterday, through our harbour and round the North Carolina, and were highly gratified with her performance. This beautiful little vessel is just 50 feet in extreme length; width of beam at the water line 9 feet, at the gunwale 11 feet. The area of her displacement at the greatest breadth of beam is a fraction over 20 square feet. She is propelled easily 8 miles an hour; and, with better engines, could easily be propelled 11 miles an hour. She has two engines; each of which, f properly constructed, would be equal to what is called five horse power; they are, however, so indifferently arranged, as to work at a loss of one-third of what should be their power; and have therefore together but six and two-thirds horse power. Calculating on this data, it will be seen that the propulsive power used in the "Germ" is equal to one horse for every 3 square feet; whereas the propulsive power used for our fastest steamers it equal to three horses for every square foot of displacement. The contrast, therefore, is very great. The well established fact, that the power necessary to propel a vessel is estimated by the area of her displacement at the greatest breadth of beam, and the advantage of speed known to resu't from great length of keel, and the application of paddle wheels of greater diameter, leaves us the interesting and valuable truth clearly self-evident, that the submerged horizontal paddle-wheels (like that in the Germ) is a much more efficient propeller than the paddle-wheel now in use. The great advantages consequent on the use of this new kind of propeller, for ocean navigation, is too evident, therefore, to require much stress. By its lateral action, the movement of the vessel is always under control; she is in no danger from broaching to, or bringing by the lee; as by the peculiar power of her paddles in the lateral action, she can easily be brought out of the trough of a sea, and be made to "head it," without the aid of a rudder, or without headway on her. And, more than this, the propellers being at all times submerged, the vessel moves through head sea with but little diminution of her speed. The Germ has the appearance of a handsome canal boat. No wheels are seen, very little smoke, and a very small escape pipe, are all that tell she is a steam boat. She moves with great velocity, and perfectly noiseless, with scarcely any rippling of the water. She turns easily, almost upon her own centre. Half the boat is formed into a neat cabin; the forward half is occupied by the engine and boiler, which is on the high-pressure plan. The boiler is made on the locomotive plan (and it appears to have been a locomotive boiler, at some time), with cylinders attached to it, larboard and starboard. In the cylinder works a small piston rod 18 inches long, from this extends the connecting-rod, about four feet long; and this last rod is attached directly to the paddle-wheel crank. The crank on each side is connected with a vertical shaft that works the paddle-wheels exactly like a man working two coffee mills with his two hands. The great feature in this boat, that is the propeller, consists of a hollow iron hub, four feet diameter, with paddles made of boiler iron radiating from it. The superficies of each paddle is one-half of a square foot, therefore the whole diameter of the paddle wheel is exactly five feet. There are two of these paddle wheels, the space between them being occupied by the keelson. These paddle wheels cannot be injured by the vessel's grounding, for the bottom of the vessel (which can be made of any desired thickness) is always below the paddle wheels, ground where she may. The Germ has an advantage over all vessels otherwise propelled, in not requiring a rudder to direct her course, by reason of the lateral action of her wheels. She has a rudder, but it is more for convenience than actual use. It will be easily seen, too, that the hull of a steamer thus constructed must be subject to less wear and tear than all others, for the power of the engine is imparted in a line with the keel, and at a point most available for propelling. Again, the paddle wheels are not subject to the irregular action of the sea, and therefore they have always a uniform resisting power, and her engines work smoothly.

On the other hand, if a vessel thus constructed chose to use sails, her paddle wheels offer less resistance than those of any other steam boat; take off the connecting rods and her wheels do not present a resistance of half a knot out of every ten knots. Her paddle whee's are of iron, made very simple but strong. They are not liable to get out of order; and although made of boiler iron, are so buoyant as to float, owing to the displacement caused by the hollow hub in the centre. Such is the Germ, and such is the new and important principle in the propulsion of vessels which has been conclusively established by the performance of this little vessel.

The fitness of these propellers to canal navigation has been fully settled by the actual working of the Germ on several canals, and the privileges already given to Lieutenant Hunter, by the directors, for the use of his valuable improvement.

MR. BROOKS IN REPLY TO MR. BARRET ON BARS OF RIVERS.

Sir—In reference to the letter by Mr. Barrett in your July number, I shall merely notice the statements that gentleman makes in defence of his own theory, and this for brevity's sake only, else I should seek to refute the false positions and strained unfair inferences with which the whole is filled. I purpose, therefore, to confine myself to the disproval of his theory and not allow him "to go off upon another tack," as he seems inclined to do by a statement which contains no notice of his much talked of theory, which is as follows: "The cause of the existence of bars is the conflicting action of effluent currents or tides, passing into the ocean *at right angles* to the shore;" and he adds as his remedy for the removal of the bar, "But if the current or tide be by artificial means conducted into the ocean so as to join the sea tide *at an acute angle*, no conflicting action can arise, and then no bar will accumulate." On the above I have stated, in page 5 of my Treatise on Rivers, "That the *casual direction* of the lower reach, or position of the mouth of a river, cannot be truly assigned as the cause of the existence of bars, is easily proved by observations on rivers subject to great variations at their entrances; the bar being always found to exist quite independent of the direction of the discharge into the sea. This fact at once refutes the third and fourth theories which have been noticed above." In the preceding, the words "independent of the direction of the discharge" mean evidently independent of "the great variations" or "casual direction of the lower reach before alluded to; but Mr. Barrett in reply states "In this extract there seems to be two distinct facts, *i. e.* the casual direction of the lower reach, and the independence of a bar, in the direction of the discharged waters: that is, he means that the deposit or bar does not occur in the direction of the egress waters. With respect to Mr. B.'s assertion of the independence of the bar of the egress waters, I have much to say, if he be correct, he has indeed "at once refuted my theory."

I submit to the judgment of your readers whether the language quoted from my work, which, be it remembered, is in direct reference to the theory by Mr. Barrett, which bases the existence of bars upon the casual direction of the discharge, can by any fairness be construed into the meaning attempted to be put upon it by Mr. Barrett to cover his own want of arguments, or facts in support of his theory? I have not made any "assertion of the independence of the bar of the egress water," the plain meaning of my language to any common understanding is, that whether the discharge into the sea be effected at either a right, or at an acute angle with the shore, the former case, or a rectangular direction of the discharge, will not cause the formation of a bar: and the latter, or where the direction of the discharge makes an acute angle with the shore, will not prevent the formation of a bar, or have any effect upon its removal; and therefore I am correct in stating that the existence or non-existence of a bar *is independent of the casual direction* of the discharge. It is disingenuous in Mr. Barrett to try to make me appear to have said "that the deposit or bar does not occur in the direction of the egress waters," inasmuch as my reply to his theory plainly states that whatever be the casual variation of the direction of the discharge, the bar will still be found attached to it; whereas, according to Mr. Barrett's theory, the bar ought to disappear by a certain change of direction of the discharge. The whole of Mr. Barrett's long lectures on bars may be included in the simple statement that he believes that a bar is caused by the discharge of a river taking place in a direction at right angles to the line of shore, and that there will be no bar when the discharge takes place in a direction which forms an acute angle with the shore. These are his assertions, which, however, he does not support by a single practical example.

Mr. Barrett's theory on the cause of bars rests solely upon the direction of the discharge, and I submit to your readers' judgment whether I have, or have not, sufficiently refuted it by showing that bars are as frequently found at the mouths of rivers which discharge their waters at acute angles with the shore, as at the mouths of those which are discharged in a rectangular direction. In illustration of this statement, even the youngest of your readers will bring forward many examples. It is, however, Mr. Barrett's duty to support his statement by bringing forward a mass of examples of rivers, which are obstructed by bars because of the rectangular direction of their discharge, and of others which are from bars because of their discharge being effected at an acute angle with the shore. In doing this, of course Mr. Barrett will not omit to notice those rivers which are free from bars, notwithstanding their rectangular direction of discharge, nor will he omit those numerous rivers which have bars, notwithstanding their discharge is at an acute angle; if he do omit to notice them, I promise to amply supply his deficiency. In Mr. Barrett's last letter I looked for practical examples to illustrate his theory on the bars of rivers, the matter in dispute! and in lieu I find advanced as proofs of his accuracy, "the Bay of Wangarver, New Zealand;" and "the Bays of Plenby and Port Nicholson" as "free from bars"; Mr. Barrett might just as appropriately have referred to the Bay of Fundy or the Baltic Sea. This same letter contains specimens of the powers of observation and of "the devotion" of which Mr. Barrett boasts so much; and I might also add, that it contains specimens of his *taste* where, writing of the "Neva, Gulf of Finland, Narva, Dantzic, Danube, Nile, he adds, "*no salt water being in the vicinity of the disemboguing site of the above rivers*," and he also adds, "that there is an absence of sloping to these rivers." By Narva and Dantzic, Mr. Barrett doubtless meant to have alluded to the Rivers Narova and Vistula; but what does Mr. Barrett mean in another part of his letter where he writes "Norway, Scotland, Ireland, Scilly Islands, Minorca, and Malta Harbours are of the first kind?"

I am your obedient servant,
W. A. Brooks.

Stockton-on-Tees,
12th July.

RULES FOR CALCULATING THE HORSE POWER OF STEAM ENGINES.

Sir—The rules for calculating the horse power of steam engines in the Clyde have long been known to be different from those employed by the English manufacturers, and it appears to me that the charge against Mr. Scott Russell's assertions, made in page 312, in the September number of the C. E. and A. Journal, is based in some degree on the unsound foundation of this difference.

The English rule for a cylinder 48 inches in diameter would be founded on two assumptions, the first, that the speed of the piston would be 220 feet per minute, and the second, that the surplus pressure on the piston would be 7·, or 7·1, or 7·3 lb. per square inch. The practice, I believe, varies within these limits, hence

$$\frac{48^2 \times \cdot 7854 \times 220 \times 7 \cdot 1}{33,000} = 90 \text{ horse power.}$$

The Scotch rule takes the actual speed of the piston per minute, and the mean pressure per square inch, and then employs 44,000 lb. as the divisor on the gross, instead of 33,000 lb. on the nett or surplus power of the steam.

The effect of this rule is an allowance of 25 per cent. of the gross power for engine resistances and friction.

Under the given conditions $\frac{11 \times 33,000}{44,000} = 10\frac{1}{2}$ lb. is the surplus steam pressure taken, instead of 7·1 lb. the assumed pressure by the English rule.

If a question had arisen, which rule is preferable, that adopted in the Clyde is, I conceive, superior in every point, especially in the closer approximation given of the real engine resistances.

We have however to deal with Mr. Scott Russell's assertions; that the Flambeau, built on the wave principle, "with the smallest proportion of power to tonnage, and smallest supply of steam, is nevertheless the swiftest vessel on the Clyde."

The assertion of greatest speed obviously referred to last season, and is granted to be correct. The least steam assertion is in fact granted by the account of the change of the boiler, but the effect of a new and probably heavier boiler is curious, and an accurate statement of the facts would be valuable. On the estimate of horse power here given, as the Flambeau is 280 tons, we have $\frac{280}{90} = 3$ tons per horse power.

Is the assertion of less power in proportion to tonnage correct or not, on this estimate? (Clyde boats are notorious for power in proportion to tonnage, an opinion due I conceive to the rule of horse power used on that river)—other boats of course being estimated in the same mode—however I should prefer a comparative estimate of both by the Clyde rules; and it would be extremely interesting, if accompanied by the dimensions of the steam boats, and of their engines, with other particulars; for though the public may but slightly regard questions relating to Mr. Scott Russell's figures, yet the success or failure of the Wave principle applied to ship building will and ought to command attention, provided satisfactory data can be supplied.

However desirable an uniform method of calculating horse power may be, yet its general adoption will be prevented, by the wish of each party to impose their own rule on others; but the fact of an existing difference cannot be too strongly brought before the public, as a decided demonstration of opinion on their part could alone compel manufacturers to adopt a decent degree of uniformity in the method of estimating engine power. Argument will be of no avail in cases of this character, where interest, or supposed interest interferes, still a steady exposure of all attempts to exalt or depreciate engines, or steam boats, when founded on the unsound basis of a difference of horse power rules will tend towards the desirable object, of producing uniformity.

I remain, Sir, your obedient servant,

Y —.

September 26. 1841.

COMPETITIONS.

Sir—An error, at least an awkward omission in the printing of my former letter will serve as excuse—if excuse be wanted—for my troubling you again, although I should hardly consider it worth while to do for the purpose of correcting it, had I not also some further remarks to offer on the subject itself. I applied the term "swindling" to the manner in which architectural competitions are frequently conducted, adding that "to give it *any softer name* would be almost to countenance it." But the words here put in italics having been omitted either by myself or the printer, the sense could be only guessed at.

I am no friend to "soft names"—to that squeamishness of language, which is unhappily so prevalent at the present day, and which designates an affair of murder "an affair of honour," and an affair of villainy "an affair of gallantry." That the *indecorous* but expressive word swindling was not at all too harsh a one is fully proved by Mr. Watson's letter, which appeared on the very same page of your Journal as my own. Nevertheless no steps of any kind seem to be adopted by the profession, in order to put a stop to the shameful abuses now practised, and reform the present juggling system of competition. As to the Institute of British Architects, they are like the Gods of Epicurus, and wrapped up in their own divinity trouble themselves not with the concerns of the lower world which they leave to shift for itself as best it may. So far from coming forward with any measures of their own for correcting the present shameful or shameless system of competition, they do not even care in any way to support or aid—I might say, even to countenance aught that has been from time to time suggested as an abatement, if not a perfect cure of the evils now so frequently and so loudly complained of by the profession generally, as individuals; and which affect not only the interests of these last, but those of the art itself, converting the opportunities for advancing it into nothing better than so many jobs and jobberies. More than once before now it has been asked "what has the Institute done for the advancement of architecture?" and we are waiting for the answer. In the mean while—and a prodigiously long while it is likely to be ere that plain question can be plainly and satisfactorily replied to, I would propose in addition to the suggestions which have already been thrown out in other quarters, that in future in every competition for a building of any magnitude—say where the contemplated cost exceeds 10,000*l.*—a lithograph copy of the selected design should be sent to each of the competitors, either when his own drawings are returned or afterwards, whereas now, nothing, if it can possibly be helped, is suffered to transpire relative to the one approved of and adopted,—or possibly, adopted without any grounds of approval or preference being assigned, supposing it were possible to do so.

As an instance I will mention the Camberwell Church Competition, for which I saw one or two sets of drawings before they were sent in, and for one of which in particular I anticipated success,—that is, supposing matters were to be managed fairly, and that success was to depend upon the merit of the design. The result, however, has contradicted me, yet it is exceedingly doubtful to myself whether the one chosen be at all better, or even so good by many degrees. Be it what it may, no one as far as I can learn seems to know what it really is,—not even those who measured their strength against the successful candidates (Messrs. Scott and Moffat) and who consequently are rather interested in ascertaining the quality of their design. Now I conceive such a regulation as that above suggested would be a very wholesome one. It would effectually remove the appearance of skulking mystery that is now allowed to hang over competitions. It would at any rate be some pledge on the part of those who selected the design, that they had confidence in its merits. Yet for this very reason, perhaps, it is most unlikely that such measure should be adopted by the "Great Unknown" behind the curtain. It must therefore be forced upon them,—and it can be done by no others than the profession themselves, who might if they pleased make a law among themselves to such effect. At any rate so long as they take no steps whatever to correct the abuses now practised with impunity in competitions, they have no very great right to complain of them. Let them join in a body and defend their own interests. Or are we to imagine that the majority of them are rogues, and consider it their interest to uphold the present corrupt and absurd system of Competition?

Vindex.

ADVICE TO PUPILS.

[The accompanying letter has been forwarded to us by a correspondent; it was written by an engineer of considerable experience to his son, a youth of 17 years of age; we consider that the sound practical advice it contains should be read by all young men entering the engineering profession, and we feel much pleasure in publishing the letter verbatim.]

Dear Son—Yours of the 19th I duly received, you inform me that Mr. B. has appointed you to superintend the bridges, on a certain railway. Now my advice is, adhere strictly to the directions of the specifications and drawings. If you feel yourself at a loss to understand thoroughly, (but first of all spare no pains in studying them,) by all means see or write to Mr. B., "not any one else by any means." I am quite sure he will feel it a great pleasure to explain any part or portion to you: but always remember Mr. B. first. Never consult any one, or give your opinion on the subject: what you speak, or explain, let it be the words, or parts of the drawings, specifications, or your instructions: and be sure always to act up to your instructions, with firmness. Never conceal any thing from Mr. B. in any shape respecting the works, for there is nothing so bad. I am perfectly aware that when any portion of the works does not come together, or remain firm as it was at first intended, the fault generally occurs in the commencement, or during its progress, by the superintendent's oversight, or fear of asking his employer; by this neglect the work is condemned; your employer is brought into contempt; and the superintendent is discharged: and all this happens, because the superintendent did not like to see trouble, or explain the faults to his employer; but will sooner give way to some foreman or workmen, and hide his or their mistakes. "Always remember and bear in mind this one thing, let your employer's duty be such to you, that you will *stand* or *fall* by, or with *him*." I am quite aware that you will find enemies for a while, but when they find that you will not deviate, (for depend on it, there is but the right way,) they then will give way and be reconciled, although perhaps against their will. Never be afraid of stating the plain *facts*, for by so doing your employer is on his guard; and then he has it in his power in time to proceed in that way which seems most prudent to him, and the safety of the work. The next thing I wish to call your attention to is, you will be sure to meet with persons on and off the works, (and perhaps some of them have great interest in the work), that will ask you many questions, and also your opinion about the works; and it sometimes occurs they will be questions which they are ashamed to ask your employer. Now in respect to these points be very much on your guard. In the first place you have no opinion to give, your place is to see the work performed agreeably to your instructions; and, in the next place, always have something in hand; for generally speaking, those characters do not address themselves to industrious persons; and if pressed hard on the subject, you can say I will ask Mr. B. if they think proper; but above all, every person must be respected agreeably to the station he holds. Every one, both *they* and *you* must know your stations. Be free and pleasant to all, but all must know their places, and every one must be kept there.

To conclude this advice, I am quite sure if servants would act straight forward with their employers, and be ready to *stand* or *fall* by them, (be sure to understand me clearly, I abhor tale-bearers,) their employers would not experience so many anxious hours; perhaps I should not be wrong if I were to say *days* or *weeks*, respecting the progress, and the ultimate safety of the works.

Now in respect to the works themselves, if it be wood-work. If there are any longitudinal beams or bearers, and they require bolting together to obtain sufficient strength, always prefer those pieces that have a camber or circle. Then by placing the inner circle of one on the outer circle of the other, you will find the beams will bear a greater burden than two straight ones. Again, never permit any sap to remain in that portion of the timber which is jointed together, for in a short time that will decay, bolts will be of no service, and the work will fail. If timber cannot be obtained without sap, let that portion be placed where it can be seen and repaired, and then it will not injure the work. Again, wherever timbers joint, bear, or overlap each other, be sure those joints, &c. are firm, square, and well put together.

Again, in respect to bolts, see that the heads are well welded on, also the nuts well cut and fitted, and the nut and head in proportion to the size of the bolt. Then again, in bolting timbers together, see that the holes are straight, for a bolt cannot be so strong if it be not straight. Again, never permit the bolts to be driven with an iron hammer, (a wooden one is best,) for it often happens that when the head comes in contact with its situation, off it goes, or almost off. (Then where is the strength? *why, it is lost.*) Again, in preparing the wood work, always have by the men a few temporary bolts, do not use your permanent bolts for every thing. Again, never permit your bolts to be longer than necessary (and also not too short), for when the work is finished, and one bolt is longer than another, it appears the superintendent had no eyes, and also it is a waste of money. Again, I find in bolting up the work, washers under the nuts are much required, for it is almost impossible to get work *firm* and *solid* without them. Also be very careful in the selection of your materials (if timber); suppose for instance, you require 20 pieces, and they be one inch longer than required, (there is 20 inches waste), the carpenter will say it is only one inch, but I do assure you, if your employer had a sack full of money, a careless servant will soon make him find the bottom of it. I am aware many will at times make many shifts in carrying on works, but if carried too far, it is *waste*: men cannot do their duty without materials, but if used too freely, then there they make *waste*. This case I consider will answer in every department. Now in respect to men, endeavour to obtain that price for their labour which is correct; also in keeping their time, or measuring their work, be *just*—never *give* nor *take*. Let them be paid for what they work and no more; for if once you go beyond that mark the man is never satisfied, either with his *work*, *money* or *master*. I also beg to state, that in carrying on and at the finish of the works, always keep them in a clear and comfortable state; then materials do not get buried up and wasted, the men are enabled to go forward with their work to much greater advantage, and also your employers can examine and inspect the work with that ease and pleasantness which should always be considered by a superintendent towards his employer. I know it will remove many anxious thoughts and unburden the minds of those above you, in passing your portion of work, after viewing the careless scenes and ways of others.

I remain, your affectionate Father,

* * * *.

VENTILATION OF THE NEW HOUSES OF PARLIAMENT.

REPORT BY THE LORDS' SELECT COMMITTEE.

That the committee have met and considered the matter to them referred, and have examined witnesses thereon, and have come to the following resolution, viz.:—

"Resolved, that it appears from the evidence of Mr. Barry, that the only expense necessarily to be incurred in the course of the next six months, with the view of making preparation for the adoption of the plans prepared by Dr. Reid, for ventilation of the new Houses of Parliament, by means of a central tower, consists in strengthening the foundation of the central saloon; that under these circumstances, and adverting to the fact, that according to the evidence of Dr. Reid, he is still engaged upon a course of experiments upon the subject of the ventilation of the Houses of Parliament, it appears to the committee that it is not necessary to come to a final decision upon the matter referred to them before the next session of Parliament."

That the committee recommend in the meantime that authority be given to Mr. Barry to increase the strength of the foundation of the central saloon, as adverted to by Mr. Barry, in case it should be found necessary, before the next session of Parliament, to proceed with the foundations of that part of the building.

October 1, 1841.

Their Lordships examined only two witnesses—Dr. Reid, and Mr. Barry, the architect. The following are extracts from the evidence:—

The Lord President in the chair (Sept. 27).

David Boswell Reid, Esq., M.D., examined.

Do you think it desirable to carry the air from the new houses of Parliament through one chimney in the manner which has been proposed?—I do.

Will you explain the course which the air would take in passing through the buildings, and the way in which you propose to manage it?—This is a general illustrative section (producing a section), intended to represent the principle, not the details. We find that the air as it is discharged generally from various altitudes in London passes horizontally much more frequently than in any other direction; hence, if there was a considerable discharge of foul air from any chimney or shaft, either from the houses or the neighbourhood, it might enter at one part of the building but not at another; it is accordingly recommended that there should be two openings provided for the ingress of fresh air, so that if the external air were blowing in one direction, and the foul air being discharged in the same line, one of these might be shut, and the other being opened we should have a purer atmosphere introduced, while at the same time the natural force of the wind filling with a plenum movement all these chambers below, and there tending to pass into all the several apartments from this reservoir in the basement, and having been led subsequently into the individual apartments, its entrance into each of those being regulated by valves, its own ascending power, arising from the heat communicated to it, would not be lost, but added, as it were, to the original impetus communicated by the wind, and tend to convey it from each individual apartment till it all centred in this large shaft; so that were this shaft adopted, or any central discharge equivalent to it, there would be at all times and seasons a power of movement upon the atmosphere throughout the whole of the buildings which would perpetually renovate the air, whether machinery were employed or not. But it is considered desirable (more especially since I have seen at the bar of the House of Lords fully nine members of the House of Commons upon every square yard—that is, a man to every foot), in order to check and prevent entirely the draughts which under those circumstances are apt to be perceived if a sufficiency of air be introduced, to assist from time to time a mechanical power whenever the apartments are crowded, by placing machinery under the central hall; so that even on those days when the air is dull and sluggish, from a similarity of temperature within and without, this moving power may be brought into operation in supplying the proper quantity of air without incurring the risk of partial draughts at the doors. Further, it has been recommended strongly, that while fireplaces may be introduced in the individual apartments, still it would be important to warm the air generally in the centre, which may be considered the heart of the building; so that, instead of local currents flowing unequally, there would be a general warmth communicated to the atmosphere of the whole building, so as to sustain not only the apartments but also the passages at a comparatively uniform temperature. It has further been suggested, connected with the general outline represented here, that smoke might be entirely avoided were particular kinds of fuel adopted which are quite competent to produce a cheerful and agreeable-looking fire, as I am prepared to demonstrate by models, and also by fireplaces which have been constructed for the purpose, the flues being led from each individual apartment and being carried into fireproof channels communicating with the central shaft. Then the risk of fire would be very much avoided, and all sweeping would be rendered unnecessary, for which there is a very considerable expenditure annually even in the present buildings; and at the same time, while comparative security from fire and general ventilation would be attained, there would be a complete and entire prevention of all return of smoke, or even where no visible smoke was produced, all return of foul air from the chimnies would be utterly and entirely averted, from the certainty of discharge insured by the power of draught in the central shaft.

Suppose this to be the east and that to be the west, if the wind is in the east you bring the air in here by this valve, and you shut the other valve?—Yes.

Then the air coming in here, you bring it to that point, and it expels the foul air up this chimney?—It does. I would beg to add, that since I had any thing to do with these houses I have sometimes found that the demand for air is exceedingly great. On the late occasion, when Parliament first met, which is the first time that there have been crowded houses in the autumn, so far as I have had an opportunity of observing, we found that 50,000 cubic feet per minute was far too small: in both houses they called for a larger supply of air; and I was obliged to put on additional power by the action of heat, which increased the supply to about 70,000 cubic feet per minute. Now, the observation I wish to connect with that is simply this, that if the pure air be driven down into those vaults below which have been left expressly for this purpose, then, during warm and oppressive weather, we shall not only be able to obtain air of comparative purity, but we shall also have the power of cooling this atmosphere in those extensive vaults, which will warm the air as much in winter as they will cool it in summer.

Would it be possible to apply this method of letting in the pure air and driving out the foul air only to the Houses of Lords and Commons, without extending it to the other apartments, and would that decrease the expense very considerably?—It would certainly decrease the expense considerably, but I should question whether it would increase the comfort, or whether it would diminish the annual expenditure. After the experiments which I made with 100 people in an apartment constructed expressly for this purpose, I found that the great difficulty in all cases of ventilation was, that when a great amount of air was required, when a number of individuals sat within a certain space, there were sensible currents. This led me to the idea of universal diffusion in introducing the air, which forms the principal peculiarity of my plans; but in adapting that universal diffusion to the new houses it occurred to me that if certain arrangements are permitted connected with the mode of placing the seating, the same extent of diffusion might be obtained without the risk of any portion of the air coming through a part of the floor on which a foot had trod. I would also beg to be permitted to say another word upon this point, namely, that even with universal diffusion it is difficult to reduce sensible currents. It is found that in this city there is a difference of temperature extending to a range of 35 degrees as far as different individuals like or dislike the atmosphere introduced. An average, therefore, only can be attained under such circumstances: and in endeavouring to attain this, and knowing the desires and requests which are continually urged upon those who are in attendance for the purpose of regulating the state of the atmosphere, I think I have at last ascertained that by introducing air in large quantity, and at a more elevated temperature than is generally given, there is less dissatisfaction connected with the amount of supply than in any other way. * * *

Are you aware that frequently peers have been obliged to leave their seats on account of currents of air that came in at the back of the neck?—I have been informed that they have; and I attribute this to the conflicting opinions entertained by different peers as to the amount of supply required, for the force of these currents can be checked in an instant, to any amount, by the present arrangements, were instructions given to that effect. It frequently happens that the most opposite demands are made at the same moment. I may also be permitted to state, that when the alterations in the House of Lords were introduced I was limited to a given sum before any estimate was made, the committee considering it not desirable to expend a larger sum when they had the prospect of occupying the new houses in a few years. At the time that sum was allowed I represented at the Office of Woods that it would be desirable to make some addition to it at all events, which was agreed to as I represented, as I was afraid I should do more harm than good if some increase was not allowed; but it was impossible with the sum that was granted to put it exactly upon the same footing as the House of Commons.

Supposing that the committees of the houses of Parliament were to decide against having this great tower or spire, in what way would you then propose to conduct the ventilation?—I should propose under those circumstances to retain everything else as it is represented, but to have the moving power here (pointing to the machinery under the central hall) increased to such an extent as to possess an equivalent power to the total discharge of the shaft. In the plan contemplated the moving power is proposed to be the shaft, conjoined with machinery to be used on particular occasions; then, if the shaft be dispensed with, it would be necessary to increase the moving power.

Mr. Charles Barry examined.

You are aware of the plan which has been proposed by Dr. Reid for the purpose of ventilating the new Houses of Parliament, and the buildings generally?—I am quite aware of it.

And you have prepared a plan with reference to it?—I have.

Dr. Reid having stated the advantage of a central egress for the air, you have prepared a drawing of an addition to the building in the centre for that purpose?—I have.

How high is it to be above the roof of the present building?—The height above the central hall of the intended building will be 150 feet to the aperture beneath the spire.

Then is all above that solid masonry?—No; it would be hollow, and might be pierced for the egress of air. There would be no difficulty in making the spire available for the egress of air, as well as the louver beneath it.

Would there be any necessity for this addition of the tower for any other purpose but for the ventilation of the houses?—There is not any positive necessity for it, except for the purpose of carrying into full effect the proposed system of ventilation.

But there is no other reason why you would wish to have this additional building?—I cannot say that there is no other reason, because I think that the addition of a tower to the intended building, in the situation and of the form proposed, would enhance considerably the importance and picturesque effect of the mass, and, therefore, upon that account I should be anxious to have it adopted.

Have you made an estimate, and are you therefore enabled to state what the additional expense would be of the erection proposed for the purpose of ventilation, independently of the fire-proofing and the apparatus?—Independently of the fire-proofing, the expense of the ventilating tower would be 20,000*l.*, of which about 8,000*l.* or 10,000*l.* may be considered for external decoration.

Under any principle of ventilation, supposing several egresses to be made in different parts of the building, it would be equally necessary to have flues for that purpose?—Certainly.

Therefore the whole sum of 86,000*l.* is not fairly attributable to the tower alone?—Certainly not; only 20,000*l.* of that amount is applicable to the tower.

Therefore the increased expense of the proposed tower, beyond the expense of ventilating by means of several egresses, would be only 20,000*l.*?—That would be the actual cost of the tower itself; but if Dr. Reid's system of warming and ventilating should be adopted, the difference in the cost occasioned by the central tower would be about 10,000*l.*, as in case of dispensing with it other works would be necessary, the cost of which would be above 10,000*l.*

That is including the provision of making the whole of the floors fire-proof?—Yes. The estimate of 86,000*l.* includes the cost of the works which are necessary to render the entire building fire-proof.

What part of the building was originally intended to be fire-proof?—The whole of the public rooms of the building were intended to be fire-proof, such as the two houses, the committee rooms, the libraries, &c., as well as the whole of the basement and ground floors, but not the official residences.

Was the roof intended to be fire-proof?—No; the roof is proposed to be framed of timber in the usual way.

Is this system of ventilation intended to apply to the official residences as well as the committee rooms and the houses themselves?—I understand so.

ON FRESCO PAINTING.

By C. Eastlake, R.A.

The present German School of Fresco Painters has been formed within the last 25 years. Its first essays, to which I have alluded, were in a great measure the result of a general spirit of imitation which willingly adopted all that was associated with the habits of the latter middle ages. It may be as well to review the origin and progress of this state of feeling in the present century. The historians of modern German art have indeed traced its rise to earlier influences, but all agree that the circumstances to which we are about to refer greatly promoted the introduction of a new taste in painting.

The efforts to create a new style of art, in Germany, in the beginning of the present century, were intimately connected with the struggle for political independence. The cathedrals and churches on the Rhine had been more or less desecrated and plundered, and the pictures by the early German masters dispersed and sold. The gradual recovery of these ended in the formation of collections of such works; this led to a higher appreciation of their merits, indulgently seen as they were by patriots anxious to restore and maintain all that especially characterized the German nation. With men thus inspired, the connexion of such feelings with the religion of their forefathers was obvious. German artists and writers again, who visited Italy, dwelt on the relation that had subsisted between Germany and Italy before and since the revival of letters, not only in politics but in the arts. The Tower at Pisa, the church of St. Francis at Assisi, and other buildings, had been erected by Germans, and it was remembered with pride, that the new life of Italy had been kindled chiefly by the genius of the northern nations. The spirit of the middle ages was thus in a manner revived, and the Germans looked with complacency on that period when the Teutonic nations, unassisted (as they assume) by classic examples, produced a characteristic style of architecture, and developed their native feeling in the arts of design and in poetry. In those ages, architecture, the most necessary of the arts, and therefore the first in date, had time to develop itself fully, especially in the north; but before painting could unfold itself in an equal degree, the thirst for the revival of classic learning and the imitation of classic models prevented the free formation of a Christian and national style. The early specimens of art which were most free from this classic influence were thus regarded with higher veneration, and the Germans of the 19th century boldly proposed to throw aside all classic prejudices, however imposing, and follow up the imperfect beginnings of the latter middle ages in a kindred spirit. This general aim connected the early efforts of Italian art still more with those of Germany, and the German painters who visited Italy, recognized the feeling that inspired them in all works which were supposed to be independent of a classic influence.

The degrees in which this spirit has prevailed have naturally varied. With many, the imitation of the earlier masters soon gave place to a juster estimate of the general character of the art. The antique has even, to a certain extent, reassumed its empire; but on the other hand, some of the best German artists have unflinchingly maintained the general principles above described, even to the present day; indeed not a few had at first returned to the old faith, and had imbibed with it a still deeper attachment to the spirit of the early painters.

It is necessary to bear these facts in mind, in order to understand the particular aim which many (perhaps the best) of the German artists have in view. The veneration for the general spirit which prevailed at the revival of art was accompanied by an imitation of the characteristics and even the technical methods of the early painters; the habits and the productions of mediæval Italy were, as we have seen, easily associated with German feelings, and to this general imitation the adoption of fresco painting is partly to be attributed, though that art was never before practised by the Germans. Fresco painting was, in short, only one of many circumstances which had acquired interest and importance in the eyes of German painters from the above causes. The predilection for the early examples of Christian art did not exclude the study of better specimens created in the same spirit, but the indications of a classic influence were sufficient to condemn the finest works, and hence the later productions of Raphael were not considered fit models for study.

Let us now consider how far we, as Englishmen, can share these feelings and aims. If the national ardour of the Germans is to be our example, we should dwell on the fact that the arts in England under Henry the Third, in the 13th century, were as much advanced as in Italy itself; that our architecture was even more characteristic and freer from classic influence: that sculpture, to judge from Wells Cathedral, bid fair to rival the contemporary efforts in Tuscany, and that our painting of the same period might fairly compete with that of Siena and Florence. Specimens of early English painting were lately to be seen—some very important relics still exist on the walls of the edifices at Westminster. The undertaking now proposed might be the more interesting, since, after a lapse of six centuries, it would renew the same style of decoration on the same spot. The painters employed in the time of Henry the Third were English; their names are preserved. Thus in doing justice to the patriotism of the Germans, the first conviction that would press upon us would be that our own country and our own English feelings are sufficient to produce and foster a characteristic style of art; that although we might share much of the spirit of the Germanic nations, this spirit would be modified, perhaps refined, by our peculiar habits; above all, we should entirely agree with the Germans in concluding that we are as little in want of foreign artists to represent our history and express our feelings, as of foreign soldiers to defend our liberties. Even the question of ability (although that ability is not to be doubted for a moment) is unimportant; for, to trust to our own resources should be, under any circumstances, the only course. Ability, if wanting, would of necessity follow. Many may remember the time, before the British army had opportunities to distinguish itself, when continental scoffers affected to despise our pretensions to military skill. In the arts as in arms, discipline, practice, and opportunity are necessary to the acquisition of skill and confidence; in both a beginning is to be made, and want of experience may occasion failure at first; but nothing could lead to failure in both more effectually than the absence of sympathy and moral support on the part of the country. Other nations, it may be observed, think their artists, whatever may be their real claims, the first in the world, and this partiality is unquestionably one of the chief causes of whatever excellence they attain. It is sometimes mortifying to find that foreigners are more just to English artists than the English themselves are. Many of our artists who have settled or occasionally painted in Italy, Germany, Russia, and even in France, have been highly esteemed and employed. The Germans especially are great admirers of English art, and a picture by Wilkie has long graced the Gallery of Munich.

If, however, we are to look to the Germans, the first quality which invites our imitation is their patriotism. It may or may not follow, that the mode of encouraging native art which is now attracting attention at Munich is fit to be adopted here. We have seen that a considerable degree of imitation of early precedents is mixed up with the German efforts; this of itself is hardly to be defended, but the imitation of that imitation, without sharing its inspiring feeling, would be utterly useless as well as humiliating. The question of fresco painting is in like manner to be considered on its own merits, without reference to what the Germans have done, except as an experiment with regard to climate. The fresco painters of Munich generally work on the walls from May to September only; the greater part of the year is thus devoted to the preparation of the cartoons. Five months in the year would probably be the longest period in which it would be possible to paint in fresco in London. But assuming the new Houses of Parliament to be thus decorated, and that the works could not be completed before the rooms would be wanted, the paintings could be continued annually in the autumn without inconvenience. The climate of England and Germany might in some respects be more favourable to the practice of fresco than Italy. The surface of the wall is in the fittest state to receive the colours when it will barely receive the impression of the finger (when more moist, the ultimate effect of the painting is faint); this supposes the necessity of a very rapid execution in a warm climate, where the plaster would dry more quickly.

Fresco painting, as a durable and immoveable decoration, can only be fitly applied to buildings of a permanent character. Not only capricious alterations, but even repairs cannot be attempted without destroying the paintings. There can be no doubt that the general introduction of such decorations would lead to a more solid style of architecture; at the same time the impossibility of change would be considered by many as an objection. This objection would not, however, apply to public buildings. In case of fire, frescos would no doubt be more or less injured or ruined, but they might not be so utterly effaced and destroyed as oil pictures in the same circumstances would be. On the whole, the smoke of London might be found less prejudicial than that of the candles in Italian churches. The Last Judgment of Michael Angelo could hardly have suffered more in three centuries from coal fires than from the church ceremonies, which have hastened its ruin. The superior brilliancy (looking at this quality alone) of frescos which adorn the galleries of private houses, where they have not been exposed to such injurious influences, is very remarkable; as, for example, in the Farnese ceiling. The occasional unsound state of some walls, even in buildings of the most solid construction in Rome, is to be attributed to slight but frequent shocks of earthquake. A ceiling painted by one of the scholars of the Carracci in the Costaguti Palace in Rome, fell from this cause. Such disadvantages might fairly be set against any that are to be apprehended in London. With regard to the modes of cleaning fresco, the description of the method adopted by Carlo Maratti in cleaning Raphael's frescos when blackened with smoke happens to be preserved; but no doubt modern chemistry could suggest the best possible means.

The general qualities in art which fresco demands, as well as those which are less compatible with it, have been already considered. It may be assumed that it is fittest for public and extensive works. Public works, whether connected with religion or patriotism, are the most calculated to advance the character of the art, for as they are addressed to the mass of mankind, or at least to the mass of a nation, they must be dignified. Existing works of the kind may be more or less interesting, but there are scarcely any that are trivial or burlesque. This moral dignity is soon associated in the mind of the artist with a corresponding grandeur of appearance, and his attention is thus involuntarily directed to the higher principles of his art. In my evidence, I expressed the opinion that although a given series of frescos must be under the control of one artist, it would be quite possible to combine this very necessary condition with the employment of a sufficient number of competent artists by subdividing the general theme. Thus, if we suppose the general subject to be Legislation, it might combine the symbolic and dramatic styles, and even subjects of animated action. It might be subdivided, for example, into the history and progress of legislation, founded on religion and morals, and producing its effects in peace and war; exemplified in the one by industry and commercial enterprise, in the other by instances of the courage which results from a due appreciation of national benefits, and the feelings of loyalty and patriotism. Any subject of great and universal human or national interest might be made equally comprehensive. It has been assumed that the practice of fresco would be beneficial to English artists technically; we proceed to consider how it would affect them in other respects.

The painters employed on an extensive series of frescos would have to devote a considerable portion of their lives to the object. Such an undertaking would require great perseverance on their part. It is needless to say that they ought not to encounter any impatience or want of confidence on the part of their employers: the trial should be a fair one. It would hardly be possible for the artists to undertake any oil pictures while so employed, and I confess I have some fears that, when debarred from the exercise of oil-painting, and confined to a severer and drier occupation, they might find their task irksome. One of the first artists at Munich, in writing to me not long since, said he sighed to return to oil-painting. If the German fresco painters can feel this regret at giving up their first occupation, for so many years, it may be supposed that the English artists would experience such a feeling in a greater degree. When the King of Bavaria honoured me with a visit in Rome, he told me he had made an arrangement with Schnorr, and had given him employment in fresco for ten years: that excellent artist has now been occupied at Munich in public works for a much longer period. No hopes could be held out to the principal painters that they would find time for oil-painting as well, for their designs and cartoons would take up all their spare time. After a few years, when assistants were well formed, more leisure might be gained, and it was under these circumstances that Raphael painted in oil when employed by Julius the Second in Rome; but for the first three years after he began the frescos in the Vatican, he confined himself entirely to those labours; and Michael Angelo, as is well known, painted the ceiling of the Cappella Sistina alone.

The more general practice was however to employ assistants, and this is one of the serious considerations connected with the present inquiry. Owing to the self-educating system of painters in this country, the younger artists are more independent than they are elsewhere, and they might have some reluctance to co-operate in works in which their best efforts would only contribute to the fame of the artist under whom they worked. In Italy, and in recent times in Germany, this subordination was, however, not felt to be irksome, and the best scholars were naturally soon intrusted with independent works. It is possible the talents thus created would be employed to decorate private houses, but the Government would incur a sort of obligation not to leave a school thus formed unemployed, especially as the artists, from want of practice, might be less able to cope with those who had been exclusively employed in oil-painting. The result, however, might be that the school would gain in design, at some sacrifice of the more refined technical processes in colouring, in which the English painters now excel their Continental rivals. It is true some Italian painters, for example, Andrea del Sarto, the Carracci and their scholars, were equally skilful in oil and in fresco. The earlier masters were, however generally stronger in the latter; and Sir Joshua Reynolds observes that Raphael was a better painter in fresco than in oil.—*Athenæum.*

PROCEEDINGS OF SCIENTIFIC SOCIETIES.

INSTITUTION OF CIVIL ENGINEERS.

May 11.—*(continued.)*

"*Experiments on the strength of Brick and Tile Arches.*" By Thomas Cubitt, Assoc. Inst. C. E.

In the course of his extensive building engagements, the author had occasion to construct some fire-proof floors: he therefore wished to ascertain how the greatest amount of strength could be attained, with a due regard to the space occupied, and the cost of the structure.

Two arches were built, each with a span of 15 feet 9 inches, and a rise of 2 feet.

The brick arch was 2 feet wide, and composed of half a brick in thickness, with cement.

The tile arch was 2 feet 4 inches wide, and built of 4 tiles, set in cement, forming a thickness of $4\frac{1}{4}$ inches.

The spandrels of the arches were filled up level to the crown with rubble work and cement. A load of dry bricks was placed along the centre of both arches, and gradually increased at stated periods, from 12 cwt. 3 qrs. up to 160 cwt. at the end of 75 days, when the abutments of the brick arch gave way; and the tile arch broke down while loading.

The deflection at three points is given in a tabular form; and although, from the circumstance of there having been no tie bars across the arches, the experiments cannot be considered satisfactory, they are valuable, as supplying data hitherto rarely recorded.

Drawings of the arches accompanied the paper.

"*Description of a Stone Bridge on the Middlesborough Railway.*"—By John Harris, M. Inst. C. E.

The bridge described in this communication is only remarkable for the flatness of the arch, the rise being 5 feet for a span of 30 feet.

A drawing, and the specification of the cost of the work, with a schedule of prices, accompanied it.

"*Description of a Bridge built of Blue Lias Limestone, across the Birmingham and Gloucester Railway at Dusbampstead.*" By Captain James Vetch, Assoc. Inst. C. E.

The peculiarities in the construction of this bridge are, that the arch was composed of very small stones of the blue lias limestone, from three to five inches thick, and squared to about nine inches long and broad; that it was erected without the usual timber centreing, and that the mode of removing the earth centreing precluded any danger from unequal sinking in the arch. The span of the bridge is 60 feet, with a rise of 10 feet. The material of the cutting where the bridge is situated, consisted of weak slate and clay, consequently the mode of construction was subjected to a severe test. The abutments being completed to the springing height, the ground was cut away roughly to the form of the arch; seven rows of pegs were then inserted with their upper ends correctly designing the proper curve; a line of planks 3 inches thick was laid transversely beside each row of pegs, and upon them were placed lines of battens on edge, gauged to the exact profile of the bridge; the earth was consolidated, and a flooring of battens laid over all to form a true bed for the soffits to rest upon. From the absence of parallelism in the lias stones, their varying thickness, and the difficult adhesion of the mortar, it was deemed necessary to introduce seven transverse bonds of free-stone, which imparted to the whole structure a tendency to settle in the lines of the radii of the arch, and also prevented any rent in the lias masonry from proceeding to a dangerous extent; these free-stone bonds were firmly fastened with iron cramps. The face had a batter of 1 in 9, from the springing to the string course, in order to counteract any tendency to bulge towards the faces, or in the line of the least resistance. The base was also extended and the crown narrowed, which gave a concave form to the string course. The whole arch being filled in with the full depth of stone work on each springing, and the bonds of free-stone all placed, the lines of each between the second and third bonds were keyed up, and then those between the third and the centre bond, which thus apparently formed the key stone.

The earth centre was removed by cutting a heading 4 feet 6 inches wide, directly beneath the key stone, and then gradually excavating on either side uniformly towards the abutments, stopping at certain intervals to allow any settlement to take place. By proceeding thus, as successive portions of the arch were left to their own bearings, regular compression ensued, and a small portion only of the work was exposed to the risk of fracture from inequality of pressure; the rising of the haunches which generally accompanies any undue depression of the crown, appeared by this method to be entirely avoided.

The author ascribes much merit to the careful manner of keying in the courses, as no cracks occurred, and the settlement of the arch did not exceed 2½ inches. He conceives this experiment to have answered completely, as there was a saving of time, the expense of erecting the usual wooden centre was avoided, and the bridge was ready when the railway cutting reached it. He considers that this system may be advantageously used in many situations upon railways, and that the span may be at least double that of the bridge now described.

The communication was accompanied by three drawings, showing the details and progress of the construction.

"*Description of the great Aqueduct at Lisbon, over the Valley of Alcantra.*" By Samuel Clegg, Jun.

This aqueduct was founded by king John the Fifth in 1713, and completed by the Marquis of Pombal, 1755. It resisted uninjured the shocks of the great earthquake in that year, although it was observed to oscillate considerably. The most conspicuous part of the work is that which crosses the Valley of Alcantra; it consists of 32 arches, with spans varying from 50 to 105 feet; the crown of the centre arch is 225 feet from the ground. The length of this portion is 3000 feet.

The sources from which the supply of water is derived, are situated in the high ground in the neighbourhoods of Cintra and of Bellas—they are eighteen in number; one of these tributaries is conveyed by a culvert from a distance of 15 miles. The main duct into which the tributary streams empty themselves, forms a tunnel of 6 feet wide, and 7 feet high, ventilated by vertical shafts, at distances of a quarter of a mile apart. The channels for the water are made with "drain tiles," 12 inches wide and 9 inches deep, open at the top. After passing over the great aqueduct, the main duct runs under ground for half a mile, is carried across the "Estrada do arco Cavallo" on seven arches of 40 feet span each on the south side of which it continues beneath the surface until it reaches the aqueduct of "Agua Livres" in Lisbon, and empties itself into the reservoir at its termination.

This reservoir is 60 feet long, by 54 feet wide and 27 feet deep. The quantity of water contained in it when the author took the measurements was 64,800 cubic feet. He was unable to obtain a section of the retaining walls, but supposed them to be about 23 feet in thickness.

The pipes through which the water is distributed to the neighbouring fountains are of earthenware and stone set in mortar. The velocity of its flow through the main duct is 75 feet per minute. The quantity discharged is about 73,000 gallons in 24 hours during the winter months.

Construction.—The particulars relating to the construction of the aqueduct, the author translated from the documents preserved at the office of Public Works in Lisbon. The foundations were laid in May 1713, and the piers, which in common with the rest of the work are of gray marble, carried up without footings. They are faced with ashlar work in courses from 1 foot 6 inches to 2 feet deep. The stones are dowelled together with bronze and iron; the centre portion of each pier is filled in with rubble masonry to within 30 feet of the top, above which it is left hollow. The voussoirs of the principal arch, to which the author more particularly refers, are carefully jointed, their thickness being on an average 8 feet at the springing, and 5 feet on the square at the crown. The figure of the arches is pointed Gothic, the rise being $\frac{1}{18}$ of the span. The spandrels are of closely jointed ashlar work, about 2 feet 6 inches in thickness. The backings are filled in with rubble quite solid; nor is there any provision made for the drainage.

The mortar used was made with lime from the gray marble of the neighbourhood, and sharp sea sand, in the proportions of one of the former to four of the latter.

Mode of raising the materials.—No mechanical contrivances were used for hoisting the blocks of marble, but they were slung upon poles from men's shoulders, and carried up a series of inclined planes to the height required. Some of these blocks weighed upwards of three tons. The scaffolding and inclined planes erected round the piers were of a very substantial description. The lower parts were trussed framings formed of double Riga or Dantzic timbers 15 inches square, fastened together with trenails of teak and chesnut. The inclined planes had a rise of about 1 foot in 6 feet, with a level space at each end of the pier to serve as a resting place, where a separate gang of men received the stone block, and relieved the others. The ends of the upright timbers of the scaffolding were not suffered to be surrounded by earth or moisture, but were placed upon blocks of stone bedded firmly and evenly upon the rock, and kept well tarred. The struts and braces retaining them were also secured from decay in the same manner. These precautions were necessary, not only from the great weight they had to support, but from the length of time they remained in use—not less it is supposed than thirty years.

The centreing for the arches was constructed by an Italian architect named "Antonio Davila." The arches were commenced from each side of the valley at the same time, and a temporary gangway erected over them as they proceeded, so that the inconvenience of raising the material from the bed of the valley was avoided. The centreings were framed in their places. The cradles which supported the bearing timbers of the lower truss, were morticed into sleepers resting upon projecting stones left for the purpose; those on the same pier were secured by cross timbers so as to balance each other. The lower framings were first fixed and secured by straining pieces, and the upper portion erected afterwards in the manner of a roof principal. All the scarfs were cut vertically, fastened by trenails of teak, and but little iron was used in any part of the structure. The striking wedges were placed under each voussoir, as in the French centreings. As the arch rose from the springing, the crown of the centreing was loaded with stones to prevent it rising, and altering the shape of the arch.

The cost of the entire aqueduct, which was about 21 miles long, with all the immediate and collateral works, and including the reservoir, was two millions and a half sterling.

The communication was accompanied by three elaborate drawings of the general construction and details of the aqueduct, with the manner of carrying the stones.

May 18.—The PRESIDENT in the Chair.

Thomas Lloyd was balloted for and elected a member.

"*On Sea Defences constructed with Peat Moss.*" By the Hon. Montgomery Stuart.

In the commencement of this communication, the author refers to the early period at which the art of reclaiming land from the sea was practised, and to the extensive districts both in Britain and on the continent, where sea defences of various kinds are constantly in course of construction. He then proceeds to detail the modes suggested by the experience of many years, and practised by him in constructing sea defences in the Bay of Wigtown, for the protection of the estate of his brother, the late Earl of Galloway. The whole of the district abounded with peat moss, possessing many properties which rendered it, independent of its cheapness, a peculiarly valuable material for constructing embankments to resist the action of the sea. Its tough fibrous nature, its elasticity, and at the same time, the rapidity with which the mass became solid, were useful qualities which he sought to take advantage of. He found also that it possessed advantages as a material for puddling; as from its absorbent nature it imbibed and retained all the moisture that approached it, and never cracked from dryness, as occurs so frequently with clay puddle. In case also of holes being made in the puddle either by vermin or external injury, they soon closed again from the elastic nature of the peat moss, and its tendency to grow together.

Uses of Peat Moss.—The author sometimes uses peat moss as a puddle between two ranges of stone walls, and sometimes as a backing instead of clay sod; but he more particularly recommends it as a backing to a stone defence parallel with the shore. For this purpose, the turf should be cut thin, placed against the bank, and the stone-work built against it; he has found this the most durable and effectual defence against the sea; the action of the waves against it even adding to its security, as from its fibrous nature it retains the silt thrown against the wall until all the interstices between the stones are completely filled, and a defence is thus formed for the wall itself by the accumulation against it. The method he employs is to build the sea-wall of rough rubble stone, laid dry, with a slope of about two to one; the peat moss backing, cut into blocks rather thicker than usual, is laid in courses well bonded and beaten together; it is thus consolidated throughout the height of the wall. Upwards of twenty years have elapsed since some of the first embankments were made on this principle; they have perfectly answered the purpose, and have been the means of effectually reclaiming a great extent of valuable land.

Warping silt.—The author also states, that he has lately been occupied in forming a defence, by warping silt, with whin or gorse kids, laid horizontally; a method which he prefers to that practised in Lincolnshire, where the kids are placed upright. He keeps the kids in their positions by means of stones laid on them, which are removed as the surface rises; fresh kids are then added, and the stones relaid.

The communication is accompanied by three sections of the sea defences, as they are executed, and by some corroborative testimony as to their efficiency, by Mr. Lewin, of Boston, who has examined and reported upon them. Full instructions are also given for constructing the different kinds of defences mentioned.

"*An account of the repairs done to the Beechwood Tunnel, upon the London and Birmingham Railway, September* 1840." By Thomas M. Smith, Grad. Inst. C. E.

The tunnel is built of brick, is 302 yards long, and passes through strata consisting of alternate layers of rock and marle, abounding in springs of water; it was completed at the latter end of the year 1837; that winter being of unusual severity, many of the bricks were partially destroyed, owing to their containing lime, upon which the weather acted. Mr. Robert Stephenson first contemplated applying a coat of cement throughout the inside of the arch, but it was apprehended that it would not adhere, in consequence of the constant dripping of the water. No positive steps were, however, taken until the effects of the winter of 1839-40 had so injured the brickwork as to render further delay dangerous; it was then resolved to line the whole length of the tunnel with an interior brick arch, 9 inches thick, so as to support and insure the stability of the old work.

For the purpose of executing the work with facility, all the trains of carriages were diverted upon the down line through the tunnel, and for a quarter of a mile at each end; no up train was allowed to pass upon the single line while a down train was in sight; a hoarding was then erected between the lines of railway throughout the length of the tunnel, to protect the workmen, and to prevent the building materials from interfering with the trains. The internal casing of brickwork, 9 inches thick, of English bond, was then carried up one side to the height of 4 feet 9 inches above the springing; a course of York paving $4\frac{1}{2}$ inches thick, was at this point bonded into the old work, and the new work was securely attached beneath the stone bond course by iron wedges, and regular half brick toothings were inserted, at intervals of 2 feet 3 inches apart, in chases cut into the old work; by these precautions the new work was secured from being detached, and from falling upon the passing trains.

One side being finished throughout its entire length, the trains were turned upon the up line, and the same mode of proceeding followed with the other side. A series of bearers, 6 feet apart, were then placed over head, and a close flooring laid so as to serve for scaffolding for the workmen, and to prevent the building materials from falling upon the rails. A pair of ribs were then raised upon each bearer, and keyed with a strut, 7 inches below the crown of the arch; the supporting stays were fixed, the laggans laid upon the ribs, and the brickwork of the arch was constructed in English bond throughout the whole length, and on both sides of the tunnel, simultaneously, to within 2 feet of the crown: a moveable centre, 2 feet 3 inches long, was then introduced, and the arch was closed in with two half brick rings.

The whole of the work was done with blue hard burnt Staffordshire bricks, laid in cement and sand, in equal proportions, for the side walls; for the arch, up to within 15 inches of each side of the crown, two-thirds of cement, and one-third of sand: the two rings for keying up the centre or crown were laid entirely in cement, without any mixture of sand. Previous to commencing the new work, a series of chases were made in the old wall, which, when closed in front by the lining arch, formed drains, $4\frac{1}{2}$ inches square, terminating in the culvert beneath the centre of the railway, and conveying thither all the water, which would otherwise have separated the new from the old brickwork.

This work was finished, and the scaffolding removed, within the short space of forty days, by Messrs. Grissell and Peto, under the direction of Mr. Robert Stephenson, and the immediate superintendence of Mr. Dockray.

This communication was accompanied by a drawing, showing the details of the scaffolding, and the mode of construction.

"*On the formation of Embankments and the filling in behind retaining Walls.*" By John B. Hartley, M. Inst. C. E.

The numerous failures of the embankments in the construction of railways, and the constant occurrence of defects in retaining walls, induced the author to offer some remarks upon the subject. He first examines the ordinary mode of commencing the embankment at the contemplated finished level, and proceeding with the work at that height throughout, leaving the material to find its own inclination; forming the required slopes on the sides when the filling is completed. This he contends (although without doubt the most rapid mode of proceeding) is defective in principle, for the material as it is deposited forms layers or strata at such an inclination as its nature permits, and always has a tendency to slide in the direction of the slope. In such cases, as the centre sinks, the sides slide away, and having nothing at the feet to resist such a tendency, they are carried out to a dangerous extent. This is particularly the case with clay embankments, for the material is generally brought from the cuttings in large lumps, which cannot be consolidated as they are deposited; the water lodges in the interstices, keeping the bottom soft, and when it begins to subside it slides away, until it has formed itself into a slope at which it can resist the pressure. To prevent this sliding, the author recommends proper footings being prepared for the sides of the embankments by cutting trenches, about 4 feet 6 inches deep, along the bottom line of each slope, and forming a "cop" of sods or of stones, placed at right angles to the line of the slopes. These footings must be of a strength proportioned to the height of the embankment, and the whole length should be completed before the filling is commenced, that they may become solid, and the sods have grown together, before the weight is brought upon them.

Proposed mode of filling.—He advises, also, that instead of carrying ou the filling in one lift, two embankments should be made, varying in height from 15 feet to 20 feet, according to the nature of the material, wide enough for two earth wagons on the top, one of them running along each side of the site of the contemplated embankment; a valley would thus be left in the centre at the junction of the two inner slopes. When they have been carried along the whole length, or to such a distance as would insure their being considerably in advance, the second or the final lift may follow. With clay or soft materials, four low lifts following each other would be advisable; with these precautions slips of the embankments would be of rare occurrence. The bottom would become solid by the passing of the weight over it, and the succeeding lift being thrown into the centre valley, must settle vertically. The subsidence, which is always in the line of inclination, would be concentrated and thrown inwards; by these means the width of the slopes would be restricted, and the work would be constructed much cheaper, there being a saving of both land and labour. Land springs, which are usually only discovered by the pressure of the weight above, would be more easily reached with the low lifts than when covered by the heavy ones.

This mode of construction has been practised by Mr. Jesse Hartley, on the Manchester and Bolton Railway, where the embankments were very heavy, and the material of the worst description; yet the work was executed in a most satisfactory manner, and the cost of the maintenance of way upon that line is quoted as being less in proportion than on any other railway in the kingdom. This method may require more time, and be a little more expensive, but the author is of opinion that the trifling difference in time and cost would be amply repaid by the freedom from expense when the road was opened.

Retaining Walls.—The author then examines the subject of retaining walls. He considers the method of filling towards the wall from the natural bank behind to be highly objectionable; the material lies in strata at the angle at which the deposit is made; as the quantity increases, the subsidence commences, and the earth slides downwards, throwing its whole weight against the back of the wall. The tendency to slide is frequently accelerated by the natural form of the ground upon which the earth is thrown, as it not unfrequently inclines towards the wall, in which case the pressure will necessarily be in proportion to the inclination of the slope, and the nature of the material of which the filling is composed. The wall at Hunt's Bank, on the river Irwell, is instanced as a failure of this description. The wall, about 100 feet in length, and 20 feet in height, 5 feet thick at the bottom and 3 feet 6 inches at the top, built of ashlar masonry strengthened by counterforts, was forced into the stream by the pressure of the earth behind it. With proper attention to the manner of filling the different materials, a comparatively slight wall may be constructed to sustain a considerable weight of backing. The author lays down as a rule that, wherever it is practicable, all filling behind walls should be commenced at the wall, and be proceeded with from thence towards the solid ground, by which means the strata would be inclined in a similar direction; ledges or benches, either level or inclined in an opposite direction to that of the bank, should be cut in the solid ground to receive the filling, and counteract its tendency to slide. The weight should not be laid too quickly upon a new wall, and if with these precautions care be taken that the counterforts are constructed simultaneously with, and well tied into, the wall, a comparatively weak structure will bear a heavy mass of filling.

The author gives as an example the retaining wall constructed on the west side of Jackson's dam, near the Brunswick Graving Docks, Liverpool. This wall, although built of slight dimensions, and filled behind with material of the worst description, resisted perfectly all strain; this could only be attributed to the filling having been gradually done in the manner which the author's practice leads him so strongly to recommend.

This communication was accompanied by diagrams descriptive of the mode of constructing embankments.

May 25.—Henry Robinson Palmer, V.P., in the Chair.

"*A Tabular Statement of the Dimensions and Proportions of Forty Iron Vessels.*" By Lieut. E. N. Kendall, R. N., Assoc. Inst. C. E.

The vessels, the dimensions and proportions of which are given in this communication, were all built by Mr. John Laird of Liverpool; they are adapted to a variety of purposes, so that they present but little uniformity. The "Rainbow" and the "Glowworm" are celebrated for their speed; their proportions of beam to length are above one to six, and more than three tons to each horse power, which is generally assumed to be the proper ratio for sea-going steamers. The tabular statement gives the dimensions and tonnage of the vessels, the power of the engines, the proportion of beam to length, and of tons to each horse power, the names of the owners, and the stations where the vessels are plying.

"On the Stationary Engines at the [illegible] Tunnel on the Liverpool and Manchester Railway." By John Grantham, Assoc. Inst. C. E.

This communication gives a description of two pair of stationary non-condensing engines, which were constructed by Messrs. Mather, Dixon, and Co., of Liverpool, from the designs and under the superintendence of the author. The steam cylinders are 25 inches diameter, with a length of stroke of 6 feet; they have side levers like marine engines, but the connecting rods are reversed, and convey the power downwards to the machinery, which is placed in vaults cut out of the sandstone rock, upon which the beam pedestals are fixed without any framing. Cast iron slides are used instead of the usual parallel motion, and after several years' constant use, they exhibit no marks of deterioration. The drum wheel is 21 feet diameter, and makes usually 22 revolutions per minute, when drawing up a train at the rate of 15 miles per hour; there is a groove in its periphery, at the bottom of which is wound a small cord to form a bed for the main rope to rest upon—this main rope encircles about $\frac{3}{4}$ of the circumference; it is made of the best Russia hemp, in three strands, patent shroud laid, the inner strand being composed of 40 yarns of white hemp, overlaid by 40 yarns of hemp, tarred to the point of saturation; this arrangement is found most conducive to the lightness and durability of the rope; its circumference was 6 inches, and its length, when new, was 4800 yards; in the first few weeks it stretched to the extent of 10 per cent. of its length, after which it remained unchanged under the tension imposed. The total weight is 8 tons 8 cwt., and the cost was 2*l.* 8*s.* per per cwt. It is guided by 474 grooved pulleys, 14 inches diameter, and by 6 sheaves 5 feet diameter. A new rope will last well for three years, after which it is renewed by splicing in a short portion each time, so as to reduce the amount of stretching.

Inclined plane.—The length of the inclined plane is 2370 yards, at varying gradients; giving an aggregate rise of 77 feet 1 inch, and a mean rise of 1 in 92. The tunnel is 2220 yards long. The average weight of the trains drawn up is 55 tons, and the time occupied is six minutes. The pressure of steam is usually from 50lb. to 60lb. when the engines begin to wind, and sinks gradually to about 30lb. in the reservoir during the time it is working.

Power required to draw Carriages up the Inclined Plane.—From some experiments made by Mr. Edward Woods, the details of which are given, it has been ascertained that each pound per square inch pressure of steam upon the pistons over and above the 7·56lb. necessary to overcome the friction of the machinery, is capable of drawing one carriage weighing 5 tons gross up the inclined plane. On the first erection of these engines, in order to comply with the provisions of an act of parliament, it was necessary to work them with steam generated in boilers, at a distance of 448 yards, and conveyed through pipes 10 inches diameter, laid in a tunnel excavated through the rock. Several experiments were made to determine the relative amounts of pressure in the boiler and the steam reservoir, and the quantity of steam which was condensed in a certain time. The results were, that when the engine was standing still, the difference of pressure was about 3lb., and when working with a load it was as much as 13lb. The quantity of steam condensed was on an average about 156 gallons per hour. Subsequently, a set of tubular boilers, similar to those of locomotive engines, were erected close to the engines, and are now constantly worked instead of those at the great distance; the economy of fuel has been considerable. The consumption of gas coke under the tubular boilers is about 15 tons per week, at ten shillings per ton. The larger boilers consumed about 30 tons in the same time.

Mr. Edward Woods gives his approval of the action of the engines, and of the employment of non-condensing engines generally for this class of work, on account of their great simplicity, and the readiness with which they may be brought into full action, so that the greatest power is always at hand to start the train; whilst during the intervals of working the steam may be suffered to accumulate. These advantages are rarely attainable with condensing engines, as unless a small engine be employed to keep up the vacuum, there is a difficulty in starting them with the train attached to the rope.

This communication is accompanied by four detailed drawings of the engines and machinery, and by a model of Mr. Grantham's apparatus for regulating the admission of steam to the valves.

Observations.—Mr. Fairbairn bore testimony to the good quality of the engines and machinery described by Mr. Grantham; their performance had been very satisfactory. The mode of keeping the rope in tension was an improvement upon the plan which Mr. Fairbairn had previously adopted at the Wapping Tunnel, of the same railway. He would present drawings of that machinery to the institution. The loss by condensation in long steam pipes is so considerable, that it has been generally found more economical to transmit power by a line of shafts, than to convey steam to any great distance. He had recently constructed some Cornish pumping engines of large size, with side levers and reversed connecting rods; they had answered extremely well. Drawings and descriptions of them would be presented to the Institution.

"On the percussive action of Steam and other Aëriform Fluids." By Josiah Parkes, M. Inst. C. E.

In a previous communication "On the action of Steam in Cornish single-pumping Engines,"* Mr. Parkes, after a careful analysis of the ascertained facts of the quantity of water which, in the shape of steam, passed through the cylinders of the engines, arrived at the conclusion that the steam's elastic force was insufficient to overcome the resistance opposed to it. On obtaining this remarkable result, he was induced to examine the circumstances under which the steam is applied, and was convinced that from the instantaneous and free communication made between the boiler and the cylinder of these engines, an action, distinct in character from the simple pressure of the steam, must be transmitted to the piston. And, in order to convey some precise idea of the peculiar nature of this action, he adopted the term "percussion" to distinguish such action from that due to the simple elastic force of the steam. Various phenomena, connected with the working of the engine, were adduced in confirmation of the views then advanced. In the present communication Mr. Parkes has resumed the subject, and brought forward numerous facts derived from experiment and observation, on steam and elastic fluids generally, in farther corroboration of his opinions respecting the percussive action of steam in engines.

The effect of the percussive action of steam may be clearly traced on the indicator diagrams (a series of which, 41 in number, taken from four engines, with different indicators, the pressure of the steam varying from 6·5 to 34.7lb. per square inch, accompanied the communication), and it will be seen that, in every instance, the piston was driven to a greater height than that due to the simple elastic force of the steam: in many instances a greater pressure was marked than existed in the boiler. The difference in the action, according as the steam is admitted suddenly, or gradually, into the cylinder of the engine, may be also distinctly traced on the diagrams. The same effects were observed on the sudden admission of steam upon the surface of mercury in the cistern of a mercurial column. In these experiments, the steam being let on gradually, the gauge marked a pressure of 40lb. per square inch, which was the true pressure in the boiler; but, being admitted suddenly, the gauge exhibited a pressure of at least 60lb., and the same results were repeatedly obtained.

The steam generator of Mr. Perkins will afford a good illustration of the effect of the steam's instantaneous action. The pressure in this apparatus is denoted by an instrument having an index moving round a dial plate. Steam of 26 atmospheres being suddenly admitted, the index was observed, during repeated trials, to register a pressure as high as 36 atmospheres, and then to recede until it remained stationary at 26 atmospheres, which was the pressure in the generator. The results of these various experiments are arranged in two tables, exhibiting an analysis of the elements into which they may be resolved.

The author then proceeds to point out the different circumstances of the pumping and crank engines, in respect of their realizing, beneficially, the steam's percussive action. In the latter, this instantaneous action takes place (as the indicator diagrams show) when the connecting rod and crank are in one vertical line, so that it is inefficiently expended; the centre, by the agency of the fly wheel, not having been passed. In the former, the load and frictional resistance alone oppose the descent of the piston; the piston is free to move, and the steam's action is wholly efficient in impelling it; and, whatever the amount of the percussive action, it will be accounted for in the effect.

A remarkable confirmation of the conclusions arrived at, and the views advanced by Mr. Parkes in his previous communication, had been furnished by Mr. W. West. The cylinder cover of the Fowey Consols engine, 80 inches in diameter, and weighing 4 tons, springs upwards at the centre ·156 of an inch, on the sudden admission of steam, which in the boiler has a pressure of 49·7lb.; and $\frac{1}{4}$ of an inch, the steam in the boiler being 61·7lb.: but no change of form, or springing, occurs when the steam is let on gradually, and fills the cylinder at the same pressure as that in the boiler.

The author adduces many other facts in illustration and confirmation of his views; as, the oscillation of the mercury in steam and vacuum gauges; the audible sounds produced in a steam pipe on suddenly checking the motion of the elastic fluid by shutting a cock; the curious phenomena connected with the impact of elastic fluids on each other, particularly those observed by Mr. Greener on firing gun-powder in long open-ended barrels; and, in conclusion, suggests whether these remarkable facts may not serve to assist in elucidating some of the very difficult and apparently inexplicable phenomena, connected with the explosion of steam boilers.

Remarks.—Mr. Lowe had recently made some experiments, which in his opinion confirmed Mr. Parkes's views on this interesting subject. A pressure gauge, attached to a line of gas pipes, showed, when the communication was slowly opened, a pressure of four inches column of water; but it invariably exhibited a maximum of oscillation of full six inches column on the sudden opening of the small stop-cock between the pipe and the gauge. In a line of pipes, full of gas, the whole volume of gas received an impulse on suddenly opening the valve at one end, and the passage of the undulating wave was indicated by the sudden and successive depression of the water in the gauges along the whole line.

Mr. Homersham could not agree with Mr. Parkes as to the effect due to

* See Transactions Institution C. E., Vol. III.

what he termed the "percussive action of steam;" he believed that the superior economy of the Cornish engines, as far as related to the action of steam in the cylinders, would be found to be due to the amount of the expansion of the steam; which depended, not only upon the opening and closing of the steam valve, but also upon the greater or less area of the aperture of the throttle valve. It was evident, that on closing the steam valve, the space between it and the throttle valve would be filled with steam of a density nearly, or quite, equal to that in the boiler; therefore, on the first admission of the steam into the cylinder, it might be presumed to act upon the piston with that pressure; considering, likewise, that a short interval of time necessarily occurs for setting in motion the beam, with the heavy pump rods appended to it; but immediately the piston starts, expansion takes place, as the throttle valve prevents the steam from following the piston freely, so that a greater degree of expansion must take place when the steam is at a higher density; for the throttle valve being then more closed, offers a greater resistance to the steam following the piston. The indicator diagram of the East Crinnis Engine showed this effect to a certain extent, although neither in that nor in the diagram of the Huel Towan Engine was there nearly the same degree of pressure exhibited in the cylinder at the commencement of the stroke, as in the boiler; but it was evident that those diagrams could not be relied upon, as they did not account for the whole duty done by the engines, either on the percussive or the expansive principle. Assuming a bushel of coal to weigh 94lb. as generally reckoned in Cornwall, and that 1lb. of coal would evaporate $10\frac{1}{2}$lb. of water, it could readily be shown, that the quantity of water converted into steam by one bushel of coal, would, when expanded in a cylinder, during $\frac{19}{20}$ of the stroke, lift upwards of 257 million lb. one foot high in one minute; which was a much greater duty than was realized by any Cornish engine.

Mr. Seaward allowed that Mr. Parkes had clearly shown, that a certain amount of effect was due to the sudden impact of the steam upon the piston of a pumping engine. Whether the term "percussion," as applied to this action, was the proper one, he would not then examine; but the effects shown to have been produced, and the phenomena attendant upon the exhibition, were so remarkable, that he conceived the subject to merit the most deliberate investigation of engineers as well as philosophers. He had previously objected to the theory, on the ground that the effect could only be in the ratio of the weight of the steam multiplied into its velocity; but he believed the subject must be examined in a different manner; and although the principle must always have existed, it was only in consequence of modifications in the application of steam, that the effects had been so fully developed.

Mr. Parkes mentioned, that since his paper had been written, he had found an experiment which was strictly analogous to his proposition. It was related by Mr. Robins, who was so justly celebrated as a mathematician and philosopher, and first discovered that the gas evolved from gunpowder was a permanently elastic fluid: "when gunpowder is fired in an exhausted receiver, the mercurial gauge instantly descends upon the explosion, and as suddenly ascends again. After a few vibrations, none of which, except the first, are of any great extent, it fixes at a point which indicates the density of the inclosed gas." He considered this result as corroborating those obtained by himself, as well as justifying the comparison he had drawn between the instantaneous action of gunpowder gas and steam. Mr. Robins's words precisely described the steam's action, as traced on the indicator diagram exhibited. The springing of the cylinder cover referred to, and in the manner stated, must, be thought, satisfy every one, that the steam's instantaneous action far exceeded in effect that of its simple elastic force, which was proved to have been unequal to produce any change in the parallelism of the cover. As regarded Mr. Homersham's investigation of the power of the steam in the Huel Towan engine, it was correct that the initial steam was in a state of expansion during $\frac{19}{20}$ of the stroke, but not all the steam, for it had not all entered the cylinder until the piston had travelled through nearly $\frac{5}{20}$ of the stroke. His calculations were, therefore, hypothetical, and not in accordance with the facts of Mr. Henwood's experiment.

THE CALEDONIAN CANAL.—THIRTY-SIXTH REPORT OF THE COMMISSIONERS.

Few undertakings have been more singularly and uniformly unfortunate than the one which forms the subject of the present report.

Though originating in the purest and most praiseworthy motives, though directed by the talents of a Telford, and supported and carried out by an almost unlimited supply of public money, this canal appears to have arrived at such a point of dilapidation and decay, and to be attended with such peculiar difficulties, that it has at length become equally impossible either to advance or recede, without incurring a further enormous outlay and expense.

In this situation, and as the lesser evil, it would appear that a select committee of the House of Commons, appointed in 1839, for the purpose of examining into the affairs of the canal, made a report, wherein they recommended that a further advance of public money to the amount of £200,000 should be made, for the purpose of completing and finishing it properly and effectually, so as to render it available for the purposes for which it was originally intended, giving it as their opinion, that inasmuch as a vast sum of money had already been expended on the concern, which, though at present unproductive in a pecuniary point of view, had still, to a certain extent, been beneficial to the country through which it passed; and as destroying the works, filling up the canal, or abandoning the undertaking altogether, must be attended with a further expense for the purpose of making the country secure from inundation, which expense would amount to as much as would put the canal in good working condition and repair, they felt that the choice left them was only one of two positive evils, either of which must be attended with an equal outlay, and that, therefore, it was not advisable to sink the money already expended and put up with the dead loss; but rather, by expending the same money in rendering the canal more easily navigable, and more adapted to the purposes of commerce, to take the chance which, though remote, might yet by possibility render the undertaking sufficiently productive to pay its own expenses, and thus leave it, if not a positive benefit to the present generation, in a commercial point of view, at least a gigantic monument to posterity of British industry, ingenuity, and talent.

In order to account for the enormous but fruitless outlay of the public money, which, in the present instance, has already exceeded £1,000,000 sterling, without including the £200,000 above-mentioned, it will be necessary to go back into the origin of this undertaking, and to trace the causes which have led to this unsuccessful result.

It would appear that, in the year 1803, France having, by successive aggressions, arrayed the whole of Europe, and more especially the great northern Powers, against her great maritime rival, and there being no naval station of any consequence in the north of England, the whole coast of Scotland or the north-west of Ireland, the enemy had it in his power to annoy this part of the country from the North Sea, by passing round the Orkney Islands, whereby the commerce of a considerable portion of the United Kingdom frequently suffered great and serious losses. This circumstance, and the idea of affording employment to the inhabitants of the highlands of Scotland, who at that time were in great distress, and were rapidly emigrating from home, were much pressed on the attention of the Government of that day, and caused the subject to be taken into serious consideration, and enlarged views were developed by describing the singular valley called the Great Glen of Scotland, which, commencing between the promontory of Burg Head in Elgin and Cromarty, passes through a succession of sea inlets and fresh water lakes to the southern extremity of Cantyre, for a distance of 200 miles, and in nearly a straight direction between the Naze of Norway and the north of Ireland, and which, it was alleged, afforded great facilities for internal navigation. It was said that the whole of this extensive valley, with the exception of 22 miles, being occupied by navigable waters, and the excepted space by a navigable canal, would save upwards of 500 miles of dangerous navigation.

With these views the Caledonian Canal was originally undertaken; but though there can be no doubt that the natural features of the country suggested the plan, yet it is doubtful whether it would ever have been entertained but for the distressed state of the Highland population, which it was an object to relieve, by affording them employment, and this being best attained by extensive public works, was the immediate cause which led to the adoption of the scheme.

Accordingly Telford was employed to examine the line of country indicated, and having testified to its practicability he was alone employed to carry the design into execution, agreeably to a plan he had furnished.

By this plan it was proposed to form a canal large enough to admit of the navigation of a 32-gun frigate throughout its whole length, and the estimated cost of the work in question was fixed by him at an amount of £350,000. This estimate was subsequently increased to £474,500, but which latter sum fell very far short of the real expense incurred in the undertaking. This singular difference between the estimate and the real cost was said to arise from the fact, that subsequently to the estimate being given in, a serious rise had taken place, as well in the value of timber as in the cost of labour (consequent on the rise in the price of provisions), and something must also be attributed to the want of experience in estimating the cost of works of such a gigantic nature; from these causes, and from other unforeseen difficulties, the canal was not opened to the public until many years had elapsed from the time of its commencement.

In the meanwhile, and during the period wherein these works were going forward, the enormous inaccuracy of the estimates became every day more apparent, and much opposition was manifested in various quarters to any further advance of the public money towards carrying out the objects of the scheme; under these circumstances, and finding increased difficulty in raising the supplies necessary to complete the work, the commissioners determined to open the canal to the public in its unfinished state, and accordingly, in 1822, the canal, though only partly completed, was opened to the public, and in which state it has remained up to this time.

The consequence of this premature opening led to numerous accidents and misfortunes, and to frequent interruptions of the navigation.

Up to the time of opening the canal, the expences of its construction had amounted to the enormous sum of £905,258, which amount had in May, 1839, been increased to £1,023,628, exclusive of a debt to the Bank of Scotland of £39,146.

From the very first hour of its being opened to the public, the canal, in a pecuniary sense, has been a losing concern, never having paid even the expenses of keeping it in repair, much less leaving any surplus available to the liquidation of its debts. On the contrary, the commissioners have been compelled every year to make application to the Bank of Scotland for advances necessary to complete repairs imperatively called for; neither has the traffic upon the canal been such as to encourage the idea of its ever being, at least as at present constituted, a very successful undertaking.

In the mean time, the works of the undertaking seem to have been gradually deteriorated until the latter end of the year 1837, when a serious accident occurred to the lock at Fort Augustus, and this being followed by other extensive damage, information was forwarded of the state of things to the Lords of the Treasury, and their attention was drawn to the bad state of the canal generally, and to the danger to be apprehended to the large district of the neighbouring country from the defective condition of many portions of the works, more especially the Gairlochy lock.

Accordingly Mr. Walker, the engineer, was directed by the Treasury to proceed to the spot, and to ascertain the nature and extent of the damage sustained, with which directions he complied, and further gave instructions for doing what was then immediately necessary.

In the year following a committee of the House of Commons was constituted for the purpose of hearing evidence on the subject of the canal, and Mr. Walker and Mr. May, the resident engineer, attended and testified to the state of the works.

From this evidence, it appeared that much danger was to be apprehended to the works themselves, and also to the country adjacent, as well as to the lives and property of individual inhabitants resident in the neighbourhood of Gairlochy. It was stated that at this lock the waters of Loch Lochie, which extend over a surface of 6,000 acres, had been dammed many feet above their natural level, and that they were supported at that height by only one pair of gates, on the breaking of which the outpouring water on the adjoining country would occasion such a loss of life and property that no time ought to be lost in guarding against such an occurrence. It further appeared, that other parts of the works were in an exceedingly bad state, and were hourly becoming worse.

Upon being questioned as to the reason of the canal not being used by shipping, these gentlemen stated that the objection to the canal on the part of the masters and owners of craft arose from the uncertainty of water, and from the want of steam-tugs, as it would be impossible to form towing paths on the borders of the lake.

Upon being pressed to state what sum would be required to put the canal in a proper and efficient working state, inclusive of everything, he estimated the amount to be required for that purpose to be £200,000 more, and advised that course to be adopted in preference to abandoning the canal altogether, as he stated, that in the event of that course being adopted, the expence of fence works, &c., necessary to prevent the country from being overflowed, would be as great as the expense of repairing, and this without the possibility of a return, not to mention the claims of parties for compensation, &c.

After hearing other evidence to the same effect from other parties, the committee became of opinion that the proposition for abandoning the canal altogether was one that ought not to be entertained, and after making numerous inquiries with the object of ascertaining whether any increase of business would be likely to accrue if a certain passage through the canal could be obtained, and having ascertained that point, and that thus the dangerous and tedious navigation of Pentland Frith might be avoided, they resolved, that the navigation of the canal was insecure; that the state of the canal should be immediately attended to, not only as regarded the preservation of the work, but also as relating to the security of life and property in the districts through which the canal passed; that they could not recommend the abandonment or shutting up the canal, and that the insufficiency of water, the imperfect execution of the works, and the absence of steam tugs, had prevented the development of the benefits to commerce which might be expected; that much benefit would arise to the trade and commerce on the canal, if the works were placed in a sufficient state of repair, if the depth of water were increased, and the assistance of steam tugs were afforded, as recommended by Mr. Walker; and for these purposes they recommended that a further sum of £200,000 should be advanced by Government.

The following are some observations upon the Report by the *Times*:—

Subsequently to this report it appears that certain propositions had been made to carry the recommendations of the committee into effect by private enterprise, by which means the necessity of application to Parliament for more money would be obviated, and this great national work rendered more available to the interests of the country without the further expenditure of public money.

In consequence of this proposition the committee re-assembled and resolved that such arrangement would be desirable under certain conditions, which were, that the Treasury should grant a lease of the canal and its appurtenances to the adventurers for a term of 99 years, gratis; that the company, before the execution of this lease and the application to Parliament, in lieu of the 10 per cent. deposit, should pay £45,000, to be applied in liquidation of the debts now owing on account of the canal; that the works recommended by Walker should be executed, and should afterwards be kept in repair, and that the company should relieve the Treasury and the commissioners of the canal from all responsibility from accidents and damage, and should, at the expiry of the time, leave it in good repair.

In the event of these terms not being acceded to, the committee recommended the matter to be again left in the hands of the commissioners as before.

It would appear, by the report now under consideration, that Government were unable to effect a transfer of the Caledonian Canal upon the terms suggested by the select committee of the House of Commons, and, consequently, the navigation has remained under the charge of the commissioners during the past year.

Notwithstanding the severity of the winter of 1840-1, no further serious damage was sustained by the works, nor is any material deterioration of the general condition of the works apparent; still it cannot but be felt, especially with respect to the very important locks of Gairlochy and Fort Augustus, that the lapse of every additional year renders their situation more precarious.

Little further of any interest appears upon the face of this report beyond the unpleasant fact that the receipts to the 1st of May for dues received to that day amounted to £2,728 9*s*. 8*d*. exclusive of a further sum of £173 0*s*. 7*d*. for rents, whilst, on the other hand, the expenditure amounted to £6,120 1*s*. 6*d*. and the total debt to the Bank of Scotland up to the same time amounted £23,592 9*s*. 1*d*.

It further appears that during this time 1,283 vessels had made use of the canal, paying in respect of tonnage rates £2,728 9*s*. 8*d*.

Little else can be gleaned from this report than what has been hereinbefore stated, nor does it appear that anything has since been done towards carrying out the recommendations of the select committee of the House of Commons.

Upon the whole, a perusal of the report affords no ground for forming any judgment on the propriety or good policy of adopting the advice of the committee to repair the canal; yet it is difficult to imagine what other course could be adopted under the circumstances of the case, as it is evident that by abandoning the undertaking the commissioners would save nothing in the way of expense, and that the amount which would be required to make the ground safe after them would be sufficient to repair the canal, and to provide that description of steam power which seems all that is required to make the passage through the canal preferable to the round sea voyage, presuming the canal to be in that perfect state of repair as to obviate the chance of danger to those travelling on it. At any rate, if we can believe the evidence adduced before the House of Commons on the subject, there can be little doubt that the steps recommended would greatly increase the traffic, and would render it, presuming the canal to be in such a state of solid repair as to be lasting, capable of paying its own annual expenses, and, perhaps, lay by enough to provide for future unforeseen contingencies. We confess we are adverse to seeing the enormous sum of money already expended absolutely sunk and sacrificed without making some further effort to make the canal useful, and we should greatly regret to see the gigantic conception of Telford's mind sink into neglect and oblivion without an effort to save it from such a fate.

REVIEWS.

An Experimental Inquiry concerning the relative Power of, and Useful Effect produced by, the Cornish, and Boulton and Watt Pumping Engines, and Cylindrical and Wagon-head Boilers. By THOMAS WICKSTEED, M. Inst. C. E. and Engineer to the East London Water Works. London: John Weale, 1841.

THIS highly interesting paper, as many of our readers may be aware, was presented to the Institution of Civil Engineers during the last session, but as there was not sufficient time left to allow of its being read the same session, the author obtained permission of the Council to withdraw it, for the purpose of publication in the present form.

Its nature and object are clearly and concisely defined in the first and last paragraphs of the preface, which we here subjoin.

"Those who take up the following paper in the expectation of meeting with a theory of the Cornish Engine will be disappointed, as it is little more than a plain narrative of the result of experiments made with a view to establish the *commercial* value of two classes of Pumping Engines."

"With respect to the calculations introduced into this paper, it is to be observed that the mode in which they have been worked is given, as well as the results recorded. If, therefore, the calculations are objected to, an opportunity is afforded of adopting a different method. The facts will remain the same, and it is hoped they cannot fail to be useful."

The work is divided into two parts; the first relating to the boilers and fuel, the second to the engines.

In the first part, the author describes the mode in which the experiments upon cylindrical and wagon-head boilers were made, which cannot fail to inspire confidence in the accuracy of the *facts* observed, although we think the deductions therefrom will bear some little modification. It is, however, satisfactorily shown that not the slightest reliance can be placed in an experiment of short duration to ascertain the duty of an engine. The author gives a statement of "the duty done each 12 hours (excepting in one instance, that of the highest duty, which was for six hours only,) by the engine, coals from the same heap being used." The experiment lasted 185 hours. In these 16 observations the highest duty was 118,522,475 lb. lifted one foot high with 91 lb. of coals, the lowest 63,650,298 lb., and the average 86,180,018 lb. From which it appears that the *highest* duty was 37 per cent. above the mean, and the *lowest* 26 per cent. below the mean.

"Finding the disparity so very great in these experiments," the author "commenced a fresh series, with a view of ascertaining the actual evaporation of water with cylindrical and wagon-head boilers under different circumstances of surface exposed to the action of heat, of coals burnt per square foot of grate, of quantity of water evaporated, and, as regards the wagon-head boiler, *with* and *without* clothing: wishing also to ascertain the comparative merits of the two engines, he recorded the average quantity of water used per stroke in the form of steam."

The following statements are calculated to give weight to the results recorded by Mr. Wicksteed in the work before us.

"The time occupied in the trials upon the cylindrical boilers was above 3400 hours, the coals consumed above 900,000 lb., and the water evaporated nearly $7\frac{3}{4}$ millions of lb. Upon the wagon-head boiler the time occupied was 1291 hours, the coals consumed nearly 600,000 lb., and the water evaporated above $1\frac{1}{2}$ millions of lb."

The quantity of water supplied to the boilers was accurately determined by means of a cistern "gauged by *weighing* 21 cwt. of water into it, and marking the height of each cwt. upon a floating gauge-rod;" which is of course the same thing as if it had all been weighed.

"The coals were actually *weighed, not measured*, into the stoke-hole, and the surplus, if any, was also weighed at the end of every 12 hours."

The results of these experiments on boilers are contained in Table No. V., in which are also given all the details of the experiments; and, from a comparison of columns 16 and 22, which show *the weight of fuel burned per square foot of grate per hour*, and *the weight of water evaporated by one lb. of coals from 80°*, respectively, we should conclude the latter to be independent of the former, since there is not the slightest correspondence to be perceived in the variations of the two quantities, if these variations be observed throughout the whole series of experiments; but the author, by comparing only the six experiments upon all four Cornish boilers, and the one upon the wagon-head boiler, when most perfectly clothed, found the evaporative effect of a pound of coals to increase with the rate of combustion per square foot of grate. He gives the following table of the mean results of the six experiments upon the Cornish boilers, three with quick, and three with slow combustion.

	Quick.	Slow.
Pound of coals per hour - - -	342·	188.
Cubic feet of water per hour - -	46·9	25·4
Pounds of coals per square foot of grate per hour	4·682	2·596
Pounds of water evaporated per lb. of coal from 80°	8·524	8·426
Ratio - - - - -	100	98·8

In this comparison the advantage of increasing the rate of combustion from 2·596 lb. to 4·682 lb. per square foot per hour, or a little more than 80 per cent. appears to be nearly $1\frac{1}{6}$ per cent. But if this advantage can with certainty be attributed to the more rapid combustion, ought we not to expect the same advantage to accrue from a still greater increase in the rate of combustion, with two or three of the same boilers?—This does not, however, appear to have been the case. The mean rate of combustion in the 26 experiments upon 2, 3 and 4 cylindrical boilers was 5,013 lb. per square foot of grate per hour, and the mean evaporation per lb. of coals, 8·224 lb. of water from 80°. The slowest rate of combustion was 2·475, with the 4 boilers, and the corresponding evaporation, 8·258 lb., or 0·41 per cent. above the mean; and the quickest rate of combustion, with two of the same boilers, was 8·708 lb. with an evaporation of only 8·082 lb. of water per lb. of coals, which is 1·73 per cent. below the mean. The mean of the six highest rates of combustion with the cylindrical boilers was 7·717 lb., and the corresponding mean evaporative effect of a pound of coals, 8·038 lb., or 2·26 per cent. below the mean of all the 26 experiments upon Cornish boilers. The rate of combustion under the wagon-head boiler (when well clothed, as the comparison would not otherwise be fair) was 10·89 lb. per square foot of grate per hour, and the evaporative effect of a pound of coals in that boiler under those circumstances, 8·301 lb.; but the engine was only worked during the day time, whence resulted a loss of effect equal to 1·78 per cent., so that the evaporation per pound of coals, if the boiler had been worked continuously night and day, as the cylindrical boilers were, would have amounted to 8·449 lb., or 2·74 per cent. more than the mean of the cylindrical boilers, the rate of combustion being rather more than double. If, however, Mr. Wicksteed had happened to make only one experiment with the cylindrical boilers (as he did with the wagon-head boiler well clothed), and that one had been the 2nd in the table, in which the rate of combustion was equal to the mean of the 26 experiments, but the evaporation 8·605 lb. per pound of coals, the advantage would have appeared in favour of the cylindrical boilers with slow combustion. It would seem, therefore, from these results, either that the proportions of grate and heated surface to the quantity of coals burned per hour exercise little or no influence on the evaporative economy of a boiler, or that experience is not yet sufficient to justify any conclusions on that head. However this may be, the facts here recorded are extremely valuable, inasmuch as they are the results of long continued and carefully conducted experiments, of which we are made acquainted with all the circumstances generally considered necessary to be known. They seem to indicate that each experiment, in order to be conclusive, ought to last as long, or nearly so, as all the experiments upon the cylindrical boilers taken together, and that all the circumstances connected with the management of the fires ought to be closely attended to, some of which are not observed at all, such as the supply of air to the furnace, and the temperature of the air in the chimney, if they can be ascertained, even comparatively; for it is very probable that these circumstances varied much in the experiments under consideration without its being perceived, and thus caused variations in the evaporative results, which may be ascribed to other causes. The experiments upon the wagon-head boiler appear, however, to prove very clearly the great advantage of efficient clothing, since the evaporative effect of a pound of coals increased invariably with the quantity of clothing, the advantage of a well clothed boiler over the same boiler entirely exposed being shown to be equal to 10·8 per cent. which produces so important a saving of fuel, that the practice of clothing boilers cannot be too strongly recommended.

We extract the following calculation made by Mr. Wicksteed to show which kind of boiler is preferable in a *commercial* point of view.

"One wagon-head boiler evaporated 54·5 cubic feet per hour, and weighed $7\frac{1}{4}$ tons. Four cylindrical boilers evaporated 46·9 cubic feet per hour (the most rapid evaporation), and weighed 48 tons. If 46·9 cubic feet required 48 tons of boiler, 54·5 cubic feet would require $55\frac{1}{2}$ tons.

	£	s.	d.
Cylindrical boilers, $55\frac{1}{2}$ tons at £27 -	1498	10	0
Wagon-head boilers, $7\frac{1}{4}$ tons at £27 -	195	15	0
Difference - -	1302	15	0

"Supposing the boilers are worked 365 days, the whole 24 hours, the coals consumed by the cylindrical will be equal to 1556 tons per annum, and by the wagon-head boiler 1569 tons, the saving in favour of the cylindrical boilers is equal to 13 tons of coals, which at 20*s.* is equal to 13*l.* It would be useless to continue the comparison of the *commercial* merits of the two classes of boilers farther."

From the results of his experiments on the evaporative power of various coals, the author has formed the following table,

"SHOWING THE COMMERCIAL VALUE OF THE COALS.

The price of small Newcastle coals evaporating 7·68 lb. of water per lb. of coals was, in 1840, 14*s.* 6*d.* per ton in the Pool; this price is taken as a standard, and the value given is according to the evaporative power of the different varieties.

	Water evaporated per lb of coals.	Value per ton in the Pool.	
The best Welsh - - - -	9·493	17*s.*	11*d.*
Anthracite - - - - -	9·014	17	0
The best small Newcastle - -	8·524	16	1
Average small Newcastle - -	8·074	15	$2\frac{3}{4}$
Average Welsh - - -	8·045	15	$2\frac{1}{4}$
Coke from Gas-works - -	7·908	14	11
Coke and Newcastle small $\frac{1}{2}$ and $\frac{1}{2}$ -	7·897	14	$10\frac{3}{4}$
Welsh and Newcastle, mixed $\frac{1}{2}$ and $\frac{1}{2}$ -	7.865	14	10
Derbyshire and small Newcastle, $\frac{1}{2}$ and $\frac{1}{2}$	7·710	14	$6\frac{1}{2}$
Average large Newcastle - -	7·658	14	$5\frac{1}{2}$
Derbyshire - - - -	6·772	22	$9\frac{1}{2}$
Blythe Main, Northumberland -	6·600	12	$5\frac{1}{2}$."

We have seen that Mr. Wicksteed's experiments upon Cornish and wagon-head boilers do not establish any certain superiority of either over the other in evaporative economy, although Mr. Parkes, in his paper *on Steam Boilers and Steam Engines*, published in the 3rd volume of the *Transactions of the Institution of Civil Engineers*, states the Cornish to be superior to the common wagon boiler by as much as one-third. It is, however, to be remembered that this conclusion is drawn from experiments of short duration compared to those made by

Mr. Wicksteed, and consequently not to be depended upon; nevertheless we cannot but think that a still longer continuance of observations is necessary to confirm the opinion expressed by Mr. Wicksteed, that evaporative economy is promoted by more rapid combustion, as compared to the slow combustion effected in the Cornish boilers, the rapidity of combustion being measured by the weight of coals burned on each square foot of grate per hour, for we do not consider it fully borne out even by his own experiments. Nor should we have supposed that the amount of heated surface which would produce the maximum of evaporation with a given weight of fuel had been surpassed, even in the Cornish boilers, which Mr. Wicksteed states to be proved by his experiments.

With the *engines* the case is very different:—the circumstances which affect the economy of *steam* are simple and manifest, and their effects easily ascertained and measured: for which reason this part of the investigation is much more satisfactory than the former. But the *duty* or effect produced by the engine with the consumption of a given quantity of fuel, resulting from the combination of the evaporative economy of the boiler, and the economy of the engine in the expenditure of steam, must necessarily be an uncertain criterion of the excellence of an engine, unless deduced from observations continued through a considerable length of time, and unless due account be taken at the same time of the various circumstances affecting the evaporative economy of the boilers. For this reason the author has adopted the judicious plan of separating the two sets of causes and effects, by ascertaining, for the boilers, the weight of water evaporated per lb. of coals, and for the engines, the weight of water used as steam in the engine to produce the observed effect. By this means he has been enabled to obtain the relative commercial values, if not of the boilers, at least of the engines experimented upon.

By an inspection of Table No. VII., which contains the particulars of the experiments upon the engines, it will be seen that the duty increases progressively with the degree of expansion of the steam in the cylinder; also that there is very little difference between the mean steam pressure on the piston and the mean resistance, that difference being in favour of the steam pressure, thus proving that there is no necessity whatever to call in the *percussive force* of the steam to assist its elastic force in overcoming the resistance, according to the new theory which Mr. Parkes attempted to establish.

It will be remarked, on examining column 27 of this table, that the mean steam pressure was always found to exceed the mean resistance, and that the excess increased progressively with the degree of expansion: but on this point we have one or two observations to make.

The mean steam pressure, (column 21), is calculated from the quantity of water in the form of steam used per stroke in the cylinder, (column 9); the quantity of steam remaining in the cylinder from the preceding stroke when the steam valve is opened (column 12), deduced from the pressure of that steam (column 9); the space above the piston upon the shutting of the steam valve (column 15), whence is deduced the pressure of the steam before expansion (column 16); the proportion of the stroke through which the steam expands, (column 20); and the pressure at the end of the stroke (column 17).

We have to observe with respect to these calculations, that the pressure of the steam is always supposed to be proportional to its density, (except in the case of col. 13, where Tredgold's rule is used to determine the volume of the steam at boiler pressure generated from the quantity of water used per stroke) which occasions a slight error in each of the columns 12, 14, and 16; and in col. 17, an average pressure at the end of the in-door stroke of 6·7lb. per square inch is assumed, but which we find by calculation from the quantity of water used per stroke, supposing the pressure in column 11 to be correct, to vary in the five experiments upon the Cornish engine from 8·02lb. to 6·09, diminishing as the degree of expansion increased. After making these corrections, as well as a slight alteration in col. 13, from the use of a different method, we find the mean pressure of steam in the experiments B, C, D, E, and F, = 12·58lb., 12·39lb., 13·06lb., 13·33lb., and 12·8lb., respectively, the mean resistance in all cases being assumed to be 12·94lb., the power thus appearing to be sometimes superior, and sometimes inferior to the resistance, but never differing from it more than 0·39lb., per square inch, which may almost be considered as a practical equality.

In the experiment H, on the Boulton and Watt engine, the excess of the steam pressure over the resistance becomes greater after the corrections; but that is evidently to be accounted for by the quantity of water used per stroke being estimated too highly, for we find the pressure at the end of the stroke 12·83lb., (instead of 10·25lb., as given in the table both for this pressure and that of the steam remaining in the cylinder before the steam valve is opened), which is no doubt erroneous. At all events these experiments sufficiently prove the capability of the Cornish engine to perform the duty it is asserted to do.

We regret that we cannot give a few more extracts from this valuable work, which contains several tables that deserve the attentive perusal of all parties in any way connected with the steam engine, particularly in a *commercial* point of view. To Mr. Wicksteed the public are greatly indebted for his indefatigable exertions and perseverance in carrying out his experiments, and laying the facts open to all without the slightest concealment or mystery.

Lardner's Cabinet Cyclopædia—Treatise on Electricity, Magnetism, &c. By Dionysius Lardner, LL.D. Vol. I. London: Longman & Co. 1841.

The Cabinet Cyclopædia has now reached its 130th volume, a sufficient proof of its popularity and its consequent utility. In the present work Dr. Lardner discusses electricity, magnetism, electro-chemistry, electro-magnetism, terrestial magnetism, &c., subjects all of the highest interest, and of the greatest importance to the votaries of science and to practical men. The progress of these sciences is most rapid, every day new powers are developed, and new and extraordinary applications are carried into effect. The mere experimental history of electricity is important as shadowing out the future, were not the results already produced sufficient to stamp its value. Under such circumstances the necessity for a popular digest of the scattered information on electricity is imperative, and also that it should be executed by one who has proved himself competent for the task. In the next volume Dr. Lardner proposes to conclude the treatise, to record the latest discoveries, and describe the several practical applications. We are glad to see the severity with which the Doctor handles M. Arago for trying to supplant Franklin by a French intruder, as he subsequently attempted to do with regard to Watt, when he received merited castigation at our hands.

View of the Ouse Valley Viaduct on the London and Brighton Railway. London: Ackerman & Co. 1841.

The great progress of those magnificent public works, the railways, has led to the publication of numerous engravings devoted to their illustration. Messrs. Ackerman, who are so successful in the pretty, seem determined to show their capability for the grand, and they could scarcely have chosen a better subject than Mr. Rastrick's Ouse Valley Viaduct, which steps across the Lowlands with 37 arches of 30 feet span, the highest standing a hundred feet above the water.

Elements of Perspective Drawing. By Augustus Deacon. London: Taylor and Walton. 1841.

This work, the designs only of which are by Mr. Deacon, but the plan of which emanates from a well-known promoter of this branch of education, is calculated to be highly useful to the student of mechanical drawing. The author grounds his system on the use of a series of models, to which, however we should object in some cases, as being too small; some system, however, is better than the present want of system.

A Letter to the Shareholders of the Bristol and Exeter Railway. By W. Gravatt, C.E., F.R.S. London: M'Dowall. 1841.

We really do not see that we can with propriety enter into the subject matter of this pamphlet, for there has been already so much unpleasant discussion and recrimination, that we are most unwilling to have our columns occupied with a subject so painful, which the farther it is debated, the more productive of ill-feeling does it become.

Outline of a system of Model Mapping. By J. Bailey Denton, Surveyor, Gray's Inn Square. London, Weale, 1841.

Mr. Denton's chief object in producing this pamphlet, has been to call the attention of the agricultural interests to the superiority of model mapping as a means of delineation, and to its application as a basis for draining and irrigating operations. The author shows forcibly the advantages to be derived not only from a proper collection of the waters on an estate, but from their proper distribution and application to useful purposes. He also proposes that model mapping should be resorted to in all designs for the draining of towns. Some of Mr. Denton's specimens we have seen, and they appear to possess a minuteness and accuracy of detail, which is calculated to give satisfaction to those who may avail themselves of this useful art.

THE CALCULATING MACHINE.

There are few efforts of the mind more fatiguing, more irksome, dry and monotonous, than the drudgery of making long calculations. The fixed and unceasing attention to a subject in itself devoid of interest, when the slightest intrusion of thought or fancy destroys the work already done, and compels us to return our weary way, is enough to addle and stupify the brain. No wonder, then, that, from times immemorial, the ingenuity of man should have been directed to the discovery of some contrivance, whereby this wearisome labour might be lightened or abridged. Hence the invention of calculating instruments and mechanical aids of various kinds. This long-sought desideratum appears at length to have been obtained; but before we present to our readers some account of the latest attempts of this kind, we will take a rapid glance at the various endeavours previously made to accomplish the end in view, and which will place in a more conspicuous light the merits of this new invention.

The instruments hitherto contrived for assisting or abbreviating calculations may be classified as follow:—

1. Such as supersede the mere setting down of figures, but requires as close an application of the mind as common arithmetic. To this class belong the calculating boxes of the Russians and Chinese, where the figures are represented by balls moved by wires. Even the Romans possessed an instrument of this kind, called Abacus, in which the figures were indicated by buttons running in grooves.

2. To another class belong such instruments as are constructed on the following principle, viz.:—Two long slender rules are divided into 100 equal parts, those parts being numbered from 0 to 100, and are thus used: If, for instance, it be desired to add 17 to 23, the rules must be so placed that the 0 of one shall be exactly opposite to 17 in the other, then by finding 23 on the first, you will have below it on the second the number 40 as the result. If, on the contrary, you wish to subtract one number from another, as 13 from 30, the number 13 on one rule must be brought opposite to 30 on the other, and under the 0 of the former you will find 17, the remainder. Such contrivances, being of very limited utility, and partaking more of the character of toys than of practical inventions, have long since sunk into oblivion. Instruments on this principle, some square, and others of a circular form, have been produced by Perrault, in 1720; Poetins, in 1728; Peregre, in 1750; Prahl, in 1789; Gruson, in 1790; Guble, in 1799, &c.

3. A third class of instruments for assisting calculators, comprises the "Virgulæ Neperianæ," as likewise the other two works of this celebrated Scotchman—namely, his *Multiplicationis Promptuarium*, and his *Abacus Arcalis* in 1617. In his footsteps followed Caspar Scott, 16_0; Demeam, 1731; Lordan, in 1798; Leopold, Pelit, and others.

Equally well known with the foregoing is the calculating scale, so much used by the English in mechanics, which was invented by Michael Scheffelt, of Ulm, in 1699.

All the contrivances above enumerated, and others which we pass over in this brief sketch, do certainly diminish the labour of arithmetical calculations, more or less, but they all require the attention to be fixed, and do not completely attain the object sought. Hence the aim of scientific men has been to invent an automaton, or self-acting instrument, for calculation, which alone can deserve the name of a calculating machine. The first attempt of this kind was made by Blaise Pascal, in 1640. His machine performed addition and subtraction mechanically; but it was so difficult to work, and the mechanism so imperfect, that it was soon discarded and forgotten. A similar destiny attended a machine for adding and subtracting, invented in England by Samuel Moreland, in 1673. His other mathematical instrument is nothing more than an adaptation of Napier's scale to circles for multiplication and division. The defects and insufficiency of these two inventions of Pascal and Moreland gave rise to subsequent endeavours to improve them. Lepine in 1725, and Hillorin de Boistissandeau in 1730, were not more successful than their predecessors; nor did Gersten's invention, submitted to the Royal Society of London in 1735, afford any greater satisfaction.

In Italy, in 1709, Polenius tried his skill on a machine of this kind, but produced only a coarse unsightly abortion, encumbered with weights, that was far inferior to those which had preceded it. In all these cases the aim of the inventors was only to work addition and subtraction. Leibnitz sought to extend the operations of an arithmetical calculator to multiplication and division. The plan of his machine was submitted to the Royal Society of London in 1673, and met the approbation of the society. A similar honour attended it a short time afterwards from the Academy of Sciences at Paris. But, despite the approbation of those celebrated learned bodies, the plan which looked so promising on paper proved impracticable in execution. Leibnitz laboured hard during his whole life to bring his scheme to perfection, expended vast sums upon it, and yet effected nothing. Death carried him off, and his work remained unfinished and forgotten. In 1727 Leupold promised to publish to the world the plan of a machine that should perform addition, subtraction, and multiplication; he died, leaving behind him only a few fragments of his plan. After this it seems that no further attempts were made for a long period, until, in the year 1799, a minister of Wirtemberg, named Hahn, came forward with a new machine, which, however, attracted no attention, as it was found to commit serious errors in arithmetic: its internal structure remains unknown, as does also that of a faulty instrumen presented to the Academy of Sciences in Gottingen, by Muller, 1786.

The machine constructed by Mr Thomas Colmer in 1820, was a retrograde step in this branch of science.

In the year 1821, Mr. Babbage of London, undertook to construct a machine for Government, which should by mechanical means form tables of progression for the use of surveyors. A portion of this machine, forming a progression up to five figures, was complete—17,000*l.* had been expended on it already, and to perfect the entire work would have required twice as much more; consequently, in 1833, the project was abandoned, and it is not probable that the costly machine will be brought to a perfect state.

The fragment or member alluded to may be seen at the inventor's. Mr. Babbage is at present occupied with the plan of a machine which is to perform mechanically all the operations of algebra. Already he has 30 plans extant; every friend of science must heartily wish that the inventor may be more successful with his new project than he was with the previous one. We come now to speak of the recent successful attempt before alluded to. For the last two years, Dr. Roth, of Paris, has been engaged in the construction of arithmetical machines, and the success that has attended his efforts hitherto, proves he has accomplished his scheme for performing automatically all the operations of arithmetic, from simple addition, subtraction, multiplication, and division, to vulgar and decimal fractions, involution and evolution arithmetical and geometrical progression, and the construction of logarithms, with ten plans of decimals. The machine in its present state works addition, subtraction, multiplication, and both kinds of progression, quite mechanically, In division alone the attention is required to avoid passing over the cipher. The arithmetical progression is of vast importance, as it operates from one farthing to millions of pounds sterling; and when we consider the variety and utility of the functions performed by a small instrument, not more than a foot wide, and its comparatively insignificant price, we cannot but congratulate the inventor on his decided success in the results hitherto obtained, and express our cordial wishes that he may meet with every encouragement to persevere in his highly interesting and important labours.

Mr. Wertheimber, the proprietor and patentee of this invention, has two descriptions of these machines—a larger one which performs sums in addition, subtraction, multiplication, and division; and a smaller, which performs addition and subtraction only. These machines have been submitted to the inspection of several gentlemen eminent for their scientific attainments, all of whom, particularly Mr. Babbage, have expressed the most unqualified admiration at their unparalleled ingenuity of construction. Mr. Wertheimber had the honour of an introduction to the Royal presence, at Windsor Castle, on Wednesday, the 6th inst., when both Her Majesty and Prince Albert were graciously pleased to express their approbation of the machines, and to order two of each sort to be supplied for their use.—*Times.*

STEAM NAVIGATION.

A war steamer has been just built and completed for sea at New York for the Emperor of Russia. She is 2468 tons burden, and is called the Kamtschatka; on trial it was found that under steam only she made nine knots, and with the aid of some of her canvass 13 knots an hour; she has 600 horse power; her spar deck is 240 feet in length, on which she has two ten-inch with two eight-inch hollow shot guns (Paixhans), and 10 36-pounders; she is built wholly of American wood and metal, at a cost of 400,000 dollars.

The Cairo, a small iron steamer, belonging to the Oriental and Peninsular Company, has arrived in our waters, and has, during the week, made several experimental trips, the result of which has been, that, for speed, she can beat any of the steam-vessels which ply between this port and the Isle of Wight very considerably. On Monday last she proceeded hence direct up the Medina to Newport Quay, to the amazement of those along the river, who never saw a steamer there before. She did the distance in one hour and twenty minutes. The engines of the Cairo are complete models; they occupy a space of only three feet by six. *Hampshire Telegraph.*

Improved Feed Apparatus for Steam Boats.—For the purpose of working the force-pumps to suppply the boilers with water when the engines are stopped, Messrs. Penn and Son have introduced into the "Father Thames" steamer, a small engine (about half horse power) occupying a space 15 by 12 inches, driven by the steam which would otherwise be blown off from the safety valve, when the engines are at rest.

The Devastation Steam War Frigate.—This fine vessel which was recently launched from Woolwich Dock Yard, has been fitted by Messrs. Maudslays and Field, with their patent double cylinder engine, (drawings and description of which are given in the 3rd vol of the Journal, p. 73,) and the apparatus for connecting and disconnecting the paddle-wheel, lately patented by Mr. Field; this apparatus is worked with the greatest ease and simplicity. The power of the two engines is 400 horse, and the armament consists of two 10 inch, and four 32 pounder guns placed on swivels, and revolving on circular turn plates let into the floor of the deck. An experimental trip was made on Tuesday the 19th ult, when the vessel attained an average speed of 11½ miles per hour.

ENGINEERING WORKS.

Aberystwith Harbour.—The progress which the works at this harbour have made during the present year, has been both extensive and satisfactory. The length of the pier having been extended seaward 41 yards. Its present length is 261 yards, and it is expected by this time twelvemonth the remaining 39 yards will be completed, which will carry out the pier to its intended length 300 yards. We are glad to state that as the pier is extended seaward, the depth of water at the entrance is found to increase considerably, the heavy weight of the sea being broken on the seaward side makes the inner harbour to be in a perfectly quiet state during the heaviest seas, and the most stormy weather. It is now found that as soon as vessels pass the end of the pier they are in perfect safety. No greater proof can be given of this than the ease and safety with which the great American timber laden ships have passed in and out during the present season. On Saturday last his Grace the Duke of Newcastle and family visited the works, and expressed themselves highly pleased with the progress made since their visit last autumn.—*Carmarthen Journal*, Oct. 1.

South Foreland Light.—The original tower, which was among the first erected in England, is now under the process of demolition, being already almost levelled to the foundation. This tower is said to have been built in the reign of Charles II., and must consequently, have experienced the devastating influence of time for about a century and a half. The original light was coals burnt upon the flat roof of the old tower, which was supplanted in 1793, when the modern one was built for 15 oil lamps. There is also a lower light-house, to enable the mariner, in time of danger, to keep the two lights in a line, and thereby avoid the Goodwin Sands. The object of the Trinity-house, who purchased the property of Greenwich Hospital, in taking down this venerable tower, is to adopt a similar light to the one on the opposite coast, at Cape Grinez, which is found to answer better and more powerfully than those already in use. These ameliorations for the safety of lives and security of property are highly commendable in this body. The height of both cliff and tower will, it is supposed, be about 400 feet above the level of the sea.—*Canterbury Journal.*

Venice.—A bridge is about to be constructed at Venice, intended to unite that celebrated city with the Continent, and to connect it with the railway to Milan. The management of this gigantic undertaking has been delivered into the hands of the engineer Antoine Busetto Pitich. The expense is estimated at 4,830,000 livres Austrian. The bridge will also contain an aqueduct, intended to supply Venice with fresh water, which has hitherto been supplied in boats from the Continent, the city being unprovided with wells and fountains, and having but very few cisterns.

The Athlone Bridge.—This work is progressing wondrously, and the operation by which the workmen are enabled, with perfect impunity, to proceed with the excavations now several yards below the bed of the river, is a subject well worth the attention of the lover of the arts and sciences. By the simple efficacy of a steam-engine of twelve horse power, two large pumps, sunk within the area of the excavation, are set in motion; to these is appended by an air joint a tail which can be extended to any necessary depth, the pumps still remaining in their original position. By this process the accumulating water of springs and leakages, inseparable from a work of this nature, is drawn up and transported to a vast distance, over the heads of the operatives, through wooden troughs or conduits, into the Shannon; and thus an agency superior to the principle that causes its irruption, almost constantly acting upon that element, the men are free from the embarrassment consequent on its aproaches, and the works are made to progress without any material impediment.—*Athlone Mirror.*

Artesian Well at Southampton.—The works of the Artesian well on the common are now proceeding very favourably: the contractors have got to the depth of 430 feet. Should no untoward accident happen, it is expected the works will be completed by the beginning of next summer.—*Hampshire Telegraph.*

The River Thames.—The accurate survey of the river Thames, from Staines to Yantlet-creek, which was undertaken some time ago under the authority of the corporation of London, has been just completed. The following official men were engaged in the survey:—Mr. James Walker, the engineer; Captain Bullock, R.N.; Mr. Charles Pearson, the city solicitor; Captain Fisher, R. N., principal harbour-master of the port of London; Mr. Nathaniel Saunders, the water bailiff; Mr. Stephen Leach, the clerk of the works to the Thames Navigation Committee; and the harbour-masters of the port of London in their respective stations. It is believed that the report which will shortly be made upon the important subject of the improvement of the Thames by Mr. Walker and Captain Bullock, will lead to the adoption of a plan of improvement of immense magnitude, and calculated to render service in a great variety of ways.

NEW CHURCHES, &c

TRINITY CHURCH, NOTTINGHAM.

On Wednesday, Oct. 13, the interesting ceremony of consecration was performed by the Right Rev. the Lord Bishop of Lincoln, at the New Church recently erected on Burton Leys. This building, which has been erected at an expense of £10,000, is a perfect specimen of architectural excellence; the simple and chaste appear to have been studied in its planning; and the grace and beauty of its tall and tapering spire have seldom been surpassed. It may not indeed emulate in grandeur and magnificence the vast piles of masonry reared by the pious zeal of our ancestors—

> "Where, through the long-drawn aisle and fretted vault,
> The pealing anthem swells the note of praise."

but for elegance of design and beauty of execution it may challenge comparison with the most admired of modern structures.

The nave is internally 80 feet long, by 54 feet wide, 30 feet high at the side walls, and 35 feet 6 inches high in the centre. It is approached at each angle through roomy lobbies, or porches; those at the West end contain the stair-cases to the galleries. The seats in the church are placed transversely, and are separated into three divisions, or ranges. The greatest part of those in the centre division are unenclosed and free. Those on each side are in pews, a few of which remain without division for the accommodation of large families; the majority alternately divided, so as to form pews of various dimensions, to accommodate respectively four, five, or six persons. The access to the pews, &c., is from four aisles, extending the whole length of the nave, from East to West, and connected with each other at the East and West ends by broad aisles, at right angles.

The galleries are spacious, and extend the whole length of the North and South sides, approached from the South-west and North-west entrances. There are four longitudinal ranges of pews, and a raised commodious seat against the walls in each gallery. The west gallery has a range of front pews only; the remainder is entirely appropriated to children's sittings, and space for an organ. This gallery has a separate communication from the outside, through the tower; and the inconvenience so often experienced in the departure of the congregation, is entirely obviated by the position, size, and number of the entrances.

The nave is lighted by five triple lancet windows on each side. At the west end is the tower, 14 feet square, which is opened to the nave by a lofty Gothic arch. The lower part is occupied by open seats, and the font, and the upper part is divided into ringing room, clock room, &c. The chancel is at the east end 25 feet wide, and 19 feet deep, and equal in height to the nave, lighted by a large rose, or wheel window in the centre, and a single lancet window on each side. An arch, similar to that of the tower, marks the division between the nave and the chancel. On the right and left are pews for the minister's family, and the communion is enclosed by a low Gothic iron railing. The floors of chancel and tower are elevated one step above the nave, and the communion another step in addition.

On the north side of the chancel is a vestry, communicating with the lobby and chancel; and a corresponding room on the south is appropriated for the warming apparatus.

The pulpit, reading desk, and clerk's pew are centrally situated, near the archway, at the east end of the nave.—The preacher is not only seen by, but faces the whole congregation, except those occupying the two pews in the chancel.

The pews have sloping backs, broad seats, and are 2 feet 11 inches wide, and the whole internal arrangement comprehends those essential requisites—space, comfort, and convenience; the absence of which, in modern churches, is too frequent.

The total accommodation in the church is 1,215 sittings, 415 of which are free.

The roof is supported by nine strongly framed trusses, alternately resting upon stone corbels. The inconvenience and unsightliness of horizontal tie beams (especially in so wide a span), is avoided, by placing the tie beams above the wall plate level, and connecting strong principal rafters at the feet of beams inclining upwards to, and abutting upon the tie beam in the centre. This peculiar construction allows the ceiling to assume the same inclination, which form is so conducive to the conveyance of sound, and effectual ventilation; for which latter purpose three large circular ventilators are provided at the intersection of the principal timbers. The whole of the wood-work of the roof below the ceiling line, is moulded and painted in imitation of oak; and the longitudinal ceiling beams divide the whole into compartments.

The details of the interior are designed with strict regard to durability and economy; due care having been taken that the eye be not offended by incongruities of style. Ornament is sparingly introduced, and in those parts only where it conduces to the general harmony and effect.

The exterior is cased with stone, and the style of architecture adopted is that called *early English*, used in this country during the 13th century. The sides are divided into five compartments, by substantial weathered buttresses, canted at the angles, and terminated at the level of parapet by sharply pointed hoods. Each compartment is filled with a triple lancet window. The centre light, higher than the side ones, is 20 feet high. The jambs and mullions are faced by the characteristic column, with its base and capital. The door-ways are deeply recessed with a trefoil over the head, covered by a pyramidal drip moulding. The staircases at the north and south-west angles are necessarily higher than the corresponding entrances at the opposite end of the church, but do not attain the same elevation as the flanks, in order to show as much of the base of the tower as possible; they are lighted by single lancet windows, facing the west. The parapet of the nave and chancel is supported by a corbel table, and the base is in two divisions, each terminated by a deep weathered horizontal moulding. The chancel is lofty, the roof being a continuation of that of the nave. At the east end is a trebly composed window; in the centre of the head is the large wheel before mentioned, which alone is glazed (with coloured glass), all the lower part being blank, to prevent the admission of too strong a glare of light behind the preacher; the jambs, mullions, tracery, &c., being sufficiently recessed to relieve the plainness of the end. The double rectangular weathered buttresses of the chancel are terminated by octangular pinnacles, and the blank spaces in the gable and sides are relieved by quatre-foils. The tower at the west end has substantial double buttresses at each angle, and a triple lancet window of the same dimensions as those in the flanks, which is seen through the archway from the church. A pointed arched corbel table supports the string course. Another compartment is formed by a string course at the level of the ridge of the roof.—From this point upwards is the clock room, with a circular space for dial on every face, and marked also by a weathered string course; at this point the tower is sloped off by weathered angles to an octagon, and four pinnacles surmount the buttresses. The belfry is lofty, and each face is pierced by a lancet window, in unison with those before described. Each angle of the tower is terminated by a pinnacle, and the parapet is pierced. Above this rises the spire, ribbed at the angles, with three tiers of openings and hoods. The whole height from the ground to the apex of the spire is 172 feet. The architect is Mr. H. I. Stevens, of Derby.—*Nottingham Journal.*

Risley Church.—This picturesque little church, having undergone considerable repairs and enlargements, was re-opened for divine service on Sunday, the 3rd of October. Alterations have been effected according to the designs and under the superintendence of Mr. Stephens, architect, Derby. A capacious aisle has been erected on the north side, connected with the body of the church by two gothic arches, capable of accommodating about 120 persons, of which 61 sittings are free and unappropriated. A beautiful window, representing the two great apostles, St. Peter and St. Paul, painted by Mr. Warrington, of London, has been placed in the chancel.

The sum of £1,100 has been subscribed by the parishioners of Tettenhall in aid of the extensive alterations and repairs which are being made in the church of that parish.

Woolwich.—The first stone of the new Scotch church at Woolwich was laid on the 8th of September, with a very imposing ceremonial, there being present above 500 of the military members of the church. Colonel Dundas officiated on the occasion. The church is to contain 1000 sittings; the dimensions of the interior in the clear are 76 ft. 3 in. by 51ft. 6 in. It is of the Norman style with a spire. The contract for the carcase has been taken by Mr. Jay for £1850. Mr. T. L. Donaldson is the architect.

St. Pancras.—A new church is about to be built in Gordon Street, St. Pancras, to contain 1200 sittings. Mr. T. L. Donaldson, the architect, has designed the front in the style of the "Renaissance." It consists of 4 pilasters raised upon a lofty stylobate. The doors are circular headed, and are between the outer pilasters on each side, the window being the centre object, divided in the middle by a column, and circular headed like those of Bramante. The whole is surmounted by a regular entablature, pediment and bell tower. The committee have accepted Messrs. Haynes' tender to erect the carcase for £2825.

The Temple Church.—Probably the public may not be generally aware of the extensive reparations which this ancient building is now undergoing. The object which the society have in view is the complete restoration of the church to its former state—to that in which it was originally completed. The church is a mixture of the Norman and early English styles, and has generally been considered the best of the few round churches of which this country can boast. The interior has been completely stripped of all its former ornaments and monuments, of which those of sufficient value, and which it is desirable should be retained, are being brought into a state which will harmonize with the character of the rest of the building. The ceiling of the choir and side aisles of the church, and particularly of the eastern portion, which is a fine specimen of early English, was originally painted and embellished in ornamental work of a very high character. The effect of this, which can already be partially seen, will be very beautiful and striking. It may also be in the recollection of some, that in the large circular tower next to the entrance of the church were several columns of the Corinthian order. These from possessing a rather dilapidated appearance, arising from their antiquity, will now be restored to the highly polished marble pillars of the time of the Templars. There are many other parts of the building to which we could wish to draw attention. The figures of the old Templars will be preserved, as also those in the porch outside the entrance. The church has already been closed for about a year and a half, and it is expected it will take full that time in addition before the work is completed. The Temple Church will then rank as one of the finest buildings of the metropolis, carrying with it, as it does, the respect due to age.

MISCELLANEA.

The Bude Light.—The new system of lighting and ventilating by means of this improved light was most successfully shown at Christ Church, Albany-street, Regent's-park, on Sunday, 1st ult., at the evening service, a more perfect illumination having been produced by two ornamental lustres (similar to those used in the House of Commons) than by the 72 argand burners previously used there. The perfect ventilation of the church was likewise effected by means of flues ascending from these lustres through the ceiling into the open air, which carried off all heat, noxious products of combustion, as well as air vitiated by respiration, so prejudicial to health in close or crowded apartments. These advantages appear to be peculiar to a light of this power, as lights of a lesser power must be placed at such distances from the ceiling, in order to illuminate the lower parts of a room or building, as would render impracticable any attempt to carry ventilating flues from each light; independent of which, the glare from a multiplicity of naked lights is not only offensive but injurious to the sight. These improvements were adverted to in a very appropriate manner from the pulpit by the rector, Mr. Dodsworth, to whom, as well as to the Hon. Captain Maude, one of the churchwardens, much credit is due for their exertions in providing a remedy for evils of this nature, which had been much complained of in this church—evils to which all unventilated apartments must be more or less liable.

Gigantic Chimney.—A chimney of extraordinary dimensions is being built at St. Rollox chemical works, and will, when completed, be elevated upwards of 600 feet above high-water level at the Broomielaw; it is founded upon a bed of solid sandstone rock, 20 feet below the surface of the ground; the diameter of the outer chimney is 50 feet at the foundation, 40 feet diameter at the surface of the ground, and will diminish in one unbroken curved line or "batter" to a diameter of 14 feet 6 inches, when it will have attained an altitude of from 420 to 430 feet. The inner chimney is a cylinder of sixteen feet diameter, rising perpendicularly to a height of 260 feet. This inner chimney is unconnected with the outer one, but comes very nearly in contact at its termination, allowing only space for the expansion arising from the temperature. The bricks used in the work are a composition of common clay and fire-clay, containing a small portion of iron ore.

New Railway Signals.—A new system of signals for railroads has been invented by Mr. Hall, the managing director of the Eastern Counties Railroad, intended to supersede the red and white flags now carried and exhibited by policemen at certain distances, and which have been sometimes found inadequate to the purpose. The new signal, which Mr. Hall calls the "Panel or fan signal," has, when put in operation, the appearance of an upright post of about 12 feet high, surmounted by a piece of woodwork resembling in shape that of a closed fan. Where they both join is a strong iron frame. In the upper woodwork three panels are encased, which are worked by machinery, and when brought down to the iron framework before described, assume the appearance of a crimson quadrant of a span sufficient to be visible in a straight line for two miles. When a train is due to start, the three panels are lowered. As soon as it has started and reached the signal, the man in charge of it sets in motion a piece of machinery, which gradually works up the three panels in 15 minutes, and the signal at the end of that time presents its original appearance. By this arrangement engine-drivers will be able accurately to calculate the time which has elapsed since a train has passed; one panel indicating five minutes, two ten, and three a quarter of an hour. The new signal will, in a few days, be put in operation on the Eastern Counties Railway.

Wear of Granite Pavement.—During 17 months, the following was the relative wear of pavement made of the granites named, laid down on the Commercial-road in London:—Guernsey, 1·0; Herm (an island close to Guernsey), 1·19; Budle (a Northumberland whinstone), 1·316; blue Peterhead, 2·08; Heyton, 2·238; red Aberdeen, 2·524; Dartmoor, 3·285; blue Aberdeen, 3·571. These differences are very considerable, and are, in a great measure, to be attributed to the mineralogical structure of the stone, granite being composed of at least three species, mica, feldspar, and quartz, of which the quartz is the hardest and the mica the softest. Permeability to wet is also a rapid cause of disintegration, especially in conjunction with frost. It is melancholy to see many of our public edifices rapidly hurrying to decay, from the bad qualities of the stone employed in their erection. Great attention should be paid to the qualities of the stone, in selecting railway blocks; although the opinion of railway engineers is now most inclined for timber bearings. Leaving out the question of first and last cost, longitudinal timbers with iron cross trees, decidedly make the most pleasant road; and the effect of this, not only on the passengers, but the engines and carriages will, in our opinion, put the ultimate cost on one side. We shall not easily forget the smoothness of the Great Western Railway, which was so evident as to admit of no doubt, although, when we went on it, we were much prejudiced against it, from what we had heard; our prejudices were soon dispelled.—*Railroad Journal.*

Discovery of Ancient Pavement.—In addition to the ancient paintings discovered lately by Mr. Devon, in the Chapter-house Record-office, he has found under the present wooden floor a pavement composed of the ancient Norman tile, which is characterized by figures in gold, burnt in brick. The figures on these tiles are very beautiful and various. Among them are the arms of England, as borne in the thirteenth century, when the building was erected, lions placed back to back, female figures seated on chairs with hawks on their wrists, David playing on the harp, musicians playing on the violin, and various other patterns, making altogether a most magnificent groundwork. The art of preparing similar tiles has been recovered, and fac-similes of those in the Chapter-house are now being manufactured in England for the Temple Church.

Absorbing Wells.—The Council General of the Department of Isere has voted the sum of 1800 francs for the application of absorbing wells to the drainage of the numerous ponds and marshes in the neighbourhood of Bourgoin. The principal engineer of the mines, Gueymard, on whose report the grant has been made, is to superintend the first experiments. If, as it is believed, there lies between the diluvial soil and the turf or peat of these marshes a stratum of clay, it will only be necessary to penetrate through it to attain the sand and diluvial gravel, which form the subordinate strata, and the success of the undertaking will then be placed beyond all doubt. The drainage of the bogs of *Verpilliere*, *Bourgoin* and *La Tour du Pin* will of course follow; and those of Dauphiny, which up to this period have been so unprofitable, will develop a new source of riches for a country, which has hitherto only considered them as a serious inconvenience. Should the absorbing wells have the success which we anticipate, the turf districts of Bourgoin will assume, in regard to Lyons and Grenoble, the same importance as those of Menecy and the department of the Eure have held in relation to Paris and Rouen. Every one is aware that turf has the property of carbonization like wood.—*Courrier de Lyons.*

New Locomotive.—M. de Ridder has completed a new locomotive in which he has found means to turn to account the quantity of steam which is suffered to escape in other locomotives. The result of this improvement is a great saving of fuel, besides diminishing the weight. The dimensions of these new locomotives are such as to hinder the use of them on iron railways. Perhaps M. de Ridder had in view the realization of his projected railway by St. Nicholas. However that may be, we have examined attentively this machinery in all its parts, and it appears to us to be one of the most satisfactory of the kind hitherto made in Belgium.—*Brussels Paper.*

China Grass-cloth.—If any person will be at the trouble of cutting a leaf from an aloe plant, which is reared and encouraged as an exotic in this country, he will, upon close inspection, detect a course of long white fibres, possessing considerable tenacity. These, when taken from the fleshy part of the leaf, and placed together by themselves, will exhibit a very beautiful clean hemp, corresponding precisely with the material of which the linen called China grass cloth is composed. The aloe grows wild and in great abundance throughout China, and the people of that country have turned it, as they do everything else, to a profitable account. The flax which constitutes the fishing lines known under the name of Indian twist, but which is in reality a Chinese production, is manufactured from the same identical commodity. There are many Chinese inventions, at present retained as a monopoly by the above people, which are easily capable of being arrived at by those of other countries, if proper attention and a very moderate share of curiosity were bestowed upon the subject.

United States Bank Building.—The extinction of the United States Bank leaves that magnificent edifice in the hands of the assignees, as a part of its available property. To what use it will now revert, is matter of conjecture. This splendid pile was commenced in 1819. It was five years in building. The original expense was 500,000 dollars, but when the old bank charter expired, it was sold to the present institution for 200,000 dollars. The building is purely of white marble, and both inside and out scarcely any wood is to be seen. From Chestnut-street the bank is reached by a lofty flight of marble steps. It presents a splendid front of 80 feet in width, with eight Doric columns, four feet six inches in diameter, and 27 feet high. The building is 161 feet long, and the porticoes at each end correspond. Both internally and externally the style and finish are equally massive and beautiful. The principal banking room is 48 feet wide and 81 feet long, with an arched ceiling, supported by rows of marble columns. Aside from this, there are a multitude of apartments, for the use of the different officers and directors, as well as for engravers and copperplate printers. It is admired for its beautiful proportions, as well as for its imposing size and classic architecture.—*Times.*

EXTRA HIGH TIDES OF THE RIVER THAMES.

The following table shows the heights of extraordinary high tides for the last 20 years, by which it will be seen that the unusual high tide of the 18th ult. was the highest:—

		ft. in.	ft. in.
1821	Dec. 28	27 1½	2 10½
1824	Dec. 23	27 3	3 0
1827	Nov. 21	27 5¼	3 2½
1834	Jan. 29	27 2	2 11
1836	May 2	26 10	2 7
1841	Oct. 18	27 7	3 5

The total heights are those of the rise of tide above the sill of the Blackwall entrance to the West India Docks, which is 24 feet 3 below H. W. Trinity standard, and 6 feet 5 inches below L. W. of the same standard. The other column shows the rise of tides above zero, or Trinity High Water Mark.

Thames Tunnel.—Considerable fears were entertained during the late flood, that this great work would have filled with water, the top of the shaft at Wapping being only three feet above the level of the surrounding ground—fortunately the water subsided without in this case doing any damage. The shaft on the Wapping side is already sunk to the level of the excavation, under the bed of the river, of which only seven feet and a half remain to form the junction, so that in about another month the Tunnel itself will be completed.

Plate Glass.—This article is of late being introduced for purposes some time back little thought of, it is now manufactured as thick as ¾ of an inch, and is used unpolished in floors where a light is required to be thrown down on a story below, even as a substitute for coal plates we have seen it used, when the top surface is ground.

Carpenters' Mallet.—An improvement has been introduced by encasing the mallet with a ferule or case of iron ⅛ to ¼ of an inch thick with the wooden ends protruding, thus a small mallet about 3 by 2 inches on the end is equal in weight to the largest size mallet made entirely of wood.

A Steamer launched at Canada.—On the 13th of September, a splendid new Government steamer, constructed by Mr. J. Tucker, Admiralty Architect, was launched from the building yard of Messrs. Millar, Edmonstone, and Allen, at Montreal. The day selected for the launch was the anniversary of Wolfe's victory. The length of the Sydenham between perpendiculars is 170 feet, the breadth 27 feet, and the depth of hold 16 feet 9 inches. She is to carry two 68-pounder guns, and be propelled by two engines of 110-horse power each. On examining the vessel after the launch, it was found she had only settled one-eighth of an inch, a result highly flattering to the skill and talent of the architect.

LIST OF NEW PATENTS.

GRANTED IN ENGLAND FROM 24TH SEPTEMBER, TO 28TH OCTOBER, 1841.

Six Months allowed for Enrolment.

JEAN LOUIS ALPHONSE PETIGARS, of Brewer-street, Golden-square, gentleman, for "*improvements in the construction of presses.*" (Being a communication.)—Sealed September 24.

HUGH LEE PATTINSON, of Bensham Grove, Gateshead, Durham, manufacturing chemist, for "*improvements in the manufacture of white lead, part of which improvements are applicable to the manufacture of magnesia and its salts.*"—September 24.

FREDERICK BROWN, of Linton, Bedford, ironmonger, for "*improvements in stoves or fire-places.*"—September 24.

THEODORE FREDERICK STRONG, of Goswell-road, engineer, for "*certain improvements in locks and latches.*"—September 28.

SAMUEL STOCKER, of Barford-street, Islington, engineer, and GEORGE STOCKER, of Birmingham, cock-founder, for "*improvements in machinery and apparatus for raising, forcing, conveying, and drawing off liquids.*"—September 28.

JOHN WHITE, of Burton-in-the-Wolds, Leicester, farmer, for "*an improved horse hoe, for use in agricultural pursuits.*"—September 29; four months.

JOSEPH MILLER, of Monastery Cottage, East India Road, engineer, for "*an improved arrangement and combination of certain parts of steam engines, used for steam navigation.*"—September 29.

EDWARD WELCH, of Liverpool, architect, for "*certain improvements in the construction of bricks.*"—September 30.

WILLIAM HIRST and JOSEPH WRIGHT, of Leeds, in the county of York, clothiers, for "*certain improvements in the machinery for manufacturing woollen cloth, and cloth made from wool and other materials.*"—October 7.

THOMAS WELLS INGRAM, of Birmingham, manufacturer, for "*improvements in shears, and other apparatus for cutting, cropping, and shearing certain substances,—parts of which said invention being a communication from a foreigner, residing abroad.*"—October 7.

JOSEPH CLISILD DANIELL, of Tiverton Mills, Bath, for "*improvements in the manufacture of manure, or a composition to be used on land as a manure.*" October 7.

MATTHIAS NICOLAS LA ROCHE BARRE, of St. Martin's-lane, Middlesex, manufacturer of cotton, for "*an improvement in the manufacture of a fabric, applicable to sails and other purposes.*"—October 7.

MARCUS DAVIS, of New Bond-street, optician, for "*improvements in the means of ascertaining the distances vehicles travel.*"—October 7.

THOMAS BIGGS, of Leicester, merchant, for "*improvements in securing hats, caps, and bonnets, from being lost by the effects of wind or other causes.*"—October 7.

BENJAMIN AINGWORTH, of Birmingham, gentleman, for "*improvements in the manufacture of buttons.*"—October 7.

JOHN JONES, of Smethwich, Birmingham, engineer, for "*certain improvements in steam engines, and in the modes or methods of obtaining power from the use of steam.*"—October 7.

JOHN HARWOOD, of Great Portland-street, gentleman, for "*an improved means of giving expansion to the chest.*"—October 7.

WILLIAM NEWTON, of the Office for Patents, 66, Chancery-lane, civil engineer, for "*certain improvements in engines to be worked by gas, vapour, or steam.*" (Being a communication.)—October 14.

MOSES POOLE, of Lincoln's Inn, gentleman, for "*improvements in fire-arms.*" (Being a communication.)—October 14.

EDWARD MASSEY, of King-street, Clerkenwell, watchmaker, for "*improvements in watches.*"—October 14.

HENRY ROSS, of Leicester, worsted manufacturer, for "*improvements in combing and drawing wool, and certain descriptions of hair.*"—October 15.

JUNIUS SMITH, of Fen-court, Fenchurch-street, gentleman, for "*improvements in machinery for manufacturing cloths of wool and other fibrous substances.*" (Being a communication.)—October 20.

JOHN BRADFORD FURNIVAL, of Street-Ashton, farmer, for "*improvements in evaporating fluids, applicable to the manufacture of salt, and to other purposes where evaporation of fluids is required.*"—October 20.

HENRY DAVIES, of Birmingham, engineer, for "*certain improved tools or apparatuses for cutting or shaping metals and other substances.*"—October 21.

THOMAS JONES, of Varteg Forge, near Pontypool, Monmouth, engineer, for "*improvements in the construction and arrangement of certain parts of marine and stationary steam engines.*"—October 21.

JAMES WHITWORTH, of Bory, in the county of Lancaster, manufacturer, and HUGH BOOTH, of the same place, machine maker, for "*certain improvements in looms for weaving.*"—October 21.

MARTYN JOHN ROBERTS, of Brynycairau, Carmarthen, gentleman, and WILLIAM BROWN, of Glasgow, merchant, for "*improvements in the process of dyeing various matters, whether the raw material of wool, silk, flax, hemp, cotton, or other similar fibrous substances; or the same substances in any stage of manufacture; and in the preparation of pigments or painters' colours.*"—October 26.

THOMAS HOLCROFT, of Nassau-street, Middlesex, gentleman, for an "*improved portable safety boat or pontoon.*"—October 28.

TO CORRESPONDENTS.

An Architect accuses us of discontinuing to give the particulars and amount of contracts of New Churches and Public Buildings; we can assure him and the Profession generally, that we have every disposition to insert any announcement that may be sent us, but we find the architects so backward in forwarding the particulars required, that it is impossible for us to give the information, although we are most desirous to do so.

We have received another communication on Competition, requesting us to announce the amount of contracts of those Buildings which far exceed the limited amount of the conditions of Competition; we are not in possession of them, but if any information be forwarded us on the subject, we shall be happy to announce it.

The next number will conclude the fourth *volume.*

Communications are requested to be addressed to "The Editor of the Civil Engineer and Architect's Journal," No. 11, *Parliament Street, Westminster.*

Books for Review must be sent early in the month, communications on or before the 20th (if with drawings, earlier), and advertisements on or before the 25th instant.

Vols. I, II, and III, may be had, bound in cloth, price £1 each Volume.

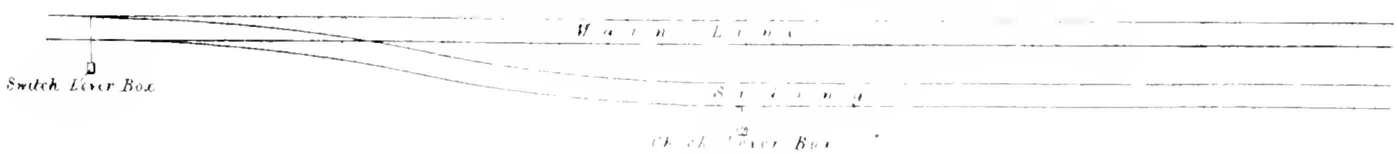
PLAN SHEWING POSITION OF CHOCK



LONDON AND BIRMINGHAM RAILWAY.

SELF-ACTING CHOCKS.

With an Engraving, Plate IX.

THE object of these chocks is to prevent carriages or other vehicles from being blown out of the sidings on to the main lines of railway, or from their being pushed out by inattention or carelessness, the consequences of which, especially during the night, have frequently been collisions of a more or less serious nature.

The chock *(a)* (forged out of a piece of railway bar) is placed upon one of the rails of the riding: the end next the switches, is turned back to the centre *(b)* from which it moves, the other end is formed to receive the periphery of the wheel, a balance weight contained in the box *(c)* is attached to the chock, and so hung as to retain it upon the rail; by means of the lever *(d)* the chock can be withdrawn from the rail, the chair *(e)* carries the centre pin *(b)*, and the chair *(f)* supports the chock when withdrawn from the rail. It is obvious that the wheels of a carriage, when pushed into a siding, will open the chock by pressing against its inner surface, and that when the wheels have passed, that the balance weight will return the chock upon the rail, and that no carriage can pass from the siding to the main lines until the chock is withdrawn by the handle *(d)*.

These chocks have been in use upon the London and Birmingham Railway upwards of 12 months, and are found to answer the purpose intended.

R. B. D.

KARL FRIEDRICH SCHINKEL.

IN this eminent individual, who died at Berlin on the 10th of October last, in his 61st year, architecture has lost one of its ablest professors and greatest ornaments an artist of whom Germany may justly be proud, and who was well entitled to the splendid funereal honours paid to him in the capital he had adorned with so many noble monuments of his taste and genius.

It was, we believe, the Foreign Quarterly Review, which first of all made the name of Schinkel known in this country, by calling attention to some of the principal works he had then executed, and speaking of them in terms of commendation, which, strange to say, so excited the wrath of Mr. Joseph Gwilt, that he thought proper—not at that time but a year or two afterwards, to attack the article in that periodical, and attempt to write down Schinkel. With that extraordinary exception, all that we have ever read or heard concerning Schinkel and his works, has been uniformly expressive of admiration. In fact, many of our readers, at least so we are willing to believe, must be well acquainted with his "*Entwürfe*" or published designs, for they ought to be in the library of every architect who can afford to purchase them.* He has been characterized as being the poet of architecture, who, instead of merely transcribing and copying the Greeks, has shown himself imbued with a kindred feeling, and has expressed himself as they would have done under similar circumstances.

Without pledging ourselves to admiration of all he has done—certainly not as regards his designs in the Gothic style—we scruple not to affirm that many valuable novel ideas and motives are to be met with in his works, although not to the extent that might have been, for he has repeated himself too frequently in many features, especially his doors, which are nearly on every occasion alike. However, reserving criticism of this kind for some other opportunity, when we may probably enter into description of some of the structures erected by him, we shall at present confine ourselves to such a biographical notice of Schinkel himself as we have the means of collecting from the sources just now at hand.

Karl Friedrich Schinkel was born at Neuruppin, where his father was "Superintendent," March 13th, 1781. By the death of that parent in 1787, he was left totally dependent upon his mother, who placed him in the Gymnasium or public school of his native town until the age of 14, when the family removed to Berlin. Having manifested a decided taste for drawing and designing, he there became a pupil of the elder Gilly, the architect, and afterwards of the son, Professor Gilly, to whose instructions he was in no small degree indebted for the liberal views he afterwards entertained of his art, as one affording scope for the exercise of invention, fancy and taste. The younger Gilly, however, died within about two years, and the completion of several buildings was in consequence entrusted to Schinkel. Not long after this period, he began to apply himself more to designing and to the study of architectural composition; also to making designs for vases, bronze work, ornamental furniture, and other things of the kind, wherein he could display taste, and which, although they do not exactly belong to the province of the architect, as it is usually defined, are not at all more alien from it than some others presumed to belong to his professional pursuits, notwithstanding that they have no connexion with art, and but very remotely with practical building.

At length he determined upon visiting Italy, and set out for that country in the spring of 1808, taking his route through Dresden, Prague, Vienna, and Trieste. After examining the antiquities of Istria, he passed over to Venice, thence proceeded to Florence and Rome, and in the following year to Naples and Sicily, returning through France, and reaching Berlin after an absence of two years. At that period the state of public affairs in Prussia was exceedingly unpropitious to his prospects in his profession, more especially in that higher department of it to which he aspired; and he therefore devoted himself for a while to landscape painting—partly views of some of the places he had visited, and partly original compositions, which he generally made the vehicle of his architectural ideas, introducing into them studies and designs of his own. These productions earned for him no small reputation, and by so doing they probably opened for him the career in which he subsequently obtained such universal celebrity. On the return of the royal family, he was commissioned to make designs for some alterations in the palace, and in 1810 was appointed *assessor* of the *Baudeputation* or Board of Works and Buildings, his duty being to give his advice upon matters of taste.

At the time of the Allied Sovereigns being in this country, he received an order from the King of Prussia to prepare designs for a Cathedral to be erected in the capital as a testimonial in honour of the military achievements so felicitously terminated. But although all the plans and drawings for this *Pracht-bau* were finished, it was considered more advisable to postpone the work itself indefinitely to some future opportunity.

Nevertheless, though he was doomed to disappointment in regard to the execution of that magnificent project, the restoration of peace was the epoch from which Schinkel's career as an architect may be dated. It was at that period his talents were first called into play, and important opportunities afforded them, almost uninterruptedly, for a series of years, during which he not only erected most of the finest of the public structures which now grace the capital of Prussia, but also many at Potsdam and various other places, besides numerous others for private individuals. To Schinkel, it has been observed, Berlin is indebted for a new physiognomy, one that imparts to it an original and peculiar character: and certainly his works, even the least successful of them give evidence of geniality, and of an inventive mind, less scrupulous as to following established precedents, than ambitious of forming precedents for others, and of extending the limits of the art. Among the earliest and certainly not the least successful of his works in the capital are the large Theatre, the Wachtgebaude, and the Museum. To these succeeded the Werder Church, Bauschule, Observatory, &c. &c. Of the buildings here mentioned, together with a great many others, the designs are given in his "Entwurfe;" and many of them are illustrated more copiously than is usual in works of the kind, not only by sections and plates of detail, but by perspective views both exterior and interior. The plates themselves are all in outline, nothing being shaded except the ground plans and solid parts of the sections, therefore those in perspective do not fully express the effect of the buildings themselves. All of them are beautifully drawn, —perhaps too delicately, for they certainly do not possess that vigour and spirit which are so captivating in some of the French architectural works *au trait*. The publication itself, however, has extended Schinkel's influence as well as his reputation, and has almost given rise to a new school of the art in Germany. Among his immediate pupils may be named, Stuler, Knoblauch, Burde, Menzel, Geisler, Strack, besides many others of rising talent in their profession. Among Schinkel's other publications is one consisting of a series of designs for furniture (Mobel-entwurfe), and "Entwurfe der Hoheren Baukunst," containing designs for the new royal palace, on the Acropolis, at Athens, for which, however, another site was chosen, and Gartner of Munich appointed the architect.

---

* Such, however, is certainly not the case, for we know of one who borrowed them of a bookseller, under the pretence of keeping them if approved of, and then ordered him to send for them again, when it was discovered by marks left on it, that he had copied one of the plates for some particular purpose, on which account he had just then occasion for the work. However as the poor devil alluded to makes only a few thousands a year by his practice, it is not much to be wondered at that he should be obliged to borrow books of the kind, instead of purchasing them Another reason for the miserable creature's not keeping Schinkel's works might be that they reproach his own for the want of every merit the German architect displays.

AN ARCHITECTURAL NOTE FROM PARIS.

By George Godwin, Jun., F.R.S., &c.

If the same spirit which now seems to pervade all classes of the population there should continue to prevail, Paris will speedily become the most elegant city in the whole world. New *quartiers* are being built, old houses razed to the ground, fresh streets opened; her ancient glories protected and restored, the modern public monuments long in progress, completed with magnificence quite regardless of expense. No person who visits Paris with his eyes and ears open, can fail to observe how much more general are a knowledge and love of art there than in England,—how much more interest all matters connected with it appear to excite, how much more competent to judge in it the majority of persons are, and consequently how much reason there is that its professors should become numerous and eminent. The result of the free admission of the people to national monuments and works of fine art, and of the liberal encouragement afforded by the government to the arts of design, is becoming more evident every day, and is seen to be in most respects good. Something more than this it is true, is necessary to ensure the perfect happiness and well-being of a state, but with this just now the writer has nothing to do: he alludes to it simply to prevent any from supposing that he considers the encouragement of the fine arts the only one thing necessary, and to answer in some degree a remark which might be, in fact which has been made, namely, that as France is not more tranquil and prosperous, politically, than we are, this cultivation of the arts has been of little service, and is therefore not greatly to be desired. Depend upon it if it were not for this, France with her myriad population,—fermenting, unemployed, would be in a much worse state than she now is. Love of the fine arts amongst the people generally, is *one* of the anchors by which the stability of a state may be ensured.

Hardly a house is now erected, even in the back streets of inferior localities, without highly enriched dressings for the doors and windows, balconies of which the soffits are sculptured, cornices richly decorated. The pediments over windows are filled with foliage, every moulding is enriched; and figures and heads (in most cases effectively, and in many instances beautifully sculptured), ornament the piers, or the spandrells of arches. Ironwork of elaborate design fills the lower part of the window openings from the top of the building to the bottom, and this being partially gilded, aids materially the general effect. The *Cité des Italiens*, a building near the Boulevard des Italiens, designed by the brothers Kaufman, (the eldest of whom died prematurely), may be cited as a good example. The window dressings are exceedingly elegant, the general arrangement excellent, in fact as a whole it quite puts to shame any specimen of street architecture of which we can boast. The interior court displays much richness of fancy. The café adjoining this building and fronting on the Boulevard, is another instance, and presents a series of elaborately sculptured adornments over the whole of its two fronts. The frieze above the ground floor is especially worthy of examination. On the Boulevard Bonne-Nouvelle; in the new quarter towards the north, near the church of Notre Dame de Lorette; in the neighbourhood of the Madeleine; indeed in nearly every part of the city, other buildings might be instanced. Stone being used universally as the staple building material, the houses as all know, have an aspect of substantiality and permanence not to be attained with our 14 inch brick walls and compo adornments. The stone generally employed does not take a good face, being full of shell-holes and cavities, but nevertheless is of nice colour and seems to endure tolerably well. It is found necessary however, to protect from the weather the tops of walls and the upper surface of large projections, such as cornices, for which purpose sheet lead is employed.

With regard to the execution of the sculpture spoken of, one cannot but be surprized at the number of workmen in Paris, for the most part very young, who are found competent for it. They form a class which we have not, but much want in England, coming between the mere stone cutter and the professed sculptor,—the first of whom cannot execute this description of work, and the latter may not. Our schools of design when made numerous will perhaps supply this desideratum, but that which would perhaps be even more effective in producing the class of artists alluded to, is a greater demand for this description of talent on the part of the public. Did we require here to cover a house with foliage and figures of stone, we should have to make search for half a dozen men capable of performing it satisfactorily, whereas in Paris there are scores, it might almost be said hundreds, judging from appearances, who could be found to execute it effectively. In the article *Carton pierre*, to illustrate the point a little further, it is found that designs sent from England may be modelled in Paris, worked in this material and returned to us, at less cost than the same designs can be executed here in an inferior manner, chiefly because of the scarcity of efficient hands.

Now we must not infer from the above that there is any want of ability, or any natural inferiority on the part of our countrymen, experience proves the contrary triumphantly: it results there can be no doubt from the little attention paid to the arts of design in the education of our operatives, the want of opportunity to study beautiful forms and to raise their standard of taste by the contemplation of works of fine art, as well as from the limited nature of the demand for artistical productions,—this latter being in part a result of the operation of the two former causes amongst other classes of society. I am glad to find Mr. W. Dyce, the excellent superintendent of the Government School of Design, alluded to this subject in his evidence given before the last Select Committee on the Fine Arts. Mr. Dyce said with respect to the effect the decoration of the new Houses of Parliament would have on the arts of design for manufactures, "we want a middle class of artists; we have only at present artists of the highest sort, those who paint pictures, and of the lowest, who make patterns of the worst description for manufactures; we want a middle class, who have the knowledge of artists, and the skill of ornamentists." And again, "I should say the same thing with regard to sculptured ornaments as I have said with regard to painted ornaments, that we want a middle class of artists,—a class of artists who could execute such statues as those in Henry the Seventh's Chapel, which are not good enough to be the work of first-rate sculptors, but still are sufficiently good for the purpose."

To return to the mode of building in Paris, it will be observed by every one that plain squared masses of stone are alone put up in the first case, and that all the ornamental parts are worked out of them after the erection is finished, beginning at the top and making all perfect as they go down. When a very hard stone is not used this method seems to have several advantages: injury to delicate parts during the progress of the work is avoided, and furthermore the effect of a decoration in its position can be judged of when first commenced, and altered if need be.

Many of the doorways in recently finished hotels are exceedingly elegant. In some cases the upper panels contain glass protected by elaborate ironwork of beautiful designs.

M. Hittorff to whom was confided the completion of that *rendezvous* of monuments, the Place de la Concorde, after the erection there of the Luxor obelisk, has constructed a theatre for the exhibition of horsemanship in the Champs Elysées, and called the *Cirque National*, which is perhaps the most striking thing of its kind ever seen. The plan is a polygon with a portico on one side adorned with sculptured figures and enriched mouldings. Colours are successfully employed here in external embellishment of the architectural members, being so far as my own knowledge extends, the only instance of their use on a stone building in France or England.* The building is of large size, and would probably contain several thousand persons. The seats, much elevated one above the other, extend all round the theatre, the arena being in the centre, and the horses and performers entering by two openings on the ground level. When filled with spectators the upper part presenting vast unbroken circles of them, the effect is very striking. The roof, which together with the rest of the interior is a mass of ornamental painting and gilding, is supported on sixteen very light columns (of iron) and arches.

Amongst the most important restorations going on are those of the *Hôtel de Ville*, (designed nearly at the commencement of the 16th century and completed at its close,) and of the *Sainte Chapelle* adjoining the Palais de Justice. At the former, which is a curious and valuable specimen of the *Renaissance* period, the style whereof in its purer shape, is now literally the *rage* in Paris, considerable additions as well as restorations are being made at a great expense. At the *Sainte Chapelle* where every one knows there is some most excellent stained glass, the whole of the interior having been originally painted and gilt, is being restored. In order that it may be made a perfect work, the municipal council have voted the sum of 4,000*l.* annually, to be paid, it is said, so long as the architect may require it for this purpose! The fact that in the interior of nearly all churches in the middle ages, colours and gilding were employed systematically to aid the architectural effect, has been but recently arrived at with certainty either there or in our own country: now however, scarcely a week passes without fresh discoveries in confirmation of its truth. In much earlier times the same aid was resorted to, as is proved by the build-

* M. Hittorff it will be remembered, was the first writer, supported by disjointed remarks on the subject by previous travellers, who boldly asserted that the Greeks systematically adopted polychromatic decoration in their buildings. See his paper "*De l'Architecture Polychrome des Grecs*," also his fine work on Sicily. It required no ordinary degree of nerve to make, at that time, such a statement.

ings of Egypt, Etruria, Greece, Byzantium,[*] and Pompeii. The painted decorations of our own churches were all coloured over or otherwise obliterated at the Reformation, (when sculpture, stained glass, and many monumental brasses were also destroyed,) and the whitewash of the churchwarden has served each year since to render the discovery of them more difficult. The spirit of restoration which now prevails in many quarters, has brought numerous instances to light, as in the Temple church in our own metropolis, to which as its renovation has been commenced, we may soon hope to refer as an example.

At the Cathedral of St. Denis, near Paris, (the stone work of which has been entirely restored,) traces of colour on the various architectural members were found almost universally. The chapels and aisle of the choir are consequently again adorned with colours, gilding and arabesques. The columns are covered with leaves, foliage and shields, the capitals being gilt: the vaultings are blue with silver stars upon them in some parts, and in others trefoils and quatrefoils in red and gold. Wherever it was practicable, it is said, they adopted the original painting as a guide, but this does not seem to have been the case very generally.[†] The large rose window in the north transept has been filled with stained glass from the establishment at Choisy le Roi, and other windows for the cathedral are in progress of execution at the same place. In the south transept one window is nearly completed, and presents a very indifferent design commemorative of a visit to St. Denis by the present king.

For the church of St. Gervais in Paris, where considerable restorations are in progress, two very excellent stained glass windows are in progress at the Choisy works. While speaking of restorations it may be mentioned that the cathedral of Notre Dame is about to undergo a thorough repair and renewal. M. H. Godde is the architect to whom the honourable task is entrusted.

The interior decorations of the *Madeleine* are making progress, but are still far from being complete. The ceiling, which forms three domes, is a mass of gilding, the flowers in the panelling being simply backed with blue colour. The capitals of the columns and the face of the fluted shafts are gilt, as is also the entablature. The sculptured frieze presents some slight colourings successfully introduced. Coloured marbles are profusely employed in the lower part of the church, (as, it may be mentioned, is the case in most of the modern French buildings,) and in the absis:—the pavement is entirely of marble, and the whole of the decorations of the most costly kind. Painting and sculpture in their highest walks are called in to aid the general effect. Several fine statues in marble are already in their places, and others are in preparation. The semicircular portions of wall above the entablature, enclosed by the pendentives of the domes are appointed to receive large paintings, indeed many of them are finished, and most of them commenced. The mode adopted is that termed in France painting *à la cire*, and by us, encaustic painting:—a preparation of wax and certain colourless resins kept in a state of fluidity by volatile oils, are employed as the medium for the colours on heated walls. M. Montabert, author of a work entitled *Traité complet de la Peinture*, was the first writer who made known to the moderns this very ancient mode of painting, and he himself executed many pictures in this way twenty or five and twenty years ago, the whole of which continue, it is said, without the slightest alteration. In France a very strong impression exists in favour of its great superiority over Fresco, and as at this moment (when the manner of decorating the new Houses of Parliament excites so much interest, and is ready of so much importance to the progress of the arts,) it is desirable that we should obtain all the information in our reach on the subject, so that the best mode may be employed, I propose offering hereafter a few detailed remarks on the subject. Besides the Madeleine, Notre Dame de Lorette, St. Denis au Marais, the Château of Fontainebleau, &c., contain specimens of this method of painting.

Mentioning Notre Dame de Lorette, I cannot avoid pointing it out as an extraordinary instance of the application of the decorative arts to church architecture, although it is now perhaps well known to all. Large pictures fill the clerestory and the sides of the chapels, figures, symbols, arabesques, and Latin texts on gold or other grounds, cover every inch of wall, the Ionic columns which support the ceiling are apparently covered with composition or varnish of a cream colour with a high polish, the ceiling of the nave is formed into panels, each containing an ornate flower, and is adorned with colours and gilding,—chocolate, blue, and white, predominating. The choir is terminated with a dome, the whole of which is painted. The cost of this extraordinary building, which occupied fourteen years in completion, and called into requisition the talents of most of the principal artists of Paris, was £82,000,—defrayed by the city of Paris.[*]

Want of time prevents me from dilating further at this moment, on the Column in the Place de la Bastille, the restoration of the sculpture in the portico of the Chamber of Deputies, the decoration of the Pantheon, the establishment of a Society of Architects in Paris,[†] and the competition designs for a monument to Napoleon in the Hotel of the Invalids, afford ample matter for much comment. The last subject, indeed, seems imperatively to demand a few words, as this proposed monument has excited the greatest interest in France during the past twelve months, and can hardly be said to be devoid of it here.

More than eighty *projets* were received, notwithstanding a general feeling against the competition prevailed in the minds of artists on account of the profound silence which was observed by the Minister of the Interior (to whom the designs were directed to be forwarded) as to the names of those to whom the selection would be confided. The designs, immediately after they were received, were exhibited to the public without restriction, in the Ecole des Beaux Arts, and attracted great numbers of persons. They were nicely arranged, none of the drawings were torn or injured in hanging, and all were seen equally well—points to which, in conjunction with the very important step of public exhibition *before* making the decision, committees here in similar cases would do well to attend.

A subterranean chapel formed beneath the dome appears to be the favourite idea. M. Visconti, M. Labrouste, M. Isabelle, M. Battard, and others, have adopted it. In M. Visconti's design the chapel is open at the top (being protected by a balustrade around it on the pavement beneath the dome), and is approached by a subterranean passage of great length opening into the *Cour Royale*, where he proposes to erect an equestrian statue of the Emperor. M. Labrouste's chapel, on the contrary, is covered by an enormous shield of bronze gilt, supported some few feet above the pavement by four white marble eagles, allowing a view of the sarcophagus containing the remains of Napoleon, in the chapel beneath. The shield, which is of elegant design, would be 50 feet in length, and could hardly fail to produce a striking effect.

M. Duc exhibited a very beautiful enclosure of gilt bronze, surmounted by an elaborate canopy, and containing a porphyry sarcophagus. Two figures of white marble sit beyond the enclosure, and the whole is surrounded by a balustrade. M. Feuchere had a model of considerable merit representing an oblong temple of eight columns on a stylobate, which is elongated at the four angles to receive figures. Within the temple is the sarcophagus, and above it a statue of the Emperor.

M. Felix Duban has designed an elegantly simple sarcophagus on a plinth, against the sides of which latter stand figures. M. Victor Lenoir has a very clever design, and the same may be said of those by M. Morey and M. Bouchet. Mr. Goldicutt's design for the Nelson monument has been worked on by several, and was produced in two or three shapes. There was one *projet* for a colossal figure of the Emperor nearly as high as the dome itself, and another (claiming

[*] Some time since M. Didron, the distinguished French antiquary, obtained from the monks at Mount Athos a very curious M.S., relative to painting Byzantine churches. It is written in Greek, consists of about 350 pages, and is divided into three parts: the first treating of the mode of preparing the colours and the ground work for frescos, the second describing the historical and allegorical subjects which may be represented, the attitude, costume, &c., and the third, the particular parts of the building appropriated to different figures. The text is ascribed to the IX. century, but this particular copy is somewhat later. A translation of it has been made, and will shortly be printed.

[†] No person interested in the preservation of specimens of ancient art can go through St. Denis, and in fact through few buildings in Paris, without feeling how much gratitude is due to the memory of M. Alexandre Lenoir, who succeeded in rescuing from destruction during the Revolution, many magnificent monuments of the middle ages, and preserving them until quieter times. His son, M. Albert Lenoir, one of the government architects, and a man of great talent and zeal, is now engaged on a fine work for the "*Comité Historique*," entitled Statistique Monumentale de Paris, which his father's collections will enable him to complete most efficiently.

[*] The following particulars may be interesting to some. When the city of Paris determined on rebuilding the church of Notre Dame de Lorette (the old church being much too small and mean for its position,) ten architects were invited to send plans, namely M.M. Caristie, Godde, Menager, Chatillon, Gauthier, Le Bas, Nepveu, Lecointe, Provost, and Guenepin, all of whom complied, with the exception of M. Godde. The commission appointed to make the selection was composed of the following gentlemen: Count Chabrol de Volvic, president; Viscount Hericart de Thury, Director of "Travaux Publics," Fontaine, Hurtault, Huyot, Thibault, and Percier, architects and members of the Academy, and M. Larribe, Conservator of the objects of art in the city of Paris, who acted as secretary. The design submitted by M. Le Bas was selected, and reported on at the Hotel de Ville, April 23, 1823; the first stone was laid August 25 in the same year, when a medal was struck in commemoration of the occasion, and the consecration of the building took place December 15th, 1836.

[†] The first meeting was held January 25, 1841.

praise for originality, if not for good taste, to hang an enormous eagle of bronze by the tips of its expanded wings from wall to wall, a little below the springing of the dome. Borne up in the talons of the royal bird, the sarcophagus would be suspended, Mahomet-like, 'twixt heaven and earth.

Although the exhibition contained much that was satisfactory, it could hardly be said to be worthy of the architectural and artistical talent existing in Paris. Some of the drawings were exquisitely executed.

ON COLOUR AS APPLIED IN DECORATION.

By Hyde Clarke, F.L.S., &c.

At the present period, when so much interest is excited as to the decoration of our public buildings, and when a better epoch for this department of art seems opening, the subject of the laws which regulate it can scarcely fail to be attractive to the profession, as the theory of colour and its relations to heat and electricity have been already explained in the Journal, (Vol. II, p. 188,) we can at once consider the practical portion of the subject; but I should first wish to call attention to M. Chevreul's theory of contrast, with some few remarks I have to make upon it. M. Chevreul says (De la Loi du Contraste Simultané des Couleurs: par M. E. Chevreul, Membre de l'Institut), that where the eye sees at the same time two contiguous colours, it sees them as dissimilarly as possible, both as to their optical composition, and as to the depth of their tone, so that there may be at the same time simultaneous contrast, properly so called, and contrast of tone. Thus if two colours *a* and *b* are in juxtaposition, they will differ as much as possible from each other when the complement of *a* is added to *b*, or the complement of *b* added to *a*. If we choose for our experiment orange and green, and if we place orange by the side of green. blue, the complement of the orange, is added to the green, which thus becomes more blue and less yellow, and so similarly the red, the complement of green, is rendered more vivid in the orange, which also becomes less yellow. M. Chevreul has not suggested the cause of this remarkable phenomenon, but I am myself inclined to attribute it to a tendency which the colours have to balance each other, in a manner like to that in which heat diffuses itself from a heated body to one of a lower temperature, and similar to the law of electrical distribution. If this should be the case, it would also be confirmatory of a homogeneity of colour, which many other circumstances would lead us to believe, so that light, instead of being considered to be composed of three simple coloured rays, would, according to that view only, owe the phenomena of colour to the different arrangement of its particles, as ponderable substances, according to the arrangement of their molecules, vary their forms. Colour, perhaps, after all, is only dependent on electrical action, and could we establish this, our way would be clear to the production of coloured representations by electricity, instead of the present daguerréotypes, and to many of the operations of dyeing.

Pursuing his remarks M. Chevreul says that it is evident that the phenomena of simultaneous contrast would increase the brightness both of *a* and *b*, and make them appear more brilliant than they would when looked at isolatedly. If the colours brought together belong to the same group of rays, and only differ in intensity, the clearest in tint will appear still clearer at the point of contact, while that deepest in shade will appear deeper, the tints will be regularly affected from the point of junction, the one set lighter and the other deeper. Coloured and white bodies, when put in juxta-position, become, the former more brilliant and deeper, and the latter of the complementary colour of the others. Thus green and white: red, the complement of the green, is added to the white, and the green appears deeper and more brilliant. In the juxta-position of coloured and black bodies, the effect of the contrast of intensity is to deepen the black and lower the tint of the juxtaposed colour; but a very remarkable fact is the weakening of the black itself, when the juxtaposed colour is deep, and of such a kind as to give such a bright complementary colour as orange, yellowish orange, greenish yellow, &c., for instance, with blue and black, orange, the complement of the blue, is added to black, the black becomes lighter, and the blue is clearer, perhaps greenish. All gray bodies contiguous to coloured bodies may present the phenomena of contrast in a manner more sensible than white and dark bodies do. Thus yellow and gray: the gray takes more of a violet cast by receiving the influence of the complement of the yellow, and the yellow appears more brilliant, and yet less iehgems.

Besides this simultaneous contrast of colours, M Chevreul distinguishes a successive contrast of colours, by which he means all those phenomena which are observed when the eye, having for some time looked on one or more coloured objects, perceives, after having ceased to look at them, images of these objects presenting the complementary colour which belongs to each. He also defines a mixed contrast, which is the result of the two others, it takes place when, having looked at a red paper, for instance, and we turn towards a blue, it will appear greenish: if, on the other hand, we look first at the blue, and then at the red, the red will appear orange. These are all well known phenomena, but M. Chevreul makes a practical application of them; he recommends the painter not to keep his eye too long fixed on his model, and the purchaser of coloured goods to be similarly careful, if he wishes to keep his eyes in a normal state to look at the last pattern, otherwise the several patterns will, after the first, appear faded, and less fresh in colour, although they may all be of the same quality. A shopkeeper who shows several silks, say red, should show others of a complementary colour, green in this case, in order to restore the eye to its normal state, and better to prepare it for the red, by making the red look more brilliant than it really is.

I shall now make another halt to give a hint to those of my readers who consult French works as to the use of several words used by the authors: thus *ton* we call intensity, tint and shade, *gammes*, the key colour or tone, and *nuances*, hues. Two or three useful rules I shall also advert to here. The best contrast, it must be remembered, is produced by the complementary colour, and all colours must be of the same intensity.

When two colours do not agree, it is best to separate them by white. Black is also useful for this purpose when applied with bright colours, and, in some cases, preferable to white.

Black may be advantageously applied with sombre colours, and with some of the dark tertiaries.

It will now be necessary to consider the several colours separately, in doing which I shall principally avail myself of Mr. Hay's work on colour,* the best and cheapest practical work on the subject, and one which, to the professional man and to the student, is indispensable.

Like Mr. Hay, I shall begin with white, the representative of light, which is regarded as produced by the reflection of the three primary colours simultaneously in their relative neutralizing proportions. Although there are eight kinds of whites, there is only one which is understood as a pure white. Its contrasting colour is black, being opposite to it in the scale, but the arrangement in which its effect is the most happy is with blue and orange. In the series it lies nearest to yellow, which may be adopted as its melodizing colour. With nearly all colours, however, it harmonizes in conjunction and opposition, and to its properties in separating two discordant colours I have already referred. It does not agree so well as gray with red and orange, and with blue, violet, &c. it is harsh. It is to be preferred to gray with yellow and blue, also with red and green, red and yellow, orange and yellow, orange and green, and yellow and green. With very light primrose, yellow forms an agreeable arrangement. All colours brought in contact with pure white must be light and cool, amongst which gray and green may be employed, and intense or rich colouring must be avoided. A south light is the best for white, which, when it is the predominating colour for a room lighted from the north, should be made of a cream colour, so as to get rid of the cold reflection as far as possible.

French white is, properly speaking, the lightest shade of purple, and is seldom used in house painting, but Mr. Syme says that he has seen it made the prevailing colour of a drawing-room in a country residence with good effect. It can only be introduced when all the other colours are light and cool in tone, as any quantity of intense or rich colouring completely subdues it.

Black, the representative of darkness, is regarded as produced by the absorption of the three primary colours, simultaneously in their relative neutralizing proportions. In the series it lies next to purple, which may be considered as its melodizing colour. Its contrasting colour is white. we may also add yellow, but it is most happy in combination with red and green, red and yellow, orange and yellow, orange and green, and yellow and green. By being associated with sombre colours, such as blue and violet, and with the lower tints of the bright colours, it may be often made to produce a very good effect. It is always happy when used with two bright colours, as orange, yellow, red, and bright green. As a separating colour it is often to be preferred to white. It is not so good as gray in combination with orange and violet, green and blue, and green and violet. It is only in arrangements of a cool and sombre character that it can be used in large quantities, and it is recommended to be used always pure and transparent. The ancients used it happily and in great profusion, and in

* The Laws of Harmonious Colouring. By D. R. Hay. London W. S. Orr, 1838.

the monuments of the Egyptians, the vases of Greece and Italy, and the decorations of Pompeii and Herculaneum. We find it in combination with the brightest colours, often used as a separating colour or as a contrast, and always with effect. Mr. Hay recommends great caution in the use of both white and black, for being at the top and bottom of the scale, they are very dangerous colours to manage. Where gorgaousness is the object, they must not be brought in.

Pure Yellow, of the power of 3, which Mr. Hay calls yellow jasmine, or a deep lemon hue, is the lightest of the three primary colours, and the nearest to white. Its contrasting colour is purple and it forms a strong contrast to black. Its melodizing colours are orange and green, which are the secondaries it forms with red and blue. Its ternary is citron, and its quaternary is brown and marrone. Being the most powerful of the primary colours, it is most offensive to the eye when used extensively in a pure state. With red, orange, or green, it does very well in combination with black, and even with gray. In artificial light yellow, it is well known, appears to be of less intensity, as is the case with all colours into the composition of which it enters.

Primrose, which is a very light yellow, forms a pleasing arrangement with pure white, being a light and cool colour.

Red, of the power of 5, is, by Mr. Hay, represented to be of the most intense geranium colour, and as difficult to be defined: it is the second of the primaries, a very warm colour, and the most positive of all colours, pre-eminent among them. Its contrasting colour is green. The secondaries with which it melodizes are its combinations with yellow, forming orange, and with blue, forming purple. Its tertiary is russet, and its quaternary is marrone and slate. With another bright colour it forms a good arrangement with black, as it does also when combined with yellow. Being a warm colour, it acts upon all colours brought in contact withit, or into which it enters, and must not be used on a large scale uncombined, requiring great skill in its use. It is heightened by artificial light. It is considered to be an excellent key colour, and when so used, it is recommended that its contrasting colour, green, should be neutralized by being brought down in tone towards olive.

The nearest hue of red towards yellow is scarlet, which is very brilliant, and requires much the same management as orange. It must never be used in large masses, except under very peculiar circumstances. Its contrasting colour is a bluish green. The ancients used black with scarlet.

The nearest hue of red towards blue is crimson, one of the most gorgeous, at the same time most cool and mellow, and very useful as a key colour. Its contrasting colour is a citron green, and its melodizing colours a bluish green and reddish purple.

Pink is the next hue after crimson, and is very useful for heightening reds in cool toned arrangements.

Blue, of the power of 8, is the deepest of the primary colours, and the nearest in relation to shade. It is a cool colour, acting upon colours used with it, and may be employed in masses with much less glare than either of the other primaries. Its contrasting colour is orange. The secondaries with which it melodizes, are its combinations with yellow, forming green, and with red, forming purple. With green, however, blue is very discordant, more so than any primary with its secondary. Its tertiary is olive, and its quaternaries slate and marrone. With orange it makes a good arrangement with white, and with green agrees with gray, and with violet it enters into composition with black. Black may be very advantageously used with it under many circumstances. White and blue are apt to appear raw in contrast. When used with green and olive, on account of the discord, blue requires the interposition of gray, or of some other neutral colour, with olive a purply gray may be used. Blue is reckoned a good key colour, where a refreshing appearance is desired: with artificial light, however, it is chilled.

We now come to the secondaries.

Orange is a compound of yellow 3 and red 5, being of the power of 8. It is one of the most brilliant colours there is, and the contrast to blue; it requires therefore to be used with a sparing hand, although it is reckoned a good key colour. Olive also forms a contrast with it. It is the melodizing colour to yellow and red, and is itself melodized by its tertiaries, citron, formed with green, and russet with purple. It is acted upon by artificial light much in the same way as yellow is. With blue it may be combined with white, and with red, yellow or green may be used with white or black. With more yellow the hues orange forms, are gold, giraffe, &c., and it then requires for its contrast purplish blue.

Green is the coolest of the medium of the secondaries, and is composed of yellow 3 and blue 8, being of the power of 11. Its contrasting colour is red, and also russet. Green melodizes with yellow and blue, and is itself melodized by the tertiaries, citron, formed with orange, and olive with purple. It is one of the worst colours under artificial light. With red, orange, or yellow it may be used in composition with black or white, but with blue or violet gray is to be used. Being such a soft colour, green may be used in quantity without fear. It requires great care when used with blue, and should be separated by a neutral tint.

Purple is one of the darkest colours most nearly allied to black; it is of the power of 11, and is composed of yellow 3 and blue 8. Its contrasting colour is yellow, and the tertiary citron, which is much used with it. Purple melodizes red and blue, and is melodized by its tertiaries russet formed with orange, and olive with green. It is a cool colour, and it suffers much under artificial light, but next to green it may be used with the most freedom. With green or orange it may be used, with gray and with blue black is to be used. With white its combinations are very raw.

Indigo is the first hue, formed by blue on its union with red, and is a heavy colour little used, except in wove fabrics.

Purple forms various hues as lilac, &c., with which citron may be advantageously used.

Gray is a neutral colour, and enters with effect into many combinations, being the medium between light and shade. It is very useful in separating blue from green or olive. Its most happy combination is with red and orange, and with orange and violet, green and blue, and green and violet.

To proceed to the tertiary colours.

Citron is a tertiary colour, in whith yellow predominates, it is composed of orange 8, and green 11, being of the power of 19, or yellow 6, red 5, blue 8, its contrasting colour is purple, and also slate: it melodizes with orange and green, and is melodized by the next series, brown formed with russet, and marrone with olive. Citron is greatly relieved and harmonized by olive. It is soft and pleasing to the eye, and is the lightest of the tertiaries, much used as a contrast amongst low hues of crimson and purple.

In russet, red predominates, being composed of orange 8, and purple 13, of the power of 21, or yellow 3, red 10, blue 8. Its contrasting colour is green, and also marrone. It melodizes with orange and purple, and is melodized by the next series, brown, formed with russet, and slate with olive. This tertiary is of great use, and particularly with green.

Olive has blue for its predominant constituent, and is composed of green 11, and purple 13, being of the power of 24, or yellow 3, red 5, blue 16. Its contrasting colour is orange, and also brown. It melodizes with green and purple, and is melodized by marrone formed with citron, and slate formed with russet. Olive has a great relation to shade, and is characterized by Hay as soft and unassuming, being of great use in all arrangement, whether cool or warm, being employed with the lower hues of warm toned or brilliant composition. It must not be brought in contact with blue, but separated by gray.

The next rank is held by the quaternaries or semi-neutral hues. These are:—

Brown composed of citron and russet, of the power of 40, consisting of yellow 9, red 15, blue 16. Its contrasting colour is olive. It is a most useful colour in the low parts of warm toned arrangements.

Marrone is composed of citron and olive, being of the power of 43, or yellow 9, red 10, blue 24. Its contrasting colour is russet. This semi-neutral is most useful in wove fabrics. It is considered to be deep and clear, and although allied to red, may be used where there is a preponderance of cool-toned colours.

Slate is the deepest of the semi-neutrals, and is composed of russet and olive, being of the power of 45, or yellow 6, red 15, blue 24. Its contrasting colour is citron, and it can only be used in cool-toned arrangements.

FIRE-PROOF CONSTRUCTION NECESSARY TO GENUINE ARCHITECTURE.

By Alfred Bartholomew, Esq., F.S.A.

The three recent great fires at the Parliament Houses, the Royal Exchange, and the Tower of London, with those at Hatfield, Lord Dinorben's, and the Marquis of Londonderry's, while they show that public and aristocratic property can, under the present vicious mode of construction, no more escape than private houses, are no doubt calculated to awaken prudence if every other warning should fail.

He who would be a reformer of any abuse must of necessity prepare himself to be accounted first a kind of monster—then if not absolutely insane, certainly not in his proper senses, and mayhap as far from right-mindedness as Don Quixote himself: but he who would conquer must often previously stoop for that end, and should as little attend to the clamor which is made about his ears by the ignorant, the superficial, and the senseless, as the lady of oriental story who went to disenchant her brothers, or Rinaldo of *La Gerusalemme Liberata* in the enchanted wood; if he persevere, some circumstance or other will be sure to turn up, which will show the mad sayings of such a Quixote, are not so mad as they appeared to be.

Perhaps the fire at the Tower may be considered a fortunate circumstance, though it has destroyed many proud trophies of national victory, since it has not only consumed an ugly inappropriate unfortress-like edifice, with a vast store of wretched useless arms which it is confessed were unfit for service, but has so harrowed up public attention to the subject, that it may be doubted whether any more such dangerous repositaries may be built for containing public records, trophies, libraries, pictures, or curiosities.

If our ideas did not "*run*" as Dr. Robison says, "*in a wooden track*," and so induce the designing of buildings upon false principles, perhaps hardly such a thing as a combustible public building would exist. The cupola of the Pantheon, Palladio's representation of the reputed Temple of Vesta at Nismes, the Cathedral of Milan, the Church of Batalha, Rosslyn Chapel, and the Kitchen of Glastonbury Abbey, show buildings may be roofed not only incombustibly, but also without loss of sectional space between a ceiling and an outer covering—a beauty which, though often discoursed upon, is but very rarely produced.

At the present day it is scarcely necessary to notice how much more handsome and architectural, are solid vaultings than flat combustible ceilings: neither in good construction nor fire-proof construction, is it likely that any thing so ugly and unarchitectural as a dome rising out of a flat ceiling could ever be found; nor is it now much more necessary to show that all the generic beauties of pointed architecture, are the direct and necessary emanation of fire-proof construction, every form from the summit of the vaulting of a church to the buttress feet, resulting from that masonic cunning which was put in action throughout the work to make every stone press to its neighbours, instead of suffering any cross strain, and snapping beneath it like modern flat stone lintels and architraves; the only parts which, in pointed architecture, are ever found violating this principle, are the ugly ill-formed combustible roofs with which so many ancient churches are covered, and which frequently being heavy, ill-designed, and badly put together, by counteracting the masonic skill contained in the walls, vaultings, and buttresses of such fabrics, cause nearly all the ruin which such edifices suffer. The finest piece of middle-age carpentry does not contain a tithe of the skill possessed by the freemasons; the imitation of ancient carpentry, in modern architecture is a positive vice: national edifices built without such carpentry would be found, in the long run, cheapest. It is to be hoped that when the London Guildhall shall be rendered safe, by the removal of its present roofing, there will be no new introduction of a roof of wooden faggots for the martyrdom of its marble monuments.

Not only may all edifices be incombustibly vaulted to appear tolerable, but to be in the highest degree architectural, and with the additional beauty of colour: for vaultings may be formed in mosaic of different coloured bricks, in herring-bone, chequered, or in any other manner: and indeed by covering over the centering with plaster of Paris, and drawing upon it any patterns, devices, or figures, every kind of pictorial representation may be made as it were in carpet-stitch, needing no plastering, no extraneous application of colour, scarcely any future repair, and requiring from time to time simply to be washed clean; parts of such vaultings may be glazed, parts may be finished with fine porcelain, and the whole may be heightened with unfading fired gilding. In some cases, patterns may be formed in light and shade by indentations in the bricks, or by sunk stippled-work; in others variety of colour may be produced by sunk indentations filled up by cement, some bricks with one colour, and others with a different one: in palaces and the higher class of edifices, embossed work and all these methods may be united to produce one rich effect. To insure security to such vaultings with the least possible material, and therefore to render them lighter, and consequently requiring less abutment, to make them, if possible, more secure, though of but an inconsiderable thickness, in all cases each brick should be secured to its neighbours by small copper pins or plugs, so that though any trifling settlements should happen to any part of the vaulting, still no derangement should occur, and no part of the vaulting should drop without either breaking the bricks or snapping off the pins. By these means Mr. Bartholomew would undertake to produce a fac-simile of the vaultings of the Temple Church, which neither fire, water, nor air should destroy.

ON THE ECONOMY OF FUEL IN LOCOMOTIVES CONSEQUENT TO EXPANSION AS PRODUCED BY THE COVER OF THE SLIDE VALVE.

Sir—I am very sorry that your correspondent Mr. M. should have found reasons for regretting any expressions of his October letter, and I can assure him that he meets with my most sincere regard, for having found them, so to moderate the tone of his communications, that he places himself in a position in which he is much less likely to meet with asperity. Mr. M. now acknowledges that he objected unjustly to the equation given for finding the area of the piston necessary for any assigned degree of expansion: which acknowledgment is of the more value, since if this equation had been wrong the whole paper would have fallen to the ground: and he also now acknowledges that in consequence of a misprint he was led into the dilemma of supposing that the area of the piston was put equal to the pressure of the steam. Having thus satisfied himself as to the accuracy of the main features of the paper, he now addresses himself to the demonstration that some functions of the question which I neglected as being of very small amount are actually so "appreciable" that even at the expence of very much complicating the analysis he would recommend their introduction. In replying to this demonstration I would have been saved all trouble had Mr. M. subjected all his objections to as rigid a calculation, as he has the effect that the waste space at either end of the cylinder has on the area of the piston, he finds, he says, that the correction which he has introduced for the waste space makes a difference betwixt my formula and his of $\frac{4}{5}$ of one per cent. upon the whole area of the piston: now I have neither investigated whether Mr. M. has correctly introduced into the formula the waste space, nor have I gone through the numerical computation, for if Mr. M. has no objections, I am perfectly willing to take for granted that he is correct in both, and shall seek to produce only his assertion that the correction amounts to so much as $\frac{4}{5}$ of one per cent. on the whole area of the piston, as my defence for neglecting the effect of the waste space.—But although Mr. M. has found the correction to be as stated above, I will at the end of this letter throw out a hint which will enable him to reduce it to much less than even what he has found it, to probably one hundredth part of it.

Mr. M. next proceeds to persuade me that he understands the mode of analysis it is necessary to follow in estimating the work performed by an engine working expansively, but in persuading me to believe this, he persuades himself that I did not understand what he meant, and I must allow that that is not only very possible, but very probable; for although I believe that I thoroughly understood his words, yet unless they happened to express his meaning, I could hardly be expected to reach it: but inasmuch as after explanation it turns out that we both meant exactly the same thing, I shall take it for granted that Mr. M. thoroughly understands the mode of analysis it is necessary to follow in estimating the work performed by an engine working expansively, and proceed to the consideration of more important matters, namely, what Mr. M. states to be the real point at issue, and that is whether the constant term (t) in the expression $\frac{a'p}{x} - t$ faithfully represents the negative part of the effect, or the resistance of the waste steam on the back of the piston. Mr. M. states that I put (t) to express both the lowest pressure of the waste steam in the cylinder and the mean resistance of the waste steam; now I most certainly never intended to make (t) express two distinct quantities, and I have examined the paper to see if I had stated any thing which could furnish grounds for supposing I had done so, but I cannot find that I did; for the satisfaction of Mr. M., however, I shall state in words (although to a mathematician I have always been in the habit of supposing the language of analysis most precise,) that (t) is put to express the mean effect of the waste steam. Mr. M. will perhaps now discover that the expression $\frac{a'p}{x} - t$ does not give too great a value by 3 or 4 lb. per square inch. Mr. M. was probably led to suppose that (t) was put to express the lowest pressure of the waste steam in the cylinder by the way in which it is involved in the equation for finding the area of the piston, but if he reconsiders that equation on the supposition that (t) expresses the mean resistance, he will find the error thereby introduced to be very small, and to be in the opposite direction from that produced by neglecting the waste space at the end of the cylinder.

Mr. M. in the next paragraph asserts that when the time given for expansion is excessively short as it is in locomotives, the reduction of temperature due to expansion is not sensibly affected by the heat of the smoke box, and ought therefore to be taken into account; but for two reasons the effect due to this alteration of temperature vanishes, in the first place Mr. M. will surely not deny that if the part of the steam pipe within the smoke box and the cylinders were filled with water it would speedily be evaporated, which must be in consequence of heat imparted, and it is certainly very evident that at least part of that heat must enter the steam; and Mr. M. will find that although the diminution of temperature due to expansion (alone considered) becomes greater with the expansion, so also does both, the surfaces of the cylinder and steam pipe, and the time for which the steam is exposed to the heat of the smoke box: again in the second place, if Mr. M. had introduced into his laborious calculations, to prove that he was right in objecting to the omission of the effect of the steam during the part of the stroke from the opening of the eduction port to the termination of the stroke, the remainder of the effect of this diminution of temperature due to expansion, he would have found that the one so balanced the other that the correction to be introduced though appreciable, is of analogous import ance with $\frac{1}{3}$ of one per cent.

The remainder of Mr. M.'s last letter is taken up in correcting the values of (a' and b) that I calculated for the four particular cases, which presents a beautiful illustration of a person, in his attempt to have the pleasure of helping another over a ditch, stepping into it himself; when Mr. M. first stated that the equations which give the values of (a' and b) are themselves correct, but that the numerical values which I calculated were incorrect, I thought he meant that I had made some numerical mistake, and therefore did not trouble myself about it, but I now see that he imagines I have made a radical error in applying the formulæ, by making incorrect substitutions for the known quantities. Had the formulæ been made on the hypothesis that Mr. M. thinks they were made on, they would (instead of being as Mr. M. thinks quite correct) have been altogether wrong; Mr. M. seems to think that the radius of the eccentric is a function of the cover of the slide, whereas such I never intended it to be, and such it is not which Mr. M. might have very easily discovered by looking at the investigation of these formulæ. The stroke of the valve being in no degree dependent on the cover of the slide does not at all effect the size of the port for the admission of the steam. Mr. M. will hence find it necessary to recalculate his values of (a and b), and make the alterations thereby caused on his laborious calculations with reference to the omission of the effect due to part of the stroke from the opening of the eduction port to the termination of the stroke.

I will now conclude this letter by remarking that so far as economy of fuel is concerned, so far as the advantage that an engine working expansively has over one working with full pressure is concerned, we may neglect taking into account all things that equally affect both, which I would recommend Mr. M. to consider in estimating the value of some of his objections.

And I remain, Sir,
Your obedient servant,
J. G. Lawrie.

Cartsdyke Foundry, Greenock,
November 15, 1841.

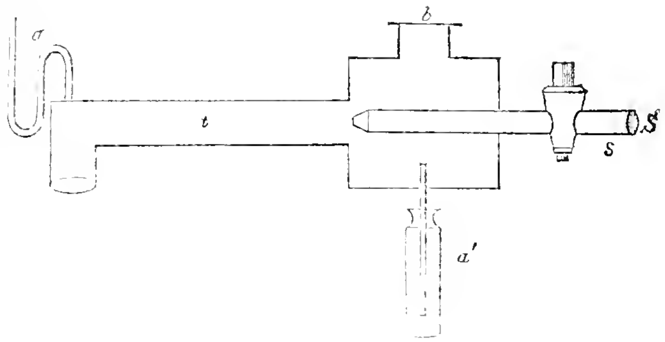
EVAPORATION OF WATER.

Sir—Having obtained a patent for certain improvements in evaporation, I take the liberty of sending you a description thereof, and also an account of the result I have obtained from the apparatus; should you consider this communication of a nature interessing to your numerous readers, I shall be happy to see it inserted in your very useful Journal.

If an open vessel containing water is placed over a fire, the water will take up heat and will retain the same until it boils, after which the water will throw off with the steam exactly the same quantity of heat that it takes up from the fire.

If the steam thus generated under atmospheric pressure is forced into a worm contained in the water, so as to acquire a pressure of about one twelfth of an atmosphere, it will be condensed therein at the rate of about 3 lb. of steam per hour for every superficial foot of refrigerating surface of the worm, and as by condensation all the latent heat of the steam will be given up to the water, a corresponding evaporation thereof will be effected, so that providing there was no loss of heat by radiation or other leakage, a liquid once brought into a state of ebullition might be constantly kept in that state by its own steam alone; loss is however inevitable, so that the liquid can be kept boiling, only with the addition of a sufficient quantity of heat to compensate for the loss by radiation, &c., and with the assistance of the power requisite to compress the steam within the worm, this compression can be effected either by means of a pump, or by a blast of high steam; the action of a pump is too well understood to need any explanation, I will therefore merely describe the mechanical action of a blast of high pressure steam employed as a substitute for a pump.

A blast of high pressure steam rushing through a tube of a greater diameter than that of the blast itself, possesses the two valuable properties of producing a pressure at one end of the tube and a partial vacuum at the other end thereof: when steam of about four atmospheres is employed for the blast, and when the diameter of the tube into which the blast rushes is about five times the diameter of the blast itself, a pressure may be obtained at one end of the tube of about 8 inches of mercury, and there will be found behind the blast a vacuum nearly as powerful,—thus



The above sketch will give a correct idea of the blast apparatus.
s, steam pipe when diameter = 1.
t, tube through which the blast rushes diameter = 5.
a', vacuum gauge.
a, pressure gauge.
With steam of about 4 atmospheres the gauge a will mark about 8 inches of mercury, and the gauge a' something less.

Now if the branch pipe b is connected to the steam chamber of an evaporating pan in which the steam is produced under atmospheric pressure only, the blast of high steam as above described, will absorb from this steam chamber about four times its own volume (when reduced to about one-sixth of an atmosphere), and will compress this mixture of high and low steam within the worm giving to the whole a pressure of about one-sixth of an atmosphere.

By the above application the water in the evaporating pan will be evaporated by the steam produced therefrom, and the whole value of the blast, minus that quantity required to compensate for leakage, will be thrown off with the condensed steam through a valve placed at the extremity of the worm, and may be utilized in a separate vessel to heat the liquid to be evaporated previous to its being admitted to the evaporating pan.

The first experiments were made with a double acting pump which drew the steam from the surface of the liquid as fast as it was generated, and forced it into the worm so as to determine an internal pressure of about one twelfth of an atmosphere, the area of the piston was 76 square inches, and its greatest possible stroke $9\frac{7}{8}$ inches, but as the pump was worked by hand the stroke was very irregular.

The pump made 800 strokes in 35 minutes, each stroke being nearly complete; had each stroke been complete, and supposing that there was no loss by the valves, we should have obtained from the valve at the end of the worm.

$$\frac{9{\cdot}875 \times 2 \times 76 \times 800}{1728} = 700 \text{ cubic feet of steam,}$$

$$\text{or } \frac{700}{1800} = 0{\cdot}39 \text{ cubit feet of water,}$$

$$\text{or } 0{\cdot}39 \times 62{\cdot}5 = 24 \text{ lb. avoirdupois of water.}$$

The quantity of water really discharged from the valve was 20 lb. avoirdupois, which was necessarily the real quantity evaporated from the pan. The fuel consumed did not exceed a quarter of a pound, we consequently evaporated 80 lb. of water with 1 lb. of coal; this experiment was repeated several times with the same result in an evaporating apparatus heated externally by fire, and containing a worm for the action of the steam, the surface of which amounted to 21·5 square feet.

An apparatus of this kind might be applied with great benefit at sea to distill sea water, no machinery or steam boiler being required, the apparatus being worked by hand, one man would obtain about 2·66 imperial gallons of distilled water every hour—the pump could be worked in many different ways.

The pump might be advantageously employed for evaporations in all situations where motive power can be disposed of, or where fuel is expensive.

If you consider this communication worthy of a place in your Journal, I will at an early period send you an account of the experiments made with the blast of high steam as a substitute for the pump.

I remain, Sir,
Your obedient servant,
H. H. Edwards.

Park Village, East, Nov. 20, 1841.

EPISODES OF PLAN.

(Continued from page 346.)

As we have laid down no *plan* at all for our "Episodes,"—which though not so divided, may be considered as so many separate papers on the same general subject, and may therefore be treated desultorily, without regard to strict connection with each other,—we shall now allow ourselves to deviate a little from our course by bringing forward an entire plan, as exemplifying a combination of episodical parts, all studied for effect, into one uniform design.

Hardly need we say that the plan is that of a villa, or detached residence, nor is it by any means upon an extensive scale,—far less so, indeed than many that are to be met with in publications containing subjects of the same class. And if, unlike them, we confine ourselves to the plan alone, without attempting to show any thing further, it is so far an advantage that it compels us to dwell upon circumstances which are almost invariably passed over without comment or remark of any kind, in the publications just alluded to, as if the plan was matter of comparatively little consequence, and provided it be free from any very obvious defects and inconveniences—which, however, is not always the case—study as to effect, variety, contrast may be dispensed with, because, however poorly the architect may have performed his part, the upholsterer will make amends when he comes to perform his. The architect or designer himself is an unquestionable person, for it is not to be expected of him that he should anticipate answers relative to all the *Whys* and *Wherefores* that his plan may suggest to other persons; or should explain the motives which have determined its arrangement.

In most cases indeed, there is very little, if any thing, to describe or explain, to note or remark upon, nothing more being attempted than to divide the plan into a certain number of rooms, without any study as to variety or effect. Scarcely ever is a new idea brought froward: on the contrary a good one seems sometimes to have been stopped short of, merely owing to the most obvious one being caught hold of at once, without further consideration being given to the subject. Yet even such crude and common-place plans are not altogether without their use—that is, to those who have capacity enough to make such use of them—because they serve to show the defects that ought to be avoided, and to make evident the deficiencies that ought to be guarded against. It is very true a house may—it considered merely with regard to its principal object as a dwelling—be an exceedingly good and excellent one, even though it should be utterly deficient in any beauties of plan: yet such also it may be though it should possess no other beauty of any kind to recommend it. And if it be worth while to study elegance of exterior form and appearance, it is surely equally so to study beauty of plan,—not mere internal decoration alone, but also piquant variety in the forms of the several apartments, and in their distribution. Nevertheless, the reverse is the usual practice, for far more attention is bestowed on embellishment, whether as to furniture or any thing else, than on the other sort of effect, notwithstanding that this last must be provided for in the plan itself, whereas deficient decoration can be supplied at anytime.

Should it be said that all this is so obvious as to appear almost impertinent, we ask why, if such be the case, architects should show themselves so negligent of the effects to be obtained from plans, and why they do not urge upon their employers the paramount importance of securing them, even should the additional cost that may be so incurred, occasion some matters of decoration to be postponed at the time the building is erected? These observations may, perhaps, be very injudicious on our part, inasmuch as the plan we here bring forward, may be thought to fall far short of the standard we ourselves set up. Most assuredly it is not for us to say that it affords a satisfactory illustration of our own doctrine, that being a point we must leave others to decide upon when we shall have explained, as we now proceed to do, what we have more particularly aimed at.

Hardly can it be objected either that the plan is deficient in compactness, or that economy has been disregarded, for the front is no more than 58 feet, and returns 27 feet at the ends; which would accord with it in their elevations, while the rest of the exterior might be left plain or nearly so, the plan being there contracted, so that the rear portion of the house would not interfere with the principal architectural mass, more especially were any sort of terrace wall or screen, although only five or six feet high, to be erected for a short distance on the lines *t t*, the ground behind them being on a somewhat lower level, so that the windows of the offices in the basement would there be just above it.

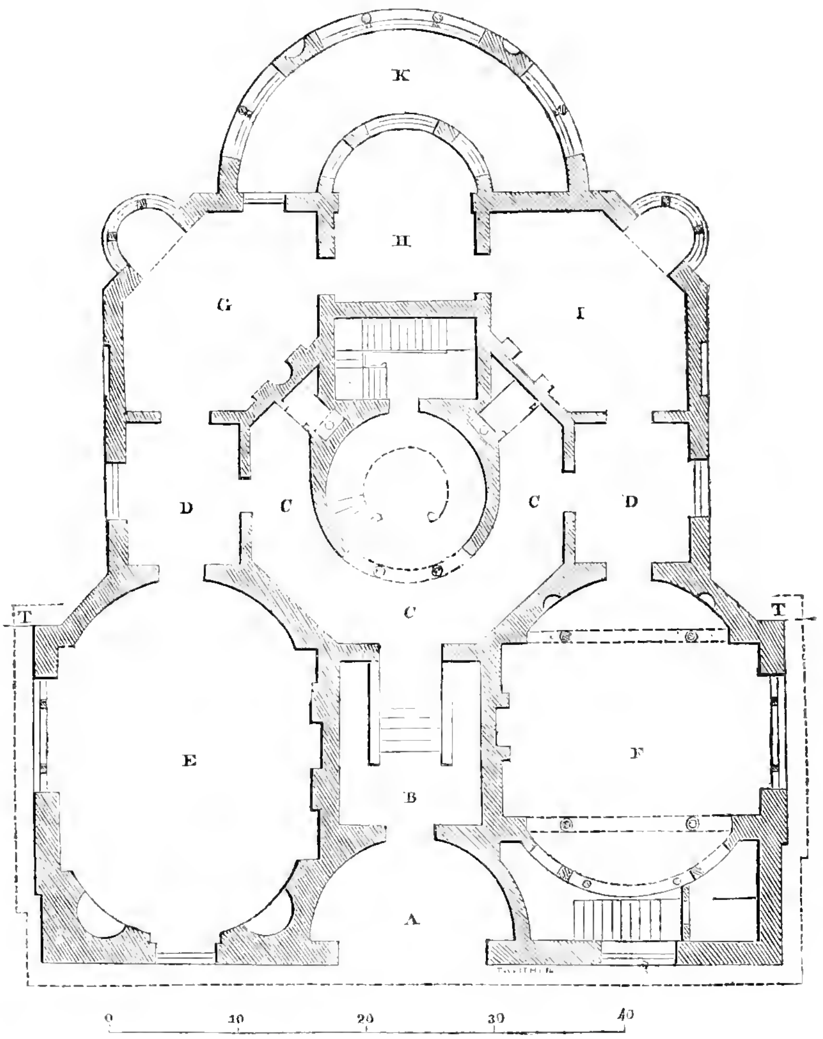
The style of the front is supposed to be Italian, and that part of the exterior to have a cornicione (indicated on the plan by the dotted lines) which would of itself tend to mark out that portion as a distinct composition there intended to terminate, its end elevations obviously belonging to the front, and being independent of the rest of the sides beyond them, where an intentional transition from decoration to plainness takes place, the latter not at all interferring in this case with regularity or consistency. Besides that much more than a single architectural elevation is thus obtained, without continuing its return, for the entire extent of the building, it is perhaps rather an advantage than the contrary, that the general outline is broken, and that formal box-like shape avoided, which generally gives such a disagreeable naked appearance to a detached square house without wings or other accompaniments.

Although the rest of the exterior is distinct from the principal composition it will be seen that that regularity is kept up in it, the rear or conservatory front (here supposed to face the west or south-west) presenting a uniform elevation that might either be plain or decorated, according as circumstances should dictate.

The principal or entrance front is exceedingly simple in composition—though capable of being ornate in character,—it being *astylar* and without breaks of any kind, and presenting only three openings in width, the centre one of which forms a lofty arch to the niche-like loggia or porch, which latter would afford a convenient shelter for servants in attendance upon carriages.

From the loggia *a* we first enter a vestibule *b*, small in itself, but presenting a striking effect in consequence of the staircase being seen beyond it (on a somewhat higher level) through the columns enclosing it, and forming that space into a perfect rotunda, covered by a dome, through which the light streams down from above, and relieves the columns. It may, perhaps, be asked if a good deal is not lost by thus inclosing the staircase,—whether it would not be better to make what is now the staircase and corridor a single octagonal hall, either putting the staircase in it, or giving up some other part of the plan to the latter. That certainly might be done, but besides that it would materially alter the present arrangement for the worse in many respects, such a hall would be too ambitious a feature in a house of this size, and while it would take off from the importance of the two principal rooms, would cause the others to look quite diminutive: whereas now there is with apparently less pretension, greater novelty of character, and sufficient degree of effect, yet not so much as to interfere with that of the chief apartments. There is likewise what we consider to be an agreeable and desirable sort of intricacy attending the arrangement here adopted, there being concealment as well as display. It is impossible for a stranger to understand from what he sees on first entering, the situation, or number of the rooms, or how they communicate with each other. They are approached in such manner as to appear at a considerable distance, consequently the house seems more extensive than it is,—certainly very much more so than would be the case, were the rooms E and F to open immediately into the vestibule *b*,—to say nothing of the much greater privacy and comfort secured by the arrangement here adopted. The privacy of the sitting rooms is further increased by none of them being made to communicate immediately with the corridor, they being entered through *d d*, two lobbies or small outer rooms—for their size hardly entitles them to be called anterooms. Their smallness, however, would not prevent tasteful architectural character being bestowed upon them,—the less so as there would be scarcely any occasion for the usual articles of furniture in them, but merely ornamental ones; on the other hand, it would by contrast serve to give an air of spaciousness to the two larger rooms, and even to render the others of good size in comparison with them.

The drawing-room, E, is the largest of all, the dining-room, F, being made somewhat less in its plan than the other, in order to obtain a staircase for serving up dinner, which must else be brought through the back staircase, corridor, and lobby. What, therefore, is lost as to size is amply made up by increased convenience, and also by variety, because, instead of being merely a duplicate of the drawing-room in its plan, it assumes a very different character; and although columns are introduced in order to define the two alcoves more markedly, there is still a clear central space of 20 by 14 feet, which is quite



sufficient for the accommodation of a comfortable dinner party. The sideboard alcove is divided from the staircase behind it by a partition carried up about seven feet from the floor, or half the height of the room, forming a screen, surmounted either by dwarf columns or caryatides. Behind this screen there is also a retiring closet for gentlemen, lighted by a small window towards the staircase, and provided with proper sinks and water-pipes.

We now come to consider the remaining rooms, which are so arranged that until shown into them a stranger might not perhaps suspect there was any thing of the kind, but suppose the rear part of the house to consist merely of secondary rooms for domestic purposes. Should he therefore happen to be quite unprepared for other sitting-rooms, all the more agreeable is likely to be his surprise on discovering that the doors on the other side of the lobbies open into rooms unusual, and at first sight perhaps apparently rather irregular in plan, but afterwards perceived to be perfectly symmetrical; besides which a change of view in a different direction from that from any of the other sides of the house is here obtained. On entering H, another form of room presents itself, not only different from any of the rest, but in a manner combined with the conservatory, into which it projects. Therefore, although too small in itself to be considered exactly as a distinct sitting-room, this would be a very agreeable little summer boudoir, with its windows thrown open to the conservatory. Between this and the adjoining room I (corresponding in its plan with G), there might be double doors kept locked, supposing I to be appropriated as the master's morning or private room, as in that case it might be more desirable to keep that as much apart as possible from the rest, but still in such manner that it might be made to communicate with them, whenever there should be occasion for throwing open the whole of the rooms to company, so that they may all be passed through from the drawing-room to the dining-room. For the reason above assigned there is no window into the conservatory from this room I, as there is in G.

Having thus far given a specimen of the sort of explanatory commentary which, we think, ought to be attached to all published plans, we will not prolong our remarks at present, but leaving our readers to supply as much more in the shape of criticism upon ourselves—either favourable or unfavourable, as they may think proper, we merely add a list of

ON CONSTRUCTION.

It is our intention to give occasionally some examples of construction which will be found useful to the student. The annexed engravings show the construction of the Roof over the Polytechnic Institution at Vienna; unfortunately the work (the *Allgemeine Bauzeitung*), from which we take the drawing, contains but a meagre description of its construction, without any reference to the scantling of the timbers; we can therefore only form our opinion of what they ought to be from the geometrical view before us. It is stated that the roof stands remarkably firm; the span is 56 feet, and the rise of the arch 18 ft. 6 in. above the chord bar; the curvilinear ribs or principals are placed 12 feet apart, and are 12 inches in depth, of pieces of timber in 4 feet lengths which are laid side by side in thicknesses so as to break joints; we should apportion three thicknesses of two inches each; upon their ribs are laid the purlins 6 by 5 inches, which carry the rafters 4 inches deep by 2½ inches placed 3 feet apart; upon the rafters is laid the copper covering. The roof is very much stiffened by the braces 6 by 3 inches on each side of the ribs, and horizontal ties of the same scantling bolted to the ribs and feet of rafters; and also caulked down to the pole plates, there are two plates 6 inches square, one lies on the wall, and the other is supported by vertical posts under each rafter; there are also two wall plates each 5 by 5 inches, the wall plates and the foot of the curved ribs ought to be well secured to a cross tie either of timber about 12 by 4 inches, or a wrought iron tie 1¼ inch diameter. The tie beam would also answer the purpose of girders to carry the floor—if it be desired to continue the curvilinear form throughout the roof, horizontal ceiling joists 4 by 2 and 12 inches apart might be notched and nailed on to the front edge of the ribs, the laths could then be easily bent to the form of the curve and plastered in the usual way; to give the room a pleasing effect, it may be lighted by means of sky-lights in the upper part of the roof, and the centre of the curved ceiling formed into circular sashes and glazed with ground, stained or embossed glass.

Fig. 1 is a section of one half of the span of the roof drawn to a scale of a quarter of an inch to the foot.

Fig. 2 is an enlarged view of the purlin secured to the ribs by the iron straps Fig. 3.

A NEW SAFETY VALVE,

Sir—It appears to me that the *corner* in your Journal which was last month occupied by "Funnel," has been filled up but in an indifferent way; I really can see no object in attempting to arrive at a simple end by means of a very circuitous route; what possible advantage can the complicated arrangement of compensating bars, cylinders and radiating arms have over the beautiful, and I may say perfect invention already in use? Mr. Funnel should have fixed a cog-wheel at the end of each arm, and a cam to each leg by way of giving his safety-valve a truly eccentric character, and on such he might have grounded its merits, as it is one feels greatly at a loss to ascertain the object of this *funny* discovery: however, as I hope to spared being levelled to a Candidus, so must I eschew the ways of that worthy, and by setting all banter apart, must merely venture to suggest that Mr. Funnel would do well to enter into such an explanation of his valve as would tend to establish its superiority, or else by screwing it down to oblivion, would acknowledge tacitly or otherwise, that after all his invention is nothing more than what our mutual friend of the Fasciculi might call "a mare's nest."

Believe me, Sir, to be, with respect,

Plug.

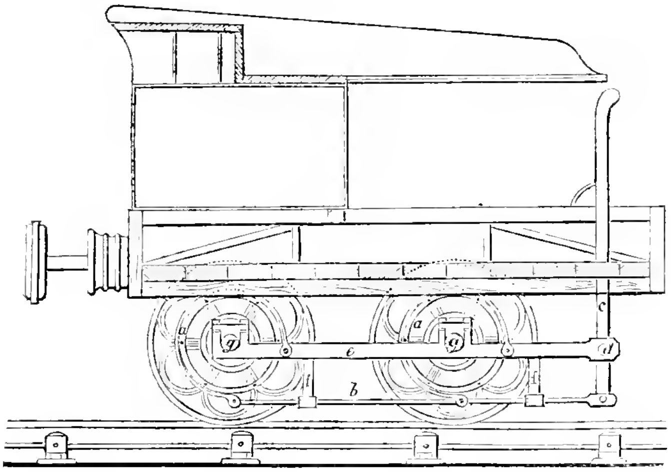
November 22, 1841.

RAILWAY FRICTION BAND BREAK.

Sir—The want of a better system of breaks for stopping or retarding railway trains, has suggested to my mind a plan which I believe to be new, and calculated to remove some of the defects existing in all those now in use; should you think the accompanying sketch and description worthy a corner in your useful Journal, I think much good would be done by directing the attention of mechanics to the subject. I need scarcely say that in the arrangements of the levers in the diagram, the object in view has been to show the principle clearly, rather than to show the best application.

I am, Sir,
Your obedient servant,
George Spencer,
Mechanical Draughtsman.

5, *Hungerford Street, Strand,*
November, 19, 1841.



In the construction of all the railway breaks in use, there appears to me to be two radical errors; 1st. The breaks are applied to only a small part of the wheel, and consequently its power is unnecessarily limited.

2nd. The bearings of the break axles being on the carriages, and the springs intervening between them and the wheel to be acted on, the pressure or friction is never uniform, and the breaksman therefore finds a difficulty in judging the amount of pressure necessary to stop the train.

Now I think these objections may be obviated, by applying the friction band so commonly used in cranes; on this plan the momentum of the train might be *received in any quantity* the breaksman might judge proper.

I think having the break axle bearings on the wheel axles, even with the present breaks would be a great improvement for the same reason.

The diagram will be readily understood by reading the references in the order of the letters.

REFERENCE.

a a, friction wheel and band; *b*, tightening bar; *c*, lever; *d*, lever fulcrum; *e*, bearing bar on axle shaft *g*; *f f*, supporting guides.

ON THE POWER OF STEAM ENGINES.

Sir—I am glad to find in your November number one modest advocate for the introduction of the Wave principle, yet when a failure does take place, as was the case with the Flambeau, we must be frank and admit it, and not clothe it with difference of opinion in calculating the horses power of steam engines.

If Y. takes the trouble to examine the calculation in my previous communication, he will find the mean pressure on the piston 14 lb. not 7, 7·1 or 7·3 as he would have it, without any reference to the pressure on the boiler. I should like to know if 7, 7·1 or 7·3 would hold good in the Cornish engines.

Again, I would ask if an engine made 27 strokes of 5 feet would that amount to 220 feet of piston? I think not; 270 feet will be about it, and Y. will find I only grant greatest speed on the Cyde at this rate.

Again, I have no objections to Y. using 33,000 for his divisor' deducting 25 per cent. on 44,000 I think he will find little difference.

Again, "the least steam assertion is granted, by the account of the change of the boiler." I would ask again, would the Cornish boilers supply steam the whole length of stroke? "but the effect of a new and probably heavier boiler is curious, and an accurate statement of the facts would be valuable." Y. might have omitted "probably'' altogether, every one knows if more steam is wanted, more heating surface must be given, consequently the boiler must be heavier, and the effect of course greater draught of water, and I think Mr. Scott Russell must have known this before he made the proposal. I think Y. will find from this enough to convince him that the assertions made in page 312 is not "based in any degree on the unsound foundation of the difference stated."

I remain, Sir,
Your obedient servant,
H

November 12, 1841.

REVIEWS.

Heath's Picturesque Annual for 1842. Paris in 1841: by Mrs. Gore.

Although some of them are not particularly fresh—rather the reverse—the architectural subjects contained in this new volume, are ably treated in themselves, being from the pencil of Allom, one of the first architectural draughtsmen of the day. It will, perhaps, be thought that Paris itself is now rather an exhausted subject, and that there is very little to be found but what has in some shape or other been exhibited to the public. This, however, is so far from being the case that we could mention several buildings, which we expected to find here illustrated for the first time, but which seem to have quite escaped the artist, notwithstanding that they are of considerable importance. Surely the Hotel de Ville, the Ecole des Beaux Arts, with its screen from Chateau Gaillon, the Hotel du Quai d'Orsay, Notre Dame de Lorette, and several structures—some of them still in progress, others recently completed, would have furnished more than the same number of subjects for the pencil. It is not without cause therefore that we feel disappointed at here meeting with many "old acquaintances," and hardly in a new dress, for the buildings are shown from nearly the very same point of view as we have before seen them represented in Pugin's Paris and other works. This might have been avoided, and we regret it the more because Mr. Allom's pencil would have been more worthily employed on edifices which are as yet little known, in comparison with some of those he has selected. We should have thought that he would have confined himself to entirely new subjects, yet as he did not, we are rather surprised he did not give us an interior of the "Pantheon," by way of companion to that of La Madeleine, in order to afford a comparison between them, as delineated and engraved by the same artists. Beautiful as they are, their merits are of very different kinds, and we are almost inclined to declare in favour of La Madeleine, if only on account of being more novel in character. Its plan is exceedingly simple, forming merely a nave or single vaulted hall, without transept or even aisles, but divided into three compartments, each of which is covered by pendentives and a segmental dome. There is besides a spacious semicircular tribune or apsis at the north end, raised a few feet above the rest of the floor, and covered by a semidome. In one respect this interior is distinguished from almost every other of its kind, namely, in being lighted entirely from above, through the centre of each dome; yet though there are only four apertures of the kind, including that over the tribune, the church is found to be sufficiently well lighted, while the effect is incomparably superior to that produced by side windows; for great breadth and repose is thus given to the architecture, whereas the other mode occasions a confused spottiness. Greatly do we wish therefore that some of our own architects would venture upon the innovation of lighting a church from its roof alone, and getting rid of side windows altogether, more especially as so far from being ornamental they are made invariably the reverse, with exceedingly mean-looking small panes of very ordinary glass, and when ground glass is used the effect is precisely that of a dense fog.

As Mrs. Gore does not trouble her readers with such dry matters as the dimensions of buildings, or in fact with any thing amounting to description of them, we may as well inform ours that those of the interior of La Madeleine are 260 feet in length by 52 in breadth. The exterior view of the same building, is by no means so interesting as the other,—in fact it might very well have been dispensed with, it being no more than a Corinthian peripteral temple, and having also been shown some time ago, in one or two of our weekly publications. We rather wonder that we do not here meet with the *Colonne de Juillet*,—not that it is a particularly good subject in itself, but because it is the newest thing of its kind in the French capital. However, although their subjects might have been more judiciously chosen, the *plates* are by far the best part of the feast—vastly better than the insipid hotchpotch which Mrs. Gore has *dished-up* on her part.

Sporting Architecture. By George Tattersall. London: Ackermann, 1841.

The Edinburgh Review has lately devoted a long article to sporting literature, and the Athenæum has made itself merry with a sporting novel. After such an advent, we were prepared for any miracle, particularly when we remembered what important influence sporting legislation has for centuries had upon the social system fabric; but in what unlooked-for form the genius of sporting was next to be found we could not say, whether lecturing upon sporting æsthetics in our older universities, places long haunted by the Newmarket Minerva, or whether in the Useful Knowledge Halls of the Gower Street College, it was not for us to divine. Imagine, then, our surprise, when we find the new offspring of this union of Diana and Apollo laid at the doors of our own Foundling Hospital, to wit, in the shape of young Tattersall on Sporting Architecture. Sporting Architecture! and why not? when horses are better cared for than men, when the hygeiene of puppies is far more studied than that of the starving thousands, why should not sporting have its architecture as well as its painting and its prose? The numerous occasions on which it is necessary for the builder to make provision for animal economy would alone induce us to give our attention to the subject; but when we have, in the hereditary tastes of Mr. Tattersall, and in his professional skill as an architect, such weighty motives for listening to his themes, we should be, indeed, inexcusable had we the adder's deafness. We can, however, scarcely forbear from a smile when we think of the Choragic Monument of Lysicrates turned into a distance post, and the Erechtheum on the top of a grand stand. With all these incongruities, we must look upon sporting architecture, or architecture for horses and hounds as a subject of considerable importance. In connection with military buildings the proper mode of constructing stables, must be carefully studied, and when we are informed that a sum of 10,000*l.* has in more than one instance been laid out on a dog kennel, 70,000*l.* on stables at Windsor, and that no expense is spared that can preserve the health of the stock, it behoves the architect to look about him. In its bearings, too, upon farm architecture, and the building of railway stations, riding houses, cattle markets, and slaughter houses, the work before us is of interest, and in fact, whether in the stable attached to a private dwelling house, or whether in buildings specially appropriated to the horse, every professional man will find his advantage in adopting Mr. Tattersall's volume as a work of reference. When we look into it we are pleased to see the care the author has taken in availing himself of information from the best sources, and we are pleased with the attention he has devoted to ventilation, drainage, soil and materials. Mr. Tattersall is a man of taste, also; we find his work well and usefully illustrated, so that we look upon it as a good addition to our professional library. Utility is Mr. Tattersall's motto, and in a subject which is generally treated *ad captandum*, it does him great credit that he should have so steadily fulfilled his promise.

Companion to the Almanac for 1842. Knight and Co.

The architectural portion of this new volume of the "Companion," which has just made its appearance so late in the month as barely to allow us to mention it—contains much interesting matter, both descriptive and critical. Among the buildings which are more fully noticed, are, the Houses of Parliament,—Royal Exchange,—the structure in Threadneedle Street,—St. George's Hall and Assize Courts, Liverpool (with plan and perspective view),—Collegiate Institution, do., (with view),—Surry Pauper Lunatic Asylum,—Savings Bank, Bath (with view),—Streatham Church (with elevation),—St. Mary's Southwark (with view),—Trinity Chapel, Poplar (with elevation and section),—and St. Chad's, Birmingham.

A Hand Book for Plain and Ornamental Mapping.—Part II. By Benjamin P. Wilme, C.E. and Surveyor. London: Weale, 1841.

Mr. Wilme's book is a collection of designs for executing the several parts of a map, including ornamental titles, sections, hills, embankments, drains, &c., and may be advantageously used by the engineering draughtsman.

ON EARTH WORK.

By Ellwood Morris (United States), Civil Engineer.

[The following extracts from the American Franklin Journal, show that our transatlantic brethren are alive to the economical working of earth work. We shall be glad to receive from some of our engineers their observations on the increase or decrease of earth work and rock when removed from cutting to embankment.—Editor.]

On the Cost of Excavating Earth by means of Scrapers or Scoops.

Of all machines known to American Engineers, and used upon our public works for the excavation of earth, and its removal to short distances, the scraper, or scoop, is, within its proper sphere of influence, by far the most economical.

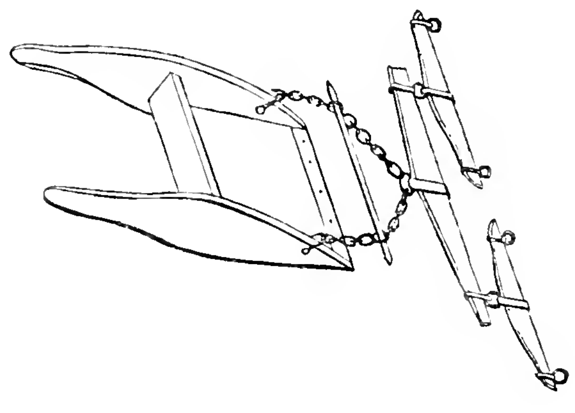
This instrument is particularly well known to canal contractors, much used by them in earth cuttings, and most frequently employed in excavating the trunks of canals, where they are so laid out that the cutting makes the bank, or nearly so; but the *scoop* may be used with success in all excavations of earth where the slopes do not exceed $1\frac{1}{2}$ to 1, if the material to be taken out yields readily to the plough, and is not required to be moved horizontally more than 100 feet, nor to vertical heights exceeding 15 feet; there are doubtless instances where both these limits may be surpassed, and the use of the *scoop* still be highly economical, but such cases are not general, and the practical scope of the utility of *scoops* may be regarded as confined to the excavation of canal trunks, and the formation of low road embankments from side trenches, for both of which purposes it is more admirably adapted.

This machine is drawn by two horses, managed by a boy, and usually requires the ground to be first ploughed; then by simply elevating and guiding the handles a little, the driver causes it to load itself, for the horses being in motion it turns in its clevisses, and inclining downward, runs under the loose dirt like a plough; the handles being released, the loaded *scoop* moves upon two iron shods runners which form the sides, and project below the bottom, and finally after reaching the place of deposit, the handles being smartly elevated, the edge of the *scoop*, which is armed with iron, takes hold of the bank, and the horses moving on, it overturns and discharges its load; in this overturned position, with the handles resting on the double tree, it returns upside down to the place of excavation, and is there loaded, &c., as before.

Although for successful scooping the ground usually requires loosening, and must not be so hard as to resist the plough; it is often the case, especially in sandy material, that it is to soft that the scoop, by its armed edge, is able to excavate it, and load itself, without any previous loosening of the earth.

All this will be rendered so evident to the reader, by an inspection of the annexed isometrical sketch, showing *a scoop*, with its double tree, and single trees, that any further description of the mode of operation seems to be entirely unnecessary.

The writer pursuing his object of acquiring, from actual experiment, a knowledge of the cost of excavating materials and forming embankments upon public works, early addressed himself to observe the effect produced by scoops, and the results of numerous observations upon scooping earth to horizontal distances of from 30 to 80 feet, and heights of 5 to 15 feet, where the slopes are 2 feet base to 1 foot rise, established in a satisfactory manner the following data:



1. That taking average earth (yielding readily to the plough,) at mean stages of weather and seasons, *a scoop load* may be taken at *one tenth of a cubic yard measured in excavation.*

2. That the time lost in loading, unloading, and all other ways per load (except in turning,) is, at an average, *two-thirds of a minute.*

3. That in every complete turn, or semicircle, described by the horses, *one-third of a minute is lost.*

4. That if the mean horizontal distance of transportation of the earth in a right line, *be added to* the extreme height scooped, measuring vertically from the bottom of the excavation to the top of the bank, then for every 70 feet of this aggregate distance, *one minute* will be consumed by the horses in going out and returning back.

5. That if the earth be all scooped to *one side*, as for instance, to the tow-path bank alone, of a canal, *two turns, or a complete circle*, will be made by the horses, for every load deposited in bank.

6. That if the earth be scooped to *both sides* of a canal, but *one turn, or a semicircle only*, will be described by the horses, for each load put in bank.

From the 5th and 6th observations, it follows that clear of the time needed to overcome the horizontal haul and vertical height, the constant amount of time lost per load, will be:—*In Double Scooping*, 1 minute, and *in Side Scooping*, $1\frac{1}{3}$ minute. Now if the sum of the mean horizontal haul, and the extreme height scooped, both in feet, be put $= a$; the number of hours wrought per day, $= b$; the number of cubic yards excavated and placed in bank, per day, by each scoop, $= x$. Then the general formula to find x in *double scooping* will be:

$$\frac{\left(\dfrac{60}{\frac{a}{70}+1}\right)b}{10} = x.$$

Transforming this equation by the rules of algebraic fractions, and substituting for b the average number of hours commonly wrought per day, $= 10$, we are able to reduce the formula to the following;

In Double Scooping, $\dfrac{4200}{a+70} = x$ . . . . I.

And for *side scooping* the general formula will be:

$$\frac{\left(\dfrac{60}{\frac{a}{70}+1\frac{1}{3}}\right)b}{10} = x.$$

Transforming which, by the rules of algebraic fractions, we have:

In Side Scooping, $\dfrac{4200}{a+93\frac{1}{3}} = x$ . . . . . . II.

Now putting *the cost per cubic yard of excavation put in bank clear of all profit*, $= y$; the daily wages of a scoop and driver, in cents, $= c$; the cost per cubic yard, in cents, of loosening the earth, $= d$; the formula to find y, the cost in pence* per yard, either in double or single scooping, will be:

$$\frac{c}{x} + d = y \quad . \quad . \quad . \quad \text{III.}$$

The actual number of cubic yards excavated and put in bank by *scoops*, in several instances, having become accurately known to the writer, the correctness of the formulæ I. and II. will be tested by those cases.

Example I. Double Scooping.

In this case, 3600 cubic yards of earth were excavated and put in bank by 90 days work of *scoops*, or per scoop, per day, 40 cubic yards, x: the mean horizontal haul was $26\frac{1}{2}$ feet; and the extreme height scooped, 8 feet; making the aggregate distance $34\frac{1}{2}$ feet. Then by the formula (I.) we have $\dfrac{4200}{34\frac{1}{2}+70} = 40{\cdot}2$ cubic yards $= x$.

Here the calculated and actual day's work of the scoops is the same within $\frac{1}{5}$ of a cubic yard.

Example II. Single or Side Scooping.

In this case, 5000 cubic yards of earth were excavated and deposited in bank by 176 days work of scoops, or per scoop per day, $28\frac{2}{5}$ cubic yards, $= x$; the mean horizontal haul was 44 feet, and the extreme height scooped, 11 feet; making the aggregate distance, 55 feet, $= a$.

Then by the formula (II.) we have $\dfrac{4200}{55+93\frac{1}{3}} = 28{\cdot}3$ cubic yards $= x$.

Here the difference between the real and calculated days work of a scoop is $\frac{1}{5}$ of a yard.

Conceiving it to be unnecessary to display at length any more of the examples, we will embody, in the following table, the results of actual experiments, and compare them with those calculated by the formulæ.

No. of Experiments.	1	2	3	4	5
Kind of scooping.	Double	Double	Side.	Side.	Side.
Mean horizontal haul	26·5	26·5	44	36	40
Extreme height scooped.	8	8	11	6	9
Value of a	34·5	34·5	55	42	49
Number of cubic yards excavated and put in bank	5000	3600	5000	5610	852
Days work of scoops employed . .	126	90	176	181	28·5
No. of cubic yards actually excavated per day by each scoop . .	39·7	40	28·5	31	30
No. of cubic yards excavated per day per scoop; calculated by formula I. and II.	40·2	40·2	28·3	31	29·5
Cost per cubic yard of the excavation calculated by formula III.	$4\frac{1}{4}d.$	$4\frac{1}{4}d.$	$5\frac{3}{4}d.$	$5\frac{1}{4}d.$	$5\frac{1}{2}d.$

In calculating column 10 of the above table, the hire per day of a *scoop and driver*, has been assumed to be 12*s.* $5\frac{1}{2}$*d.*, and the cost of loosening, at 1 cent (·54*d.*) per cubic yard.

The near coincidence of the results in columns 8 and 9, shows how closely the calculated number of cubic yards, excavated per day, in each of the kinds of scooping, agrees with the real day's work *of each scoop*, as actually ascertained in excavating 20,052 cubic yards of earth; consequently we may regard the formulæ which we have deduced, *as being sufficiently confirmed to justify a full reliance upon them in practice.*

* We have adopted the English pence for calculation, instead of the dollar and cents, as given in the original paper by the author, allowing 54 pence for the dollar.—Editor.

ON THE COMPRESSION OF EARTH, AND THE INCREASE OF ROCK IN EMBANKMENT, COMPARED WITH THE VOLUME IN EXCAVATION.

I. *On the Compression of Earth in Bank.*

It is well known to practical engineers, that when earth is excavated and formed into embankment, it occupies *less space in bank* than in the cut whence it came.

Although experience has sufficiently established this fact, yet a contrary opinion is often entertained by persons who have not bestowed much attention upon such affairs; and this idea is encouraged by inadvertent paragraphs, which are sometimes met with in works of high professional authority.*

Thus even in Professor Mahan's able treatise upon Civil Engineering, (page 118,) we find the following sentences:—"In determining the relations between the volumes of the embankments, and the excavations by which they are furnished, it must also be borne in mind that earth, in its natural state, occupies less space than when broken up; and as the embankments, when first formed, are in the state of earth newly broken up, an allowance must be made according to the nature of the soil. This allowance will generally vary between one-twelfth and one-eighth; that is, earth, when first broken up, will occupy from one-twelfth to one-eighth more bulk than it does in its natural state."

Now, so far from this being the case with embankments of earth, it is directly the reverse, and the fact is in practice, that the *compression*, and not the *expansion*, of earth, when formed into bank, is usually found to be from *an eighth to a twelfth part* of its volume in the natural state.

Although it is evident that a subject of this nature does not admit of a precise determination, because an almost endless variety exists in the consistency, and hence in the compressibility of earths; still it is quite possible to form an approximation which will not, in general, err very far.

* The most common error upon this subject, which we meet with in books, is the supposition that a certain amount of earth excavation, will form the same quantity of embankment; which, in practice, can never be the case in banks that are made with carts.

Thus in Professor Millington's excellent "Elements of Civil Engineering," we find it stated (at page 184,) that by a particular arrangement of levels, "one-half of the canal will be in excavation, and the remaining half in embankment, and the soil that is dug out of one end will serve to form the embankment at the other." The same idea runs through other works, which we might quote if it were necessary.

A few years ago the writer made some observations upon embankments formed from excavations, in three different cases, and upon a tolerably large scale, where the accurate cubic content, both of cut and bank, was known, and the amount of the latter exceeded 39,000 cubic yards.

The details of these experiments, all of which refer to banks formed in layers by cart and scoop, are to be found in the following statement, of which we may further observe, that one winter intervened between the commencement and completion of each bank.

Number of the embankment.	Earth excavated to form each embankment.	Embankment made by the preceding quantities of earth.	Shrinkage or compression of the earth in bank.	Rate of the compression of the earth in bank.
	Cubic yards.	Cubic yards.	Cubic yards.	Cubic yards.
1*	6970	6262	708	9·84
2*	25975	23571	2404	10·80
3	10701	9317	1384	7·73
Total.	43646	39150	4496	

By these tabulated observations, we perceive that 43,646 cubic yards of earth, transferred from its natural locality into the embankment of a public work, suffered by the operation a diminution, or shrinkage, in bulk, of 1,496 cubic yards, or *one-tenth* of its mass.

Some other observations, upon a smaller scale, indicated that the compression which took place in *gravelly earth*, when used for embankment, amounted to about *one-twelfth* of its bulk in the cutting.

Consequently, at least until more ample experiments are made, these results seem sufficient to justify the assumption of the following rates for the compression of earth in bank, viz.

In light sandy earth, $\frac{1}{8}$ of the volume in excavation.
In yellow clayey earth, $\frac{1}{10}$ "
In gravelly earth, $\frac{1}{12}$ "

In computations made for the purpose of equalizing the excavation and embankment upon roads, canals, or railroads, a strict attention to the above considerations is indispensably requisite; for if they are neglected, it will be found that excavations, which have been laid out as sufficient to furnish the materials for a given embankment, will be deficient in quantity, and an unexpected resort to side cutting will become necessary to complete the bank, as has been witnessed by the writer in more than one instance.

In tracing out a canal, if the depth of cutting sought by the centre line, as necessary to form the banks from the excavation of the trunk, has been calculated without due allowance for the compression of earth in bank, the trunk of the canal will not supply material enough, and a resort either to cutting below bottom, or to side trenches, will become unavoidable, to make up the amount deficient.

II. On the Increase of Rock in Bank.

By careful observations made by the writer, it was found that the excavation of 22,625 cubic yards of hard sand-stone rock, which quarried in large fragments, formed 32,395 cubic yards of embankment; showing that in this instance the increase of the rock in bank was 9,770 cubic yards, or about $\frac{3}{7}$ of its volume measured in the cut.

In another case, it was noticed that the excavation of 16,982 cubic yards of blue slate rock, that broke up into small pieces, formed 27,131 cubic yards of embankment; showing that here the increase of the rock in bank amounted to 10,149 cubic yards, or nearly $\frac{6}{10}$ of its measured bulk in the cutting.

From these observations, made upon the increase of near 40,000 cubic yards of rock-cutting carried into bank, it would seem that the augmentation was about one half: but as in lime-stone, and other rocks, it might be found to vary, both with their relative frangibility, and the dimensions of their quarried fragments, more experiments upon this point appear to be necessary to enable correct rules to be framed.

Philadelphia, September 1st, 1841.

Spark Protector.—The German journals state that an engineer of Vienna, named Klein, has invented a method of preventing sparks and ashes from the fires of the locomotive engines of railroads from falling on the passengers in open wagons, without, however, diminishing the current of air necessary for the fire. The experiments made on the Vienna railway have been so satisfactory that it has been resolved to adopt his apparatus, and to burn wood instead of coke.—M. Klein has taken out a patent for his discovery.

* Embankments 1 and 2 were yellow clayey soil, and No. 3 light sandy soil.

HINTS ON ARCHITECTURAL CRITICISM.—Part 3.

It may appear quixotic, perhaps, to raise an opposition for the sake of advancing to a point, especially to men, who, from an estimate of its worth, love their profession; still, though it would pain me so to insult the enlightened perception of many whose genius I revere, I must even assume the attitude of Cervantes' Don, and fight against impediments as they appear to stand betwixt criticism and the truth. It is from a painful conviction that architecture is beset by enemies in the guise of friends, whose opinions mostly discolour what they touch;—it is from the spirit of common disquisition afloat respecting her beautiful figures, that I have been so particular in establishing her claims, and it is also that I may help to raise her to that pinnacle which is her due, that one more part is devoted to confirm them.

Candidus, in his peculiar way, has long since taught us to infer, how that many comment on architecture, who can remark on nothing else, and if I affirm that many assume the airs of architectural connoisseurship whose coarse minds would famish on the delicacies of poetry, I am not farther from the truth than the gentleman alluded to. Let not then the man of taste question the benefit of any attempt, however humble, which has for its object to inculcate purer notions concerning an art whose monuments, above those of every other art, embody the most extensive combinations, whether of beauty or of grandeur.

In furthering my idea, then, the questionable character of proportion invites regard, since to this the student of architecture first looks, as he measures to be great. This measurement for beauty, which is now the great feature in early tuition, and which sprang originally from a desire to appreciate more fully what seemed so exquisite in design, first gave us those ideas of proportion we denominate classic. Whilst, however, we were gaining acquaintance with the treasures of antiquity, an evil was creeping insidiously in upon us, inasmuch as, that beauty herself was becoming from habit systematic, and we ourselves were in danger of ranking as engravers, rather than as artists, whilst we reduced or transferred her objects. In spite of that love of antiquity, which affected us towards the adaptation of Athenian or of Roman architecture, in spite of our admiration of parts for their intrinsic merit, an idea of proportion became engrafted on the mind, which, as it pursued either one style or other, fixed upon that mind first a prepossession towards certain division of parts, with their arrangements, to the prejudice of other division of parts, with their arrangements, until finally, this prepossession settled down into a confirmed choice for certain proportions, which were soon adhered to inflexibly. The necessities of the art, too, requiring the easiest adaptation of form, inasmuch as it was (and is) dependent upon very many contingent and urgent wants, led the architect to apply eagerly, as he did with exactness, newly discovered beauties, especially when every one admired, and when it was deemed creditable to his taste so to do. Ideas of proportion were thus formed, so that with a reducing compass, or a rule, symmetry was regulated, until amateurs, and would-be amateurs, discovering a key to elegance, learned with very little trouble how to commend or repudiate. Proportion soon became a word narrowed in definition, as habit in practice and criticism applied it; and when the complacent regard of many for ancient examples, became fanned into a stronger feeling, so as to produce a frown at what was different, then the spirit of originality fled, and proportion became sacrificed to a few favourite forms with rules to shape them, whilst the word itself was a definition only of their parts, or else explanatory of the comparisons made between those parts, and others of a natural figure. The consequence of all this was soon felt, for proportion being seen the great concern of an architect—the principle he seemed so to labour with, the spectator laughed to witness the accouchement of ideas, which resembled Æsop's mouse in their littleness. The poverty of the art was next challenged by many ignorant of its luxuriant beauties, and the professor was at last judged by a low standard, when the poetry of design was found so easily contrived; from all this has sprung that race of pigmy critics, whose buzz is so discreditable to our eloquently moving art.

It is against these and not against the artist, that I raise a feeble voice, and it is to meet the simple conclusions drawn from their crude notions of proportion, that I seek to generalize the word by extending its signification. Proportion as a desideratum in architecture, we say is evident, and we are inclined the more feelingly to assert this, because the ancients, chastening their most beautiful designs into the severity of fixed proportion, left little to the licence of unstudied art, to affix or improve.

In considering proportion, it would matter little whether, according to Burke, it be a mere negation, unless contrasted with deformity, or whether, according to Allison, it is in itself a source of emotion. I say, that it would matter little either way, provided that it be essential, were it not for certain notions entertained of it by many, which notions, arising out of habit, or want of study, cause the word to be incorrectly viewed in a composition. Proportion may be defined to be the arrangement of parts in a form, inasmuch as, according to the mutual fitness or disagreement of those parts, we have an idea of the whole, or of its symmetry; it is from this idea of the proportion, that we speak of a figure as being well or ill-formed.

It is evident, therefore, that proportion to be entertained, must require our attention given to those parts, and it is evident also, that pleasure to arise from them must vary as the power to perceive existing harmonies: but it is also evident that the mind must at the same time be thoughtfully engaged. Now, if great emotion be the effect of a composition in art, and if severity of thought be opposed to great emotion, which it is, proportion as fitness cannot be entertained for its own sake in the composition of beauty. Allison has taken considerable pains to confute the ideas of Burke upon this subject, by showing the nature of satisfaction felt from the consideration of fitness in a figure, and by arguing that if unpleasant associations (destructive to ideas of the beautiful) connected with a figure be removed, that then the fitness of parts will produce emotion. But the very necessity to have unpleasant associations removed before parts can be balanced in the mind, argues in favour of Burke, since, if our emotions in relation to beauty, being that beauty moves us and not we beauty, proportion would first of all affect us, independently of associations, were it a sharer in beauty's influence. There is undoubtedly a satisfaction felt by the mind, in discerning the perfection of figure. The anatomist might feel delight in theories, the very mention of which would shock, but it is only satisfaction that is felt, arising out of the effective exercise of our reasoning powers, or it may be extending into a livelier feeling, from the pleasure of having conquered, when by labour we have been able to discern the ingenuity or wisdom of another. This delight is an emotion different from that engendered by beauty, for it is an emotion resembling triumph. The spectator in such a case can sift his own emotion, and is differently affected to him who, viewing the beautiful, yields up his emotions and is conquered. It is no argument either in favour of proportion as being necessary to beauty, that the naturalist may deem a pig or a toad beautiful, because long study has prepared him for such a conclusion, and the mind naturally delights in perceiving that which reminds it of passed difficulties. In perceiving the harmony of contrivances, the naturalist views with the eye of habit, and feels an emotion because the *cause* of that appears which habit has made essential to his delight. Such a man from habit would view the skeleton of a woman with extacy, whilst the poet, who feels the poetry of beauty more than any one, would shudder, or mournfully meditate on the decay of beauty which he saw not. The one would see with satisfaction hollow cavities in the skull, the other would be wandering with melancholy over soft and oval features which were gone; the one would perceive the delicacy of bones and joints, the other would suggest to memory undulating and retiring beauties now no more:—the anatomist would reason, but the poet would feel. If proportion were minutely essential, our ideas would be full of it whilst viewing a building, but the reverse of this is the case. In buildings where the mind is encouraged to deep emotions, the trivialities of parts could not be entertained, for if they were, an admiration of them would change the character of deep emotion into that of mere pleasure—the grand cause of the effect being that reason is overbalanced; and hence it is, that the moment the eye becomes critical, then reason being restored, the impression is lost. In buildings, too, where the mind is more tranquilly engaged, and where the emotion is more softened, if proportion were minutely essential, we should seek out for every part to understand its relations, and be restless unless we discovered all; but how opposed is this to that law of beauty which always conceals a part and never displays the whole of her melting figure. If proportion were minutely essential, the design would be only one of contrivances, like that of a machine, which sets the mind thinking and perplexing itself before it can admire; and if we were to regard the design as we would a machine, our minds would be led from ourselves, who ought to be solely affected, to dwell on the ingenuity or skill of the contriver. It is only in severe and chaste designs, where the mind has its pleasure tempered by expectation, such as when a temple is erected to Minerva (and we contract an evenness of thought), that the idea of proportion is consecutively entertained, but the poetic sentiment is nevertheless sacrificed to this exercise of comparison, for we are more as admirers of the goddess than as beings affected by her power, our thoughts are not allowed to repose on beauty, but our repose is checked by the demand of beauty *requiring* us to admire—we are not allowed the languor of uncertainty, but we must rouse ourselves to perceive the fitness of harmonies.

My remarks tend, then, to make proportion only *indirectly* essential to a composition of beauty, and I am the more inclined to agree with Burke, because it is the *expression* of form which pleases us and first invites us to regard; and the only idea we have of fitness to the beautiful in figure, is the fitness of its expression, or of that which conveys in one unbroken harmony, ideas of delicacy, ease, grace, &c. Objects of beauty, too, although affecting to the mind, are also seen by a determination of sense, which, exquisitely acted upon by the most subtle influence, catches the spirit of a figure. Beauties in architecture are seen in this way. The beauty of the Grecian Ionic column for instance, would never charm us as it does, however well proportioned, unless a certain delicate softness of form were also apparent, which we trace in circles, cavettos, volutes, and beads. Our Creator, who, for wise purposes, has made us deeply sensitive to beauty, has given us sensations which, to be perfect, require either the accord of all our senses, or the quiescence of those unaffected; because, if one be disturbed, then the other is affected, and hence, it is in the proportion of the column, I love the sweeps and bends, because my eye wanders, sinks and reposes, like the touch, which, perchance, resting on a form of beauty, would wander, sink and repose. Besides, we sympathize to a certain extent with the object, before we think it beautiful, by giving it a personality. The poet is *wooed* by the gentle landscape, and is *kissed* by a pensive moonbeam—an ideal embrace is traced on such a mind, under such influence, with all that softness which sense in reality would feel; hence objects cannot be deemed beautiful that do not thus affect us, and hence the pig and the toad are both disgusting, spite of their proportion.

Proportion to architecture is however essential, but I do not say what are its degrees; the difficulty of explanation would be long and tedious, and beyond the narrow limits allowed me, which limits confine me to a prejudice confronting criticism, viz. that importance paid to minute divisions, to which the general sentiment of a composition is often sacrificed. Proportion in its most extended signification is expressed by fitness, and, as applied to composition, it is the adaptation of forms to some general idea, so that in their arrangement the general idea may not be broken. It is the poetry of forms, and their comparative magnitudes and altitudes, which is then required, assisted by that relative position which makes proportion in one case to be no proportion in another, and this leaves the mind open to that general emotion which *all* feel, when buildings of beauty or of magnificence appear to move or arrest them.

I do not mean, however, to say, that proportion in itself is not a source of delight in composition, for the contrary is instanced in the connoissenr, who, studying in Greece and Rome, has learned to examine critically and minutely, the exquisite parts of architectural figure found there. Habit has made his eye nicely alive to minute errors and delicate defects, or he feels an emotion in viewing their absence in forms, which careful study has discovered to him admirable in their fitness; but he resembles the anatomist, whose scrutiny furnishes his emotion. His delight is undoubtedly that of proportion, but it is a delight which springs out of severity, or habit of thought, and whilst this minuteness of thought engrosses him, it prevents the sentiment of a composition from operating on his mind. A second man might have studied the same figures, and as carefully, and yet have only discovered an expression of beauty in them. He might, too, before this, have seen the fitness of parts; but let him recur back to forms and figures, and he remembers them only by their expression, which expression it is, which makes them beautiful or sublime: and this remark is quite in accordance with taste, for, let a man be ever so cultivated, it is the expression of form which, after all, must influence the emotion of beauty arising out of figure. An idea of grace from difference of association, may be more refined in one man than in another, and his idea of loveliness may require greater delicacy of form to induce emotion; but, although the form which moves him is more symmetrical than that which moves another, it is, after all, the *expression* of the form which operates. Thus it is, that the association of the youthful artist with all the delicate chasteness of Greece, causes him to perceive expressions of beauty which a man of vulgar taste would lose. So that I do not quarrel with proportion, but only with the idea that it is entertained for its own sake in a composition of beauty. In speaking of figure, we say often, the form of such a girl is faultless:—what do we mean? We surely do not conceive the anatomy of her frame—the very emotion which induces such a remark prevents our reason from so working. What then do we mean? We mean that there is every thing in her form to express the delicate ease of beauty. An increased severity of mind in the spectator always bears a ratio to the decrease of poetic sentiment; hence it is, that an assemblage of few parts simply connected (deducting the accessories of situation) contributes to bestow on the rustic habitation its powerful charm. Finally these, and the foregoing observations, lead to an idea, already half expressed, that proportion, independently of the classification of forms, has its individuality in a whole—that it has its expression and meaning always in the extremes of a composition, and that those divisions which have no immediate connexion with its terminations, come under the head of beauty's accessories. If we look at a composition of the beautiful in nature, we shall discover our eye wandering along its principal boundaries. The idea of declension, which is an idea peculiar to beauty, will be traced along the principal lines. The foreground of a picture will conduct us perhaps to a widening landscape, which lessens as the eye advances, thence the eye will wander to a lake, lessening away, and thence to the mountains, dying into the horizon: and thus we shall find merely from those lines which suggest that unbroken idea of declension which the lover of beauty seeks, and which these lines, forming a pyramid on plan, show. Those who have watched the slight pencillings of an artist, may have discovered how this idea is sought for in his sketch, which cannot be called the mere effort of memory, because the same coincidence of idea is general, whilst nature has her pictures in every degree of aspect. All this is the proportion of a piece made up of lines, and is not to be confounded with the infinite variety of undulations and curves of the landscape, confined within a boundary, nor yet to be blended with the diversity of objects scattered in lovely confusion around.

As the argument here ceases, it may be suggested by some little critic or other, what has the gentleman proved by his labour? Has he taught the profession to become immaculate, or does all his argument tend to prove only that our ideas upon a few points are incorrect? Should such an amusing chirp be heard, it is only an unwilling argument in favour of my argument. Whenever our mind has been the subject of consideration, the most careful and philosophic spirits have exerted all their powers to detect the secret impulses which move it, nor has it been deemed by men of mighty intellect, a frivolous employment to exert every ingenuity to fix with certainty the causes operating on one simple affection of the mind. Nor can we be too careful in sifting and analyzing our minds, when we approach to consider the compositions of art, since, according to our perception of influences, so is our judgment, whilst, in proportion to the judgments of criticism, we are to judge of the refinement or debasement of that art. I can only add that proportion is essential, but it is a mere skeleton, hidden by the softest skin and concealed by the loveliest undulation, whilst it is lost to sense amidst the lights and shades and flowing dress of nature, and that architecture maintains her influence over the mind, not from the mere adaptation of parts but from her tales and pictures of sentiment.

November. FREDERICK EAST.

COMPETITION DESIGNS IN ROME.

[WHATEVER is connected with competition designs at the present moment, we consider is worthy the attention of the architect; we therefore with much pleasure give the following extract relative to competition designs, from a very interesting work recently published in Rome by Count Hawks le Grice, entitled "Walks through the Studii of the Sculptors at Rome."]

Large sums are annually expended by the Papal government on public monuments, from the sumptuous mausoleum to the simple statue; and all the treasures of art preserved in the magnificent museums of Rome are liberally thrown open to the gratuitous inspection and imitation of every artist, whatever be his creed or his country. Nor are the best means of developing artistic talent neglected. Public works are not given to a favoured few: they are placed under the direction of the Academy of St. Luke, a corporate body composed of the most distinguished artists in Europe, whose suffrages generally unite in the choice of the most competent. Hence the correct taste prevailing in every department. The most disinterested feelings are found to actuate the members of the Academy: and it has not unfrequently happened that the successful candidate has been until then one whose merit was known but to few. Such in truth was the first step made by the great Canova towards the temple of Fame; for until his genius burst forth in his famous monument to Clement XIV. in the SS. Apostoli, his name may be said to have been altogether unknown to fame. We have still a more recent instance of the impartiality with which merit is patronized in Rome even by private individuals. When the present Prince Torlonia, who is a most munificent patron of the arts, signified his intention to erect a monument to his late revered father, himself a princely patron, he invited all the artists of Rome to send in designs, which he engaged to leave implicitly to the Academy of S. Luke. The sum to be expended was considerable, but the glory to be acquired was still greater. The artists therefore entered the lists with no ordinary zeal; overtures and intrigues were not wanting; the patronage of the great was sought: but, to its honour be it told, that, deaf to every indirect influence or selfish interest, the Academy out voted itself, and resigned its own pretensions, declaring with one voice a young sculptor, 'till then unknown, the successful candidate. The noble Prince could not help expressing the apprehensions which he felt in entrusting to one of so little experience a work of so much importance: but the decision of the Academy was irrevocable, and the Prince, touched by their rectitude, not only acquiesced in their decision but advanced the necessary sums to enable the fortunate candidate to commence the work.

Under the direction of this same Academy, whose members are composed of artists of all countries without religious distinction, premiums are awarded with the same liberal spirit; and it is honourable to this country as well as to our own that, at their annual distributions, several English artists have been distinguished by prizes. The Academy has considerable funds; but the Roman Government, without assuming any right to influence its decrees, contributes largely to its maintenance. Their President is chosen without reference to creed or country: and hence we find Thorwaldsen at one time, and the Chevalier Don Solá at another time, their President. The professors of the Academy, who are at the head of their profession, give gratuitous education as well in the University as in the Orphanotrophia in painting, sculpture and architecture, and in the sciences necessary to their full development; and hence it cannot be matter of surprise that the fine arts flourish in Rome. These instructions however are not confined to Romans or Italians: they are imparted gratuitously to persons of every clime and creed. Such is the spirit of public beneficence which animates the institutions of Rome, and prompts private individuals to their imitation. In our time, for instance, the immortal Canova left behind him a tribute of munificent piety worthy of his great name, by consecrating his large fortune, the fruit of a life of toil, to the erection of a magnificent temple in his native country to the Omnipotent, from whom all talent and knowledge flow as from their source. He who promotes the arts must necessarily be hailed as a benefactor to his country, for he contributes not only to its wealth but also to its civilization.

> " Ingenuas didicisse fideliter artes
> Emollit mores, nec sinit esse feros."

Amongst such public spirited individuals must be numbered Canova, as several of his benefactions in Rome attest; amongst them must be numbered the present Prince Torlonia, who is in truth the Mecænas of his age; and amongst them stands pre-eminent the present reigning Pontiff, Gregory XVI., who vies with a Leo X. in his munificent encouragement of the arts.

COMPETITION AFFAIRS:—PADDINGTON CHURCH.

THERE are some matters in respect to which it is exceedingly difficult to make any impression on the public, except by such repeated hammering, that the very mention of them almost becomes a bore. Architectural Competition is one of them, and has been so frequently noticed of late, and apparently to so very little purpose, that many may be disposed to ask "*Cui bono?*"—what service is it to continue remonstrating against abuses, when the exposure of them seems to produce no effect whatever—neither the caution of decency on the part of delinquents, nor co-operation on the part of the profession to put down the malpractices complained of, so injurious to many of them individually, and so discreditable to them as a body?" Such is likely to be the plausible interrogation of easy indifference; and the advice couched in it is, no doubt, precisely that which the offenders themselves would wish to see followed. "It is of no use," settles the matter very comfortably.

The difficulty of putting down the abuses now so rife—the underhand manœuvring and jobbing now practiced in so many instances, that an honourably conducted competition may be considered an exception—this difficulty ought only to stimulate to greater energy, and to strong and determined measures on the part of the honest members of the profession. Or are we to suppose that these last are so insignificant in number, and are left in such a terrible minority, that their utmost united efforts for the correction of abuses would prove of no avail? If such be really the case, reform is altogether hopeless, and it is indeed of no use to expose fraudulent practices of which nearly all are more or less guilty, if the opportunity be afforded them. Still, as the profession will hardly admit such to be the case, any attempt to expose unfairness in competition may be supposed to be certain of obtaining their approbation.

The competition for the new church at Paddington does not appear to have been an immaculate one, but on the contrary, so conducted as to give rise to no little scandal. Among the competitors were several of note—Wild, Vulliamy, &c., and the fortunate one was a young architect of the name of Lindsay, whose design, which was in the Grecian style, was approved of by the committee. Mr. Lindsay was, however, doomed to be convinced practically of the truth of the proverb, "Between the cup and the lip," for incredible as it may seem, the committee afterwards thought fit to rescind their decision very cavalierly, entirely setting aside the whole affair of the competition, and appointing Mr. Gutch, a surveyor, and, as is asserted, actually one of the committee, as architect conjointly with Mr. Goldicutt. They—or one of them, but which we are unable to say—then produced the present Gothic design, the expense of which, it is understood, will not be at all under £10,000, although the competitors were limited in the first instance to £7,000; therefore it ought, at all events, to be something very superior to what was originally contemplated. How far such be really the case, is what we have not the means of judging; but if the published lithograph view may be relied on as a tolerably fair representation of the building, we think the committee have made after all an exceedingly bad bargain. In regard to style it is a mere jumble, while, looking at it merely as a composition, it is poor, trivial, and insipid.

As to the manner in which the competition has been conducted, and the original competitors treated, should there be any error or misstatement in our account of it, we shall be glad to be corrected, and to be assured that whatever the adopted design may be in itself, there was no kind of manœuvring on the part of any one in the case.

V.

Sir—Enough has already been said respecting the present system of competition, it is now high time for the profession to do something in order to redress their grievances. A Society might be formed of as many architects (I would not exclude those who practice surveying also), as would join themselves together for mutual protection, binding themselves not to compete for any building, the committee of which would not conform to certain fair and impartial rules adopted by the society; there are no doubt many gentlemen in the profession well qualified to organize such a society, and surely all honest architects would join in the attempt to remove their liability to such dirty actions as it is too well known often disgrace "respectable" committees.

I sincerely hope that the influential part of the profession will take the matter up.

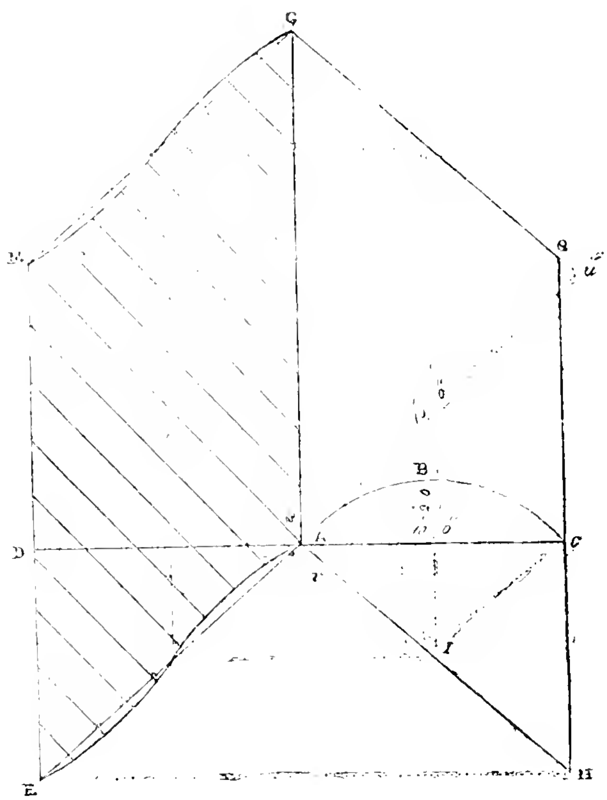
I am, Sir, your most obedient servant,

Parvo.

[We do not see the utility of any other Society than those already established in the metropolis and various parts of England and Ireland; if they would do their duty, they might, in some measure, put an end to the present deplorable state of competition. As far as we are concerned, we shall be at all times happy to give a helping hand to improve the system, but we must have the assistance of the Members of the Profession, who ought to act in *concert*, and not as now, opposed to each other.—Editor.]

ON THE CONSTRUCTION OF OBLIQUE ARCHES.

Sir—In your Journal for September 1841, Mr. Barlow in his reply to Mr. Nicholson, has thought proper to make some severe observations on the "Guide to Railway Masonry," published by that gentleman, and as I think very unwarrantably; Mr. B. only selects a small portion of that work, and because the whole of the oblique arch is not contained in his selection, he cannot award that merit to Mr. N. to which he is entitled. To take Mr. B.'s proposition, viz.: "suppose it was required to construct an oblique arch of the following dimensions, span = 10 = A. C. rise 2·5 = angle 45° = A. H. C.—Width of bridge 16 = A. U." I will now endeavour to show, aided by the instructions derived from the above publication, that the work can be correctly accomplished. Having laid down the plan and development, &c. &c. as per sketch, H Q G A and E F G A, then at page 10, Guide to Railway Masonry, will be found nearly the following directions: divide the straight line E A into nine equal parts, and let S U be respectively the eighth and ninth parts of division from E, draw F *r* perpendicular to A E meeting it in *r*, and as the point *r* falls between the eighth and ninth point, but nearer to the ninth *r*, than to the eighth *s*, join F and divide each springer line E F A G into nine equal parts, &c. Thus it will appear from the above that Mr. N. was not so "ignorant" of the fact, of the necessity in some cases of adjusting the



angle of intrado; and I believe that the first time Mr. Buck mentions the subject, is at page 9, and Mr. N. in his work, at page 10, showing that both Mr. Nicholson and Mr. Buck considered all the instructions preceding these pages, to have been preliminary. It is rather singular to find Mr. Barlow condemning Mr. Nicholson's "Approximations," when he in your Journal for October, arrives at the very same conclusion. "I guess" your readers will understand his position. Certainly no one can deny the "duty" of Mr. Barlow or Mr. C. to "expose errors," &c. Great men should be actuated by great and generous actions, and not as it appears in Mr. Barlow's case, made the means of suppressing the work of a worthy, intelligent and laborious old man. Highly creditable will it be to Mr. Barlow should he be permitted to attain to the same venerable age; could he exclaim, I too have been as useful to the artisan as a Nicholson.

I am, Sir, your's, &c.

M. Q.

York, October 8, 1841.

STEAM NAVIGATION TO THE PACIFIC BY THE ISTHMUS OF PANAMA AND ALONG THE WESTERN COAST OF SOUTH AMERICA.

(From Silliman's American Journal.)

Some interesting pamphlets on the subject named in the title were placed in our hands early in 1840 in Boston, by a brother of Mr. William Wheelwright, to whom mainly the world is indebted for an undertaking which may be with propriety ranked the first among the enterprises by steam. Mr. Wheelwright has laboured several years at this undertaking and is now on the eve of success. From himself we have just received a communication, which, although not intended for the public eye, contains many facts in which the world is interested, and we therefore venture to annex certain portions of his letter or abstracts from it.

Talcahuano, March 8, 1841.

TO PROFESSOR SILLIMAN.

Dear Sir,—I had the honour of receiving your valued favour only a day or two since, having left the United States about the time it was written, to take up the superintendence of the Pacific Steam Navigation Company, which I had previously formed in England.

Two of our steam ships, of about 700 tons each, the Peru and Chile, arrived in this port in 55 days from England, passing through the Straits of Magellan, from sea to sea, in thirty hours: sails were employed when the winds were fair, otherwise steam, and the voyage may be said to have been one of the most brilliant ever undertaken. The field for steam navigation in these seas is so ample that our first voyages came off most successfully, proving and fulfilling every statement made: unfortunately, however, the directors in England, neglecting to send a supply of coal, as previously arranged, the operations of the company have ceased, for the present, and I am now engaged in this place in mining for coal, an operation never before undertaken in this country, and which of course presents a thousand difficulties. My first object when I arrived here was to make a practical examination, to ascertain the strength of the coal, and see its influence upon our boilers and fire bars; for this purpose I proceeded south, with the double object of proving the coal and exploring Valdivia and the island of Chiloe. After some unsatisfactory experiments, we finally came to such an arrangement of our fire bars as to produce a result decidedly favourable; the excess of expenditure over the best Welsh coal was 27 per cent., which is nearly as good as Newcastle coal. The formation of clinker is great, but it is not of an adhesive character, and the fires are easily cleared; the coal seems to possess no sulphur, and there is nothing disagreeable in the smoke: the ashes are white and the coal free from smut. The coal lies in horizontal strata, rising or falling not more than ten or eleven degrees; is about three to four feet wide, and is found most generally, cropping out on the precipitous sides of hills; the upper stratum is generally soft; the next stratum, which is what I now send you, is found from twenty to forty feet beneath; and I am now engaged in sinking a perpendicular shaft for the purpose of finding a third stratum and still better coal. Some two or three cargoes of this coal have been shipped, and spontaneous combustion has been produced, which set fire to the vessels; it must be considered that the coal first used was never mined, and was taken merely from the surface. I have ascertained that in two instances the vessels which have been set on fire had vegetable matter on board—the first was a cargo of wheat stowed over a deep bed of coal: the next, the coal was shipped in what are called here *chequas*, made of grass. What influence they may have had in producing spontaneous combustion it is not in my power to say, and I should be much obliged if you could account to me for its spontaneous ignition. I cannot at present make any large deposit of this coal until I make some experiments, and for this object I shall load one or two small vessels with the coal, and watch it carefully, keeping it free from any vegetable matter, and from water, and giving it all the ventilation in my power; it is a great drawback upon my operations at present. On board the steamers we have iron bunkers for about ten or eleven days' fuel, and it causes me no anxiety in putting it on board. I had this arrangement of our bunkers made with a view of using this coal.

On my voyage south, I found at Valdivia and Chiloe the same strata of coal, and in a line of coast of more than 400 miles there does not appear to exist the slightest difference in quality. It is perhaps worthy of remark, that the coal found at Boca del Toro, on the Atlantic side of the isthmus of Panama, and near Cherokee on the Pacific side of the isthmus, is the same to all appearance as that found in this district.

I am at present mining about fifty tons a week, but hope in the course of a few days to open some more mouths, and mine in much farther than I am doing at present; my only fear is that in sinking a shaft I shall be obliged to contend with a large quantity of water. As it is a new thing and a work in which I have no knowledge, I am obliged to adopt a common sense view of it, and work on as well as I can, until miners can be sent me from England. The cost at the pit's mouth will not exceed two dollars per ton; should I get it lower down, it will be necessary to clear it of water by a steam engine, which will render it somewhat dearer. Notwithstanding our operations are paralyzed at present, I feel persuaded that by the end of this year our line of intercourse to Panama will be completed, and our communication with North America and Europe greatly facilitated.

I have no doubt that the coal beds here will bring about sooner the steam intercourse westward from Europe to Australasia: this has been a favourite plan of mine for several years, and I hope that the arrangements which I made before I left England, patronized by Sir Edward Parry, Captain Fitzroy, Mr. Montague and others, will soon go into effect. Perhaps the greatest change ever effected will be produced by opening an intercourse westward from Europe to Asia, and making America the stepping stone between them. The isthmus of Panama is destined to become one of the most interesting spots in the world; a ship canal will be formed, and it will be formed, and it will become the highway between the Pacific and Atlantic oceans. I have been frequently on the isthmus, have passed often between the two seas, have examined with much attention the facilities and obstacles which it offers for the object proposed, and have satisfied myself of the perfect feasibility of establishing a communication between the two oceans. On leaving England, I was requested to report upon my journey over, and to examine the isthmus with care, as well as the river Chagres. As it may, perhaps, be acceptable, I extract from the report such parts as I conceive may prove interesting to you.

"Having prepared myself with the necessary apparatus, I commenced by sounding the Chagres bar, where I found at low tide 14 feet of water; the river being then swollen 18 inches, left 12½ feet of water, from thence upwards to the junction of the rivers Chagres and Trinidad, (which you will find in the map in my pamphlet,) where there are four and three fathoms close to bank, which vessels might use as a pier to discharge goods. A little above the junction the water shoals to seven or eight feet—the channel below is never less than 300 to 400 feet, and often 1000 to 1200 feet; a steamer of 500 tons, properly built, might navigate as high up as the Trinidad, with perfect safety and ease; at this point it is also perfectly healthy; from this junction the distance is 28 miles to the Rio Grande, which empties into the Pacific about three quarters of a mile from the city of Panama. Vessels of any size may enter this river, as the tide rises in spring 22 feet; the space between the two points has but a very slight rise. I should say that it could not exceed 40 feet, for in passing over to Panama from Gorgona, I found there was not a hill to ascend, and that a good carriage road could be formed without making a single cut. While the land to the left towards Cruces was mountainous and broken, that to the right seemed to decline to an unbroken plane: hence, it appeared to me, that Lloyd's statement respecting that line was strictly true.

"My impression is, that the first object, before thinking of a canal, should be to make a good road from the junction of the rivers Trinidad and Chagres to the Rio Grande or Panama; by this means an intercourse between the steamers on the Atlantic and the steamers on the Pacific could be effected in three or four hours with perfect ease, and a cargo even transported in that time."

As it regards steam navigation in the Pacific, I feel convinced that it will gratify you to know, that the great work is going on. Even the few voyages made between Chile and Peru have shown, so palpably, its advantages, that the stopping of the steamers has produced a great sensation throughout the land; it is impossible to form an estimate of what it will do for these countries—the governments of Chile, Peru, and Bolivia, have granted every protection and continue to give me every support; and I am under the firm conviction that when once perfected, its advantages will be found vastly beyond what I have described them. I am very much indebted for the insertion in the American Journal of Science, of my paper on iron steamboats. I have made considerable efforts to bring forward that subject in England; I have gone into its detail and examined with all minuteness the whole subject, and I am perfectly convinced that not only all our western waters will be navigated by steam vessels built of iron, but that transatlantic steamers will and must be of iron. Mr. Brunel, the celebrated engineer of England, wrote me a letter of thanks for the paper, and promised to lay it before the board of directors of the Great Western Company, and I have reason to believe that it was mainly instrumental in bringing about the building of the great iron steamer, which will shortly ply across the Atlantic, and show herself as vastly superior to the Great Western, as the Great Western was superior to others, when she commenced transatlantic navigation.

THE PUBLIC WORKS IN FRANCE.

The following remarks on the public works in France are taken from a letter which lately appeared in the *Constitutionnel*, they present a melancholy picture of the state in which various public works have been left throughout France in consequence of the disastrous policy of "arming against all Europe," at an expense which not even the greatest financial prosperity could justify.

"The Count Daru has aptly characterized our actual situation—we commence great works on every side, and finish none. The great leading lines are scarcely sketched out, when the sums which should be destined to their completion are exhausted in opening unproductive branches. The interest of enormous capitals is lost, taxes are increased, and there is no augmentation of revenue. The generation which makes such generous sacrifices will derive no fruit from them. Canals, destined to enrich the country, are at this moment in the actual condition of lands purchased for their weight in gold, and yet shamefully remaining sterile. Each year we must recommence what was almost finished the preceding year; and, in place of diffusing wealth, we everywhere organize ruin.

"The canal from the Marne to the Rhine, for example, has been deplorably retarded. I am convinced, from a visit which I have just made to the principal industrial establishment of the department of the Meuse, of the disastrous consequences of this delay. I have seen throughout that active and laborious country a true desolation reigning. All the hopes which had been conceived of this grand and magnificent communication vanish in the saddest disappointment, and each contemplates with grief these immense works, created by an enormous expenditure, which will be doubled by this fatal interruption.

"It was in the session of 1838 that the Chambers voted the epening of this canal, which is the admirable work of the engineer Brisson. The Director-General of the *Ponts-et-Chaussées* declared that eight years at the most would be required to open this canal to the industry of the country, and, in effect, from that period down to the commencement of 1841 we must accord to the Administration the justice of admitting that nothing was neglected which could expedite the prompt completion of the work. So extraordinary was the activity which was therein exhibited that it might have been fearlessly affirmed its termination would not be later than 1846. Unfortunately, however, at the commencement of the present year, the Administration ordered a general slackening of the works, not only for the current year, but also for those which are to follow. Nay, more, it has announced that the credits allotted for the work in 1842 will be still less than those of 1841. It is easy to conceive the injurious effect of this determination, as well upon the unfinished works as upon the industry of the department of the Meuse, which reckoned upon the prompt execution of this undertaking to rescue it from the crisis which it has undergone, and which threaten now to become prolonged. It will be sufficient for me to make known the state of the works in this department, with the sums necessary to urge them forward in 1842, with a slight degree of activity, and to acquaint the reader with the sums actually voted last session. This information I have derived from the best possible sources, including the engineers themselves, to whose zeal and skill I cannot render too high a public homage.

"Setting out from the limits of the department of the Meurthe, the Marne-Rhine Canal is almost finished for a length of 17 kilometres in the department of the Meuse. The principal work is the bridge-canal on the river Meuse: this was commenced in November, 1840, and all the arches are at this moment closed. To finish this portion of the canal at the very most only the paltry sum of 300,000f. (12,000*l*.) is requisite: and this outlay would make it perfectly certain that in the course of 1843 the canal would be opened to the industry of the whole district, which would derive from it the greatest possible advantage. Well, this miserable sum it has been impossible up to this day to obtain.

"The interval between the Ornain and the Meuse, which is that portion of the canal where the works will be most tedious and expensive, has been commenced throughout its entire length. Besides the cuttings, which, according to the adjudications, amount to nearly 2,000,000f., this portion comprises the tunnel at Mauvage, which will be about 5,000 metres in length. The difficulties which arise, as well from the nature of the ground as from the great quantity of water which is met there, give every reason to apprehend that if the works are not carried on with the utmost activity the expense, which has been valued at 9,000,000f., will become doubled. From the Mauvage tunnel to Vitry le Français, where the canal effects its junction with the lateral canal at the Marne, the want of money alone prevents the immediate termination of the enterprise. What have the Chambers voted for the Marne-Rhine Canal for the current year, and for 1842? A sum of 3,000,000f., to be distributed amongst four departments. A million will be probably allocated to the department of the Meuse, which absolutely requires four.

"The result will be, of course, an enormous loss to the state. To finish the works twice the time must be employed, and perhaps twice the capital. Inevitable injuries to all the portions that are not yet finished, and indemnities to the contractors, who have engaged to terminate within a given time the portions adjudged to each, and who, having made all their preparations in consequence, have found themselves suddenly arrested in the execution of the works here, are the first only and most obvious consequences of this ruinous system.

"The point at which the most immense loss will be sustained by the Government, if the works are not resumed with pristine vigour, is the Mauvage tunnel. In point of fact all the wells, to the number of 17, several of them 120 metres in depth, are already pierced, and the galleries are commenced. The tunnel is formed of potter's clay, which easily becomes diluted in water. If the work is for a moment suspended at the end of four or five days the whole will be inundated: the wells and galleries will be filled with a liquid slime, and it will be more troublesome to repair what is done than it was to do it originally. Better never have commenced. And, yet so extraordinary was the activity at first displayed, that there was every reasonable expectation of its being finished within three years, which would have caused a saving of 1,000,000f. But, with the miserable pittance accorded by the Government to-day, no term can be foreseen either to the labour or the expense. All must be arrested, all suspended. The payment of the indemnities alone for the ground purchased will absorb the entire credit. These, Sir, are facts of public notoriety which a great number of persons engaged in manufacturing industry, agriculturists, and good citizens, would have communicated to the Minister of Public works, if, on his return from Alsace, he had visited, as we had generally hoped, this important portion of the Marne-Rhine Canal. But these sad details will nevertheless reach him, and it is surely impossible that they could escape his patriotic solicitude.

"It was easy to conceive that the 'eventualities' of war would lead to such results. Men do not reckon up sacrifices when the honour of the country requires them; but that the already brimming measure should still be filled to overflowing, when it is loudly proclaimed upon all hands that there is no longer any danger for the peace of Europe—this is what confounds and amazes every man of sense. What sort of peace is that which nips every amelioration in the bud, and disarms nothing but useful public works?"

To this powerful letter may be appended as a commentary the following paragraph from another portion of the same paper:—"So frequent is the occurrence of accidents on every portion of the works connected with the fortifications of Paris, that near each fort and detached wall there have been established temporary hospitals, at which surgeons are stationed from the different regiments employed at the works."

ON LEVELLING INSTRUMENTS.

Sir—Having observed in the Journal of this month a description of some improvements in Levelling Instruments, by Mr. T. Stevenson, may I be allowed through the medium of your widely circulated columns, to offer some observations on a subject which has engaged much of my attention.

The real practical value of Mr. Stevenson's improvements must very much depend upon the purpose for which they were designed. In some particular scientific researches, where the greatest nicety is required, and time little or no object, I can conceive a vernier adjustment both for the level and staff may be desirable. But for engineering purposes, as it is found that any slight errors in reading within the $\frac{1}{100}$ of a foot, which is the usual graduation of the staff, are not carried on and increased, but eliminated or rather balanced, in any series of observations, it is surely needless to seek greater accuracy in the scale, at the expense of much additional time and labour. And in fact, without regard to the tediousness of the operation, and the greater liability of casual mistakes, the delicacy of a vernier reading must be wholly lost and cancelled in practice, until we can command at all times a perfectly still atmosphere, and a true constant of refraction; and even with these it will be necessary to provide ourselves with a vernier adjustment for the spirit bubble—cross wires which are true mathematical lines "without breadth"—materials on which heat and moisture have no effect, and at the same time a rod, absolutely rigid, and perfect in graduation, before we can insure the nicety here sought for in the reading of the staff alone.

The real chances of error then in levelling operations consist, not in the imperfection of the instruments so much as in our powers of applying them—thus principally in the difficulty of securing at all times a perpendicular line in a long staff, from the effects of the wind or even its own weight in bending it, and at the same time the unsteadiness of the holder in handling and turning it. The dependence, indeed, under which he is placed to his staff-holder for correct results, in spite of his utmost care and attention, must be painfully felt by every accurate observer. To remedy, in part these uncertainties in handling, I have lately had constructed, under my own observation, a staff similar in graduation to those in general use, but differing in its joints and fittings, the chief object having been to obtain a length of rod tolerably unyielding, with a firm and immoveable basis.

I regret that I am obliged to speak from description only, and therefore liable to mistake; but if I rightly understand Mr. S, the whole length of his rod when extended is twice $12\frac{1}{2}$, or 25 feet, and that this is packed into a box $3\frac{1}{2}$ feet long by 4 inches square. Considerable ingenuity must be displayed in this arrangement, and great convenience obtained for travelling, but it does not say much for the strength of the staff, and with so many joints as must be necessary, I should consider that it could scarcely support its own weight in the perpendicular, much less resist the slightest force of wind: and I need scarcely add how little adapted it must be for the accuracy which the author appears to have sought in its construction.

Again: I believe it is generally admitted that the chief desideratum in a levelling instrument is a steady and secure basis, independent as far as possible of the wind, or any accidental movement. Now the ball-and-socket joint introduced by Mr. S, on which the whole weight of the level must rest cannot be considered so firm and secure as the common table-plate usually employed, and I have myself had more than one instrument of the usual construction pass through my hands, which, from not being originally well balanced and centred, has been considerably affected in its adjustment by a simple revolution on its axis—the additional weight of metal given to one side probably acting unequally on the bearing surface at different points of the circuit. How greatly must the liability of such derangement be increased when the support is thrown on the rounded surface of a ball, instead of on a strong horizontal plate.

The independence of the nature of the ground and the actual position of the legs, in setting up the stand is, however, a decided improvement *in itself*, in the plan of Mr. Stevenson, both as regards the economy of time and labour, and the usual wear and tear, and consequent irregular action of the levelling screws under the common form. In a level, which was submitted to the notice of the Institution about a month before that of Mr. S., I had endeavoured to obtain the same object by placing a small circular spirit bubble in the head of the stand itself, by which this may be brought to an approximate level, previously to the instrument being placed upon it, and this may be done upon any ground where there is standing room to use it. But at the same time a wide and steady base was deemed of so much importance, that I more than doubled the usual levelling surface of the plate, by adopting a modification of the tripod-stand for the 6 inch theodolites used by Col. Everest in the Indian survey.

Having had some experience in the use of engineering and astronomical instruments, I have ventured to trouble you with these observations, not for the sake of depreciating the ingenuity of Mr. Stevenson's improvements, but because I deem it of some importance to the profession that we should not be led to mistrust the accuracy of the instruments in common use, and thus to refine on points which in practice become non-essential, whilst we overlook what is of far more importance for correct results—the handling of the tools on which all our operations depend;

And I am, Sir,
Your's, &c. &c.,
Yarmouth, Nov. 13. George Townsend.

ON MEASURING DISTANCES BY THE TELESCOPE.

By Edmund Bowman.

[The following very interesting paper was read at the last meeting of the British Association. We consider it well deserving the consideration of the Profession, as such we have given the paper without abridgment.—Editor.]

Many years ago having had the charge of a level belonging to a celebrated engineer of the present day, while assisting him in taking levels, &c. for a bridge over a river in the north of England, my curiosity was excited (being quite a boy at the time) to know the utility of a narrow transparent scale in the field of view of the telescope, and which I afterwards conjectured was for the purpose of measuring distances. Having a few years afterwards procured a telescope level, and having made a reading staff, at that time quite a novelty, I tried a few experiments to find out what proportion, if any, existed between the distance of the object and the diameter of the field of view, when I found that, after the first 100 feet, the distances were nearly in proportion to the diameter of the field of view, read off from the reading staff held at these distances from the level—this might be in the year 1830; it occurred to me that the reading staff, when properly divided into feet, tenths, and hundredths, furnishes, by its image in the focus of the object-glass of the telescope, a much more correct micrometer scale, than any screws or a slip of any transparent substance can furnish. For instance, the diaphragm or focal aperture of a 20 inch telescope is ·39 inches, and at the distance of 10 chains it covers 1380 parts or hundredths of a foot, or 13 and 8-10ths feet; now, each of these parts is distinctly perceptible, or at least appreciable, but to divide 2-5ths of an inch into 1380 parts, so as to be equally accurate and visible, and the figures likewise equally distinct, would, I think, be no common task, be the artist who he might, and the substance divided, what it would; but could even such a thing be done, the reading-staff would still be preferable (and in any case it would be necessary to have a staff) as will appear on the perusal of this paper.

In the year 1840, about Midsummer, having procured one of Troughton's best levels, with a 20 inch telescope, I made several experiments with it with the intention of finding out, by means of careful observations, the exact relation which the diameter of the field of view bore to the distance measured, taking care, while making these observations, to keep the eye-piece to one mark for viewing the image of the staff and cross-lines stretched over the aperture of the diaphragm, and to make the adjustment for focal distance of the object-glass, as correct as the eye could appreciate; and having carefully observed the results, and with these results, and interpolating between them, having made a table of distances with their corresponding diameters or readings, I then, with the level and staff alone, took observations, connected for many miles, and after reducing the same by the above tables into distances, and summing up the whole, measured over the same ground with the chain, when the agreement between the chain measure and the telescopic measure was found very near, the difference not exceeding the [illegible]th part of the whole distance; and as part of this might possibly arise from the rating of the telescopic measure, and the other part from the inequalities of the ground, the truth might lie between these two methods.

I have also tried this method with correct surveys done many years ago, and have found it correct: field for field, fence for fence, all in their correct places, and over many miles in direct distance.

Now, since it would be very convenient, if the tables could be dispensed with, and if each reading of the staff either gave the actual distance or a proportion that could be determined—with this view I afterwards took a series of observations, with measured distances as before, but with a smaller instrument, beginning with the nearest limit of distinct vision, and proceeding by degrees to a distance of [illegible]ths of a mile; then compiled a table as before, taking care to place a mark to all those readings and distances which were actually observed and measured: upon comparing and examining these results, and those of the former table, I obtained the idea that the readings can all be made to bear a certain proportion to the distance by adding to each, be the same great or small, a certain fixed quantity or constant, peculiar to each instrument. The superior simplicity of this operation renders the tables now no longer of any use.

The cause of the inequality of the readings is the aberration of focus arising from the object or radiant point being at different distances, and the object-glass itself not being at the centre of the station. At first it occurred to me that it might be possible to enlarge and contract the diaphragm containing the image by some contrivance, with the view of keeping the image and the diameter of the diaphragm always in proportion to the inverse ratio of the distance, or what may perhaps be generally better understood, that the angular amount of the field of view might remain the same for all distances; but this has the objection, that the screws or levers by which this contracting and expanding would be effected, would be liable to get out of order, from wear and other causes, and no longer perform accurately, and even if they did so, the readings would only be in proportion to the distance from the object-glass, and not from the centre of the station or instrument.

By fixing the diaphragm and the object-glass at one invariable distance, and producing distinct vision for the various distances by having a lens or part of the object-glass within the telescope, moveable by screw adjustment two or three inches to or from the object-glass, all objects beyond a distance of 10 or 20 feet might have their images produced at the same distance from the object-glass; this method also would require reduction to the centre of the station as in the previous case, and moveover the achromatism of the object-glass would only be good at one point of its motion, and in no case be so good as with an united or cemented object-glass.

But these two methods and others have been rejected for the more simple and convenient one mentioned above, and which the following paper proposes to explain more amply, both as regards its theory and practice, and which method is simply to add a fixed quantity to each reading of the staff to make the said readings proportional to their respective distances, a small reading having thus an equal increase with a large one; the objection that might be raised to this method is this, that the accuracy of it evidently depends upon the distance between the object-glass and the focus or image of the object at the diaphragm being precise, and as the telescope, without alteration, is used as it is, this point might admit of reasonable doubt, as to extreme accuracy; but these doubts have been entirely removed by the method of determining the exact focal point for any distance, thus setting the matter at rest with respect to accuracy, and leaving nothing more to be desired.

For this method of determining distances, the telescopes upon the levels, as at present constructed, are quite sufficient; but if this meets the approbation of the scientific world, opticians will no doubt add the convenience of a scale, upon the slide part of the tube, for aberration, or determining the precise focal point for any distance: the fixed quantity or constant also can be marked upon the tube; attention being paid to the diaphragm, both that it be truly circular, and the field of view up to this circle distinct, &c., the advantages of these will appear by-and-bye.

Having made the experiments above mentioned in a public situation close to a large town, and being at the time also connected with a public undertaking, my doings, of course, did not escape observation. Some part of the public press has also favoured the idea, and as a sort of curiosity has got abroad respecting the matter, perhaps these papers, tending to explain my ideas of the matter, may not be altogether unacceptable to the public; being quite aware of much that has been written upon the subject of measuring distances by the telescope by Sir David Brewster, and other gentlemen eminent for their scientific knowledge. Yet, as the reading-staff was then little known, and as the practical surveyor, whose every day occupation such subjects must necessarily be, has advantages in this respect over the amateur or theorist, and more especially when theory does not deny him also her assistance—with this apology, I hope that this attempt at elucidation of what appears to the many, a complex subject, will meet with the indulgence which it may merit: for my own part, I can state that it is far from me to uphold or puff off anything of this kind which has not solidity for its foundation, and utility for its superstructure; on the contrary, I think that I cannot do a better service than unfold my ideas upon a subject which has been both pleasing and useful to me, and may be to others likewise.

Before I conclude these prefatory remarks, I beg leave to suggest some of the advantages peculiar to this method, and in what operations it can be applied with advantage, leaving it to the reader to supply all omissions in the list, which his practice or ingenuity may suggest.

By this method of measuring distances, the reading-staff, with a level having a good telescope, furnishes the surveyor with all the instruments required for accurately and expeditiously taking a plan and section; by this method the engineer is enabled to dispense with the assistance of the two chain-men in running a line of levels across a country; by this method the distance as well as the level is read off from the same instrument, the service of two men and the carriage of the heavy chain, &c. are saved, which, in thinly peopled districts, or where labour is both scarce and dear, are advantages not altogether inconsiderable; by this method facilities are given for running lines of levels for either geological, railroad, canal, or road purposes. For the amateur or for trial sections it is much adapted, for it is much more pleasant to be dependent upon the hire of one man than of three men, and, in many cases, the chain-men being strangers to the work, are not good to depend upon; whereas, in the other case, all that is required is the staff-holder, the engineer himself reads off the distance, for which also he himself is thus enabled to vouch; the distance taken by this method is the true horizontal distance, whereas with the chain in undulating or hilly ground, the distances taken are not the horizontal, but have to be reduced to it by the application of tables, &c. This method also has great advantages in taking levels and distances over corn fields or ground covered with crops of any kind, over gardens, rivers, bogs, or swamps, over ravines and rocky ground, and over other places, either not convenient, or difficult to go directly through from various circumstances. The convenience of this method in the above cases will be fully appreciated by the practical surveyor; in taking soundings of rivers, &c., it might be attended with very considerable advantage, as both insuring accuracy and light expense; in marine and military surveying, also, it might be applied with advantage, &c. &c.

On the Measurement of Distances by the Telescope, with both Practical and Theoretical Elucidations.

The method of taking distances is this;—if the survey is for a section, the level is first taken in the usual way; then for the distance take the number of feet, tenths, and hundredths subtended by the diameter of the diaphragm of the object-glass; that is, the diaphragm upon which the cross lines or wires are stretched; and this is readily done by screwing up the top or bottom of the said diameter to some primitive division of the staff, and then counting the divisions from top to bottom, or from bottom to top of the field of view; then this quantity of divisions read off from the staff, increased by a fixed quantity or constant (each instrument has a constant peculiar to itself), will make a sum or augmented reading which will be in every case either the distance itself, or some determinable proportion of it, depending upon the make of the instrument, &c.

The ratio of this proportion must be found by actual experiment, of which the following is an example.

With one of Troughton's 20-inch levels the reading at the distance of 10 chains from the centre of the instrument is 13·80 feet.

The constant for this instrument is ·05 feet, therefore the quantity read off must be increased by the addition of this and it becomes 13·85 feet; at one chain distance the reading is 1·335 feet, and by the addition of the constant it becomes 1·385 feet; and at the distance of the $\frac{1}{10}$th part of a chain the reading is ·0885 feet, and the constant ·05 feet added to this gives ·1385 feet for the augmented reading; it is evident that the augmented readings 13·85 feet, 1·385 feet, and ·1385 feet are exactly in proportion to the distances 10 chains, 1 chain, and $\frac{1}{10}$th of a chain. From these experiments it is evident that the quantities read off with the addition of the constant ·05 feet make augmented readings which are proportional to, or make equal ratios with their respective distances.

This constant (·05 in the above case) is dependent upon, or is a function of the principal focal distance of the object-glass, and also of the distance of the said object-glass from the centre of the instrument or station, of the diameter of the diaphragm or field of view, and also of the divisions of the staff or reading-rod.

The diameter of the diaphragm might be diminished by two screws or blunt points, projecting an equal distance into the field of view until the number of divisions of the staff included between the aforesaid points, together with a similarly contracted proportion of the fixed quantity or constant would make an augmented reading, the numerical amount of which would be precisely the same as the number of links in actual distance, and thus by writing chains and parts instead of feet and parts, the augmented readings would give the respective actual distances without any reference to proportion whatever.

And by enlarging the diaphragm upon the same principle the augmented readings in feet and parts might correspond to chains and parts, the chain in this case being composed of 100 feet instead of 100 links of the common size.

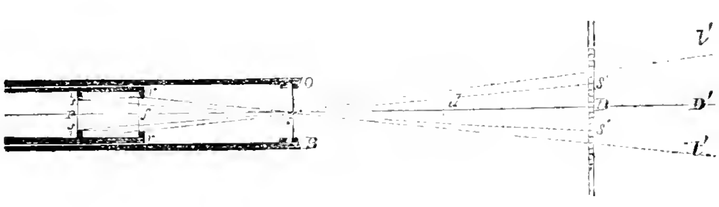
In the actual experiments where 13·85 feet corresponded to 10 chains the constant was ·05; but when the diaphragm is contracted so that 10 feet correspond to 10 chains in distance, or as each foot of the staff is divided into 100 parts, then 1000 such parts give a distance of 1000 links, and the fixed quantity undergoing a corresponding reduction likewise, it will become ·036 feet, but for general purposes ·04 feet will be quite near enough, for 1385 : 1000 : : ·05 : ·036 or ·04 nearly.

Having the augmented readings to correspond with the actual distances is no doubt a very great convenience, and it ought to be attained in new instruments, though there is very little inconvenience in making a scale to suit any proportion, the scale for parts being, as in the case above, to the scale for links in the proportion of 1385 parts for every 1000 links, and, for my own part, I prefer keeping the diaphragm as it is, for the greater the angle or number of divisions of the staff read, the less value each becomes with respect to distance, and, consequently, any error arising from the staff becomes of proportionately less value when reduced into distance.

The constant ·05 in the above example is the correction arising from aberration of focal distance, and the correction arising from the object-glass not being in the centre of the station conjointly; and first, the correction arising from the aberration of focal distance may be explained in the following manner:—

Let OcB be the object-glass of the telescope, f and d the principal foci, or foci for parallel rays, or rays from very remote objects, and let $t'D't'$ be supposed to be very remote, let F be the focus for rays proceeding from an object or radiant point D at no very great distance from the object-glass OcB, but beyond its principal anterior focus d. (See fig. 1.)

Fig. 1.



Now by optics the formula for aberration is

$$\frac{\text{Principal focal distance} \cdot \text{principal focal distance}}{\text{Distance of object from object-glass} - \text{principal focal distance}} = \text{Aberration}$$

$$\text{or} \quad \frac{fc \times cd}{cD - cd} = Ff$$

Now $eD = ed + dD$, therefore $ed = Ff$: dD and therefore $Ff : fe : : ed : dD$ and by composition $Ff + fe : fe : : ed + dD : dD$ or simply $Fe : fe : : eD : dD$

Now the aperture of the diaphragm which limits the field of view is unchangeable in diameter in any part of its motion, and it is evident that while it is at f it subtends or includes the angle tet or $t'et'$, and while at F the angle ses or $s'es'$, and that while at F the diaphragm ought to be enlarged to the size $tsFst$, to include the same angle that the same diaphragm rfr does at f, and to read off a portion of the image of the staff, which would be always proportional to the distance, for the angle remaining the same, the tangent varies as the radius, or the subtense of the angle as the distance.

Now because the number of divisions of any staff $s'Ds'$ or $t'Dt'$ forming the subtense of any fixed angle $t'et'$ is greater or smaller exactly in proportion as the distance of the said staff from the angular point e is greater or smaller, it is also evident that the diaphragm rfr or sFs will, while at f, show a larger angular proportion of the image of the staff than it does while at F, and that the proportion will be as tFt : sFs or as tF to rf, but $tF : rf : : Fe : fe$ and it has been shown that $Fe : fe : : eD : dD$, therefore by inverting $dD : eD : : sFs : tFt$, and since $tFt = sFs + 2st$ then $dD : eD : : sFs : sFs + 2st$, that is to say, the distance of the staff from the anterior focus d of the object-glass is to the distance of the same staff from the object-glass as the actual reading of the staff is to the reading augmented by a quantity $2st$.

$$\text{Now } dD : eD - dD : : sFs : sFs + 2st - sFs,$$

$$\text{or simply } dD : ed : : sFs : 2st.$$

That is to say, as the distance of the staff from the anterior focus of the object-glass is to the principal focal distance, so is the actual reading of the staff sFs which is the only part of the image visible through the diaphragm to the quantity $2st$ which makes when added to sFs (the actual reading) an augmented reading tFt,

$$\text{Now } dD : sFs : : ed : 2st, \text{ or } \frac{dD}{sFs} = \frac{ed}{2st},$$

$$\text{Again } dD : sFs : : eD : tFt, \text{ or } \frac{dD}{sFs} = \frac{eD}{tFt};$$

$$\text{therefore } \frac{dD}{sFs} = \frac{ed}{2st} = \frac{De}{tFt}.$$

Now eD and dD may be any quantities whatsoever, and as tFt and sFs vary respectively as eD and dD, therefore tFt and sFs are also variable quantities, and may be of any dimensions; but ed, the principal focal distance, is an invariable quantity, therefore $2st$ is also an invariable quantity, for it varies as ed varies, the variation of which is nothing; therefore, the variation of $2st$ is also nothing, or $2st$ is a constant quantity.

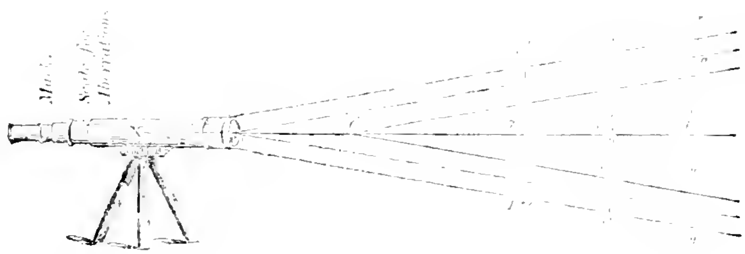
To find practically this constant quantity $2st$ for any telescope and staff, which $2st$, when added to the reading, makes an augmented reading always proportional to the distance of the object from the object-glass of the telescope. First adjust the eye-piece to distinct vision of the cross lines upon the diaphragm, and mark the sliding part of the eye-piece, so that it may afterwards be kept to the same point; then on some clear night, observe carefully some star or planet, and when by moving the slide of the object-glass a little to and fro, the sharpest and most clearly defined image of this star or planet has been obtained, mark carefully this point upon the slide of the object-glass as the adjustment for the principal focus, and as the highest limit of a scale to be afterwards graduated upon this slide; the telescope being kept at this adjustment, the distance between the cross lines on the diaphragm and the object-glass will be the principal focal distance fe or ed. (Fig. No. 1.)

Then the instrument being fixed in any convenient open place, measure any distance eD, and observe the reading sFs, the image of part of the staff seen over the diameter of the aperture of the diaphragm; then as dD, that is to say, the distance eD less the principal focal distance, is to the said reading, so is the principal focal distance to the constant $2st$, which, when added to the reading, makes an augmented reading, which is always proportional to the actual distance of the object from the object-glass; but as it would be more convenient still to have a fixed quantity or constant to make the readings when augmented by it always proportional to the distances from the object to the centre of the instrument or station, and that such a quantity exists may be found out by accurate experiments, and may also be thus demonstrated.

Let X be the centre of the instrument or station (see Fig. No. 2); let e be the object-glass; let d be the anterior principal focus of the object-glass; let D be any distance beyond this focus; and let rDr represent the portion of the staff visible over the diameter of the diaphragm of the telescope, or as it is called simply the reading; it has been shown that the reading rDr varies as the distance dD varies; from the centre of the object-glass e, draw et, et parallel to dr, dr, and from the centre of the instrument X draw Xw, Xw parallel to dr, dr, and produce Dr, Dr, to t, t and w, w, then by similar triangles,

$dD : rD : : eD : tD$, now $2rD = rDr$, and $2tD = tDt$, and by transposing, &c., the above proportion $dD : eD : : 2rD : 2tD : : rDr : tDt$, but it has been before shown that $dD : eD : : rDr$, or the reading: to the reading + a constant quantity; therefore tDt = the reading + the constant, and it is equal to $rDr + 2rt$, therefore $2rt$ is the constant corresponding with $2st$ in Fig. 1.

Fig. 2.



Again, by the construction (similar triangles, Fig. 2) it is evident also that $dD : XD : : rDr : wDw$, or as $dD : Xd + dD : : rDr : rDr + 2wr$,

and by subtraction $dD : Xd : : rDr : 2wr$, or $\dfrac{dD}{rDr} = \dfrac{Xd}{2wr}$, now dD and rDr are variable quantities and vary as each other, but Xd is for the same instrument an invariable quantity, and as $2wr$ varies as Xd varies, therefore $2wr$ is also an invariable or a constant quantity, and it is the amount which must be added to the reading rDr to make a quantity wDw, which shall be proportional to the distance of the object from the centre of the station, or by a suitable construction of the diaphragm the quantity wDw shall be the actual distance itself.

From the inspection of Fig. No. 2, it is evident that if the parallel lines be produced beyond wDw, and lines $w'D'w'$, $w''D''w''$ &c. be drawn parallel to it, that the readings $r'D'r'$, $r''D''r''$, &c., will increase or diminish as the distances dD', dD'', &c., while the quantity $2wr$ will remain constant and always equal to $2w'r'$, $2w''r''$, &c., which by the construction of the figure, are all equal from the point d where the readings of the staff begin, or are at Zero.

Taking a practical example with the telescope of the 20 inch level before mentioned, the distance ed measures 18·5 inches, or 2·33 links, the distance Xe, or from the object-glass to the centre of the tripod, is 1·27 links, therefore the whole distance Xd is 3·6 links. Now, when the staff is held at 1000 links or 660 feet from the centre of the instrument, or $1000 - 3·6 = 996·4$ links from the point d, the reading is 13·80 feet; now here $dD = 996·4$, $XD = 1000$, $rDr = 13·80$ feet, and it is required to find wDw and the constant $2wr$.

$$\text{Now } dD : XD : : rDr : wDw, \text{ or}$$

$$996·4 : 1000 : : 13·80 : 13·849 \text{ or } 13·85 \text{ nearly}$$

and because $wDw - rDr = 2wr$, therefore

$13·849 - 13·80 = ·049 = 2wr$, or the constant which equals ·05 nearly, and the augmented reading is 13·85.

Again, taking another example at the distance of 200 links, 2·72 feet were read off, now $200 - 3·6 = 196·4 = dD$, and $196·4 : 200 : : 2·72 : 2·769$ or 2·77 nearly and $2·769 - 2·72 = ·049$ or ·05 nearly, which is the constant as in the former case, and the augmented reading wDw in this case is 2·769 or 2·77 nearly.

Therefore ·05 is the constant number to be added to each reading to make augmented readings proportional to the actual distances, when this instrument and staff graduated into feet and decimal parts, &c. are used.

The scale for this instrument is, therefore, 1385 divisions, each the $\frac{1}{100}$th part of a foot, corresponding with 1000 links in distance, and therefore to plot a section at the rate of 2000 links to the inch, the scale will have to be a 27·7, instead of a 20 to the inch, when the divisions of the scale will plot the readings in distance.

The diameter of the diaphragm of this telescope is ·39 inches, but by fixing screws or points on the circumference of this diaphragm, the diameter of this aperture might be contracted, so that the distance between the points of the screws might not exceed the proportion of 1000 divisions of the staff to 1000 links in distance; but as the advantages peculiar to each (that is, whether it is best to keep the instrument as it is, and read off proportional distances only, or reduce the diameter and read off actual distances,) have been treated of before in this paper, it is quite unnecessary here to go over the subject again.

A smaller level with an inverting 10 inch telescope, gives with the same staff the constant quantity (from the centre of the station) ·07 feet.

The principal focal distance of this telescope is 10·5 inches, the diameter of the aperture of the diaphragm ·53 inches, the distance of the object-glass from the centre of the tripod 6·4 inches;* by this instrument 1000 links in

---

* Here it may be observed, that the distance between the object-glass and the centre of the instrument ought to be invariable, and that the increas

distance are measured by 33·3 feet, and of course under four or five chains distance, the reading staff or ordinary dimensions will be very convenient; but with the 20 inch level erecting telescope, 1000 links in distance are read off by 13·8 feet, therefore a 14 feet staff is very convenient for this telescope for all distances under 10 chains, and by having a longer staff, or by taking a semi-diameter or other known proportion of the diaphragm, the length of the observed distance may be increased at pleasure, and be limited only by the power of the telescope to read the staff distinctly. Taking facility of reading the staff and the consequent accuracy of the observations for ordinary levelling operations into account, distances not exceeding from 3 to 5 chains for the small 10 inch level, and from 7 to 12 chains for the large 20 inch level described above, are the best and most convenient, as insuring speed with most accuracy; but any distance, down to 12 feet by the small level and 20 feet by the large level, can be found quite accurately; at distances smaller than these, the range of the sliding tube is too short to admit of distinct vision, but it is not important to have this range increased, as distances smaller than these are not often required, and when so, the levelling rod furnishes the ready means of ascertaining the amount by direct application.

The large telescope, with the erecting eye-piece, is decidedly superior for the purpose of measuring distances to the smaller one; but care must be taken that the diaphragm of the object-glass is not at all intercepted by the diaphragm of the eye-piece, which is nearer to the eye, and this can easily be found out by illuminating the diaphragm of the eye-piece by a piece of white paper, and then by giving the eye-tube a motion in its slide to or from the diaphragm of the object-glass. By this means the two diaphragms will become apparent, and if, when the eye-tube is fixed at the proper adjustment for viewing the cross-lines, the diaphragm in the eye-tube intersects in the smallest degree (for these circles are not always concentric) that of the object-glass, or with the cross lines, then the diameter of this latter must be contracted by points or screws projecting at equal distances into the field of view, so far as to clear the inner circumference of the diaphragm of the eye-piece, and these screws, when driven to their proper places, must be so firmly fixed that they will not readily be disturbed. No doubt the fine lines of a spider's web, or very fine wire, might answer the same purpose; but as the eye-tube in the generality of good telescopes of this sort has to be taken out and replaced on every occasion of its use, it is difficult to divest the mind of the possibility of the lines being disturbed by this motion, whereas in the case of the inflexible metal of the diaphragm no such objection can possibly hold good; moreover, the cross lines serve as a guide to find the true diameter. Opticians have been in the habit of placing two parallel upright lines, and at right angles to these a horizontal line, in the field of view of the telescope, and some people have the idea that these may be used for the purpose of distances, but besides the objection stated above they have two very serious objections—the first is that they should have been horizontal for this purpose, and the second is that they are much too close together and include much too small an angle to give more than an approximation to the distance, and it may be added, that they never were intended for anything of the kind, but probably only as a guide to keep the reading staff vertical while taking levels, but in the case of extraordinarily long distances these cross lines may be serviceable in taking semi-diameters, &c.

The constant quantity for the 10-inch level being ·07, and for the 20-inch level ·05, and as these telescopes or levels are nearly of the smallest and largest sizes used for general purposes, the constant in feet for a medium size may be somewhere at about ·06 feet.

In favour of this method of observing distances it may be mentioned that with the telescope of the 20-inch level, and with no further adjustment for focal distance of the object-glass than what appeared at each observation to be distinct vision, distances can be taken of many miles by the accumulation of distances such as those required in levelling; that is to say, not often less than 20 feet, often averaging 8 chains, and seldom so much as 20 chains, with quite as much accuracy as by the common method of the chain. The superior accuracy of the measurements taken from the reading staff during the process of levelling a circuit of many miles and returning to the same point, when, on balancing the numerous rises and falls, the near agreement within an inch or so proves the accuracy of the work, also favours the idea that this method of measuring distances is capable of great accuracy, for the self-same staff is used, and the vertical position is the most natural and least difficult to find, and the level itself gives the telescope the horizontal direction. From all these causes, and from the perpetual inequality of the ground in chaining, there can be no doubt that, on these heads at least, this method has superior claims to the chain in point of precision, and as a further refinement, will be especially of great service to those telescopes whose defining power is not of the first-rate description, and, for any telescope, removes all doubts of want of precision.

Let the aberrations for focal length for every distance of the object be graduated upon the slide of the large tube, from the principal focal mark before mentioned to the extremity of the slide. The aberration or distance from this principal focal mark is found thus.

[illegible]gth of the focus for near objects ought to be obtained by having the rack and slide adjustment behind the centre, and not in front; from this it appears that those tubes which move at the object-glass, are not precisely adapted for this method, inasmuch as the increased distance of the object-glass from the centre of the station would, for the short distances, increase the length of [illegible], and of course the constant would have to undergo a similar increase, which would be absurd.

Without referring to the former figures, the principal focal distance is generally called F, and the distance of the object from the object-glass is called simply D, and these two being given, the aberration which is called e is found by the formula in optics, which is this:—

$$\frac{F^2}{D-F} = e$$

From this formula, a table of aberrations can be calculated for as many distances as the short slide of the tube is capable of receiving, and of having graduated upon it; but what would be better still, instead of or in addition to the scale for actual distances, would be to have a scale of readings of the staff; or in other words, the adjustment for focus should correspond with the reading of the staff.

Now, it has been shown that the reading of the staff varies as $D-F$ varies; but $\overline{D-F} \times e = F^2$; now F^2 is a constant quantity, and $D-F$ is a variable quantity, therefore e is also variable, and as the product of these two variables is always a constant quantity, it follows that e varies inversely as $\overline{D-F}$, therefore also e varies inversely as the reading of the staff; that is to say, when the rays are parallel and the distance infinite, and consequently the reading infinite, then the aberration is Zero, or at the principal focal mark; again, when the reading is at Zero and $D-F=0$, or $D=F$, or when the staff is held at the principal anterior focus, then the aberration is infinite; again, taking the case when $D-F=F$, then $e=F$; for $D-F \times e = F^2$, and also $D=2F$; that is to say, when the distance is twice the principal focal distance from the object-glass, the aberration e and focal distance F are equal.

Now, because the aberration varies inversely as the distance $D-F$.

When $D-F=0$,	the aberration is	Infinite.
When $D-F=F$,	the aberration is	F
When $D-F=2F$,	the aberration is	$\frac{F}{2}$
When $D-F=4F$,	the aberration is	$\frac{F}{4}$
When $D-F=100F$,	the aberration is	$\frac{F}{100}$
When $D-F=$ infinity,	the aberration is	Zero.
&c. &c.		&c.

Now, the readings, always varying as $D-F$, will be proportional to Zero, F, $2F$, $4F$, &c., and the aberrations for these readings to infinity, F, $\frac{F}{2}$, $\frac{F}{4}$, &c. This furnishes a very ready method for graduating the sliding tube of the telescope with the aberrations for the different readings which must be marked thereon in figures.

Taking a practical example, the large telescope of the level ($18\frac{1}{2}$ inches principal focal length) when the slide is out 1·6 inches beyond the principal focus, or nearly its extreme length, making the augmented focal length 20·1 inches; then when the reading is properly taken for this adjustment, that is to say, the staff held at the requisite distance for distinct vision, the reading is found to be ·40 feet.

Then, since the reading varies inversely as the distance, the following shows how a table of aberrations for any reading may be constructed, thus,—

When the reading is	The aberration at ·40 into the inverse ration of the reading		The aberration from principal focal point in inches.
·40 feet	$1·60 \times \frac{40}{40}$	gives	1·60
·50 do.	$1·60 \times \frac{40}{50}$	gives	1·28
·60 do.	$1·60 \times \frac{40}{60}$	gives	1·066
·80 do.	$1·60 \times \frac{40}{80}$	gives	·80
1·00 do.	$1·60 \times \frac{40}{100}$	gives	·64
1·60 do.	$1·60 \times \frac{40}{160}$	gives	·40
4·00 do.	$1·60 \times \frac{40}{400}$	gives	·16
8·00 do.	$1·60 \times \frac{40}{800}$	gives	·08
16·00 do.	$1·60 \times \frac{40}{1600}$	gives	·04
32·00 do.	$1·60 \times \frac{40}{3200}$	gives	·02
&c.			

Now, the reading of 32 feet corresponds with a distance of 23 chains; so then at a distance of little more than a quarter of a mile the aberration is only the $\frac{1}{50}$ part of an inch, and at 46 chains the $\frac{1}{100}$ part of an inch. Beyond this distance, therefore, the principal focal mark will be quite near enough without any further subdivisions: for, although they can be carried to any wished for degree of minuteness, yet supposing that the adjustment for focal distance was not nearer than the $\frac{1}{100}$ part of an inch, the size of the image being exactly in proportion to the focal distance, and this distance being supposed to be in error by the $\frac{1}{100}$ part of an inch, then the $\frac{1}{100}$ part of an inch over a space of 18·5 inches is only the $\frac{1}{1850}$ part of the whole, and when the focal distance is 20 inches, the $\frac{1}{100}$ part of an inch will be the $\frac{1}{2000}$ part of the whole, and thus the reading, and consequently the distance, true to the $\frac{1}{2000}$ part of the whole.

For the sake of rendering the demonstration more simple, the scale above is shown how it can be deduced from one observation alone; but as one observation cannot have the accuracy which the mean of a greater number will have, it will be better to observe correctly other readings also, such as 1·00, 2·00, 3·00, 4·00, &c., and mark these points likewise, and by taking the mean of the whole, the scale can be made as accurate as it is possible to graduate it. The smaller divisions of the scale can be filled up by the assistance of the rule—"that the aberration varies inversely as the reading."

The tube of the telescope being thus graduated, and having found the best adjustment for the eye-piece to view the cross lines, mark upon the slide of the eye-piece this adjustment also, and let the eye-piece be always set to this mark on every observation. As this adjustment is important, and though mentioned before and understood to be done previously to taking the observations for the scale of aberrations, the repeating the caution here may not be considered altogether uncalled for.

The telescope being levelled, is now prepared for taking distances; the staff being held at the distance required to be measured, the object glass of the telescope is brought to as near the proper focus or distinct vision as the eye of the observer can appreciate, the divisions of the staff counted and the sum or reading taken; then, having got the reading, look at the slide of the telescope, and if the focal adjustment points to the same figure as the reading is, which it generally will do, then the reading first taken is correct, and only requires the addition of the fixed quantity to make it the actual distance itself; or in any case a proportional measure of the distance, if the divisions of the staff do not correspond exactly with the divisions of the measure for distance, but if they do correspond, then the augmented reading is the distance itself.

But if the slide shows a reading greater or less than that read off from the staff, then the first adjustment for focus by the eye has not been sufficiently precise, and the slide must be adjusted to the same figure as the reading of the staff exactly, and then the reading observed again through the telescope and taken; and this approximating process can be repeated as often as required, but once will always insure sufficient accuracy for ordinary purposes, and even this once will, in many cases, not be necessary; this corrected reading, then, with the addition of the constant, will give the distance either actual or proportional as the case may be.

By this process, after the first correction if required, a degree of precision will be attained so as to leave nothing more to be desired on this head; and by repeating the process, the smallest imaginary quantity of error may be got rid of, and thus the uncertainty as to which is the true focal point for any distance is removed, and all cause to doubt the accuracy of this method obviated.

Take a practical example with a 20 inch telescope, by rendering the focal distance precise to the $\frac{1}{500}$ part of an inch; now there being 10,000 such parts in 20 inches, the greatest error in distance will only amount to the $\frac{1}{10000}$ part of the whole distance, and in taking a great number of distances, there is no reason to suppose that even these minute errors should be more on one side of the absolute truth than on the other side. It follows that in the aggregate of these distances, even such minute errors will vanish by mutually counterbalancing each other, this being the case then, even with the adjustment for focus by the eye alone, and without the first approximating process, a very near approach to the exact distance is obtained in the long run, and by the approximating process, a degree of precision will be attained far exceeding that by the common or direct process of the chain, and the more especially on uneven ground.

PROJECTED RESTORATION OF HEREFORD CATHEDRAL.

In May last Mr. Cottingham made a discovery in Hereford Cathedral which, while it adds greatly to the interest of that venerable fabric, furnishes a valuable addition to the instructive and pleasing remains we possess of the architecture of the 11th century. The discovery referred to was made on taking down the modern Italian wainscot screen, of the Corinthian order, erected by Bishop Biss 120 years ago, enclosing the whole of the ancient remains of the east end of the choir. The screen, on being removed, was found to have completely shut out the view of the Ladye Chapel, which must once have possessed surpassing excellence. The beautiful drawing of the restoration, just published by Mr. Cottingham, presents to us an architectural gem of the first water. It consists of a Norman arch, above which are three Gothic windows, and between the windows and the arch, a screen or belt. The arch occupies nearly the whole width of the east end of the choir, and is very massive; it is decorated with foliage and zigzag mouldings. The arch is supported by four columns, with rebated pilasters, the capitals being highly enriched with foliage and sculpture, the latter presenting curious devices to represent the security and triumphs of the Christian. The belt running above the arch is composed of 24 semi-Normal columns. The three windows are of the early pointed style, and have evidently been formed since the erection of the building by cutting away the Norman groining to introduce the Gothic, which at the time was rising in favour. The three windows throw a flood of light on the beauties of the choir. At the time of making the discovery Mr. Cottingham found in the wall, just above the belts, five apertures of the early English age, completing the narrow walk all round the choir.

On looking into the Ladye Chapel from the high altar, a beautiful and unequalled effect is seen to result from the presence of two columns, which stand in a line with the centre of the Norman arch, and support the early English groining which connects the north and south transepts, the capital of one being of the Norman, and that of the other of the early English age, but both erected at the same time.

This discovery is highly important, as it adds to the proofs already obtained that by slow degrees the heavy semi-circular Norman arch has passed into the light and pointed Gothic. The evidence of this fact is quite clear on comparing the upper with the lower part of Mr. Cottingham's drawing, and also on noticing the difference between the capitals of the two pillars at the entrance of the Ladye Chapel. It is much to be desired that the beautiful restoration designed by Mr. Cottingham may soon be realized, as it will furnish to every admirer of cathedral architecture a treasure of unparalleled beauty. The necessity for the extensive repair of the whole cathedral is but too obvious. The tower, which has long been in danger of falling, is even now in little better than a state of jeopardy, being shored up by a series of timbers 13 inches square, so as to support the whole superincumbent weight, while the defective piers are cut out and reinstated. It is gratifying to find that the people of Hereford are fully sensible of the value of their venerable cathedral, and that they nave wisely avoided allowing party politics to interfere with the design of effecting its thorough and tasteful reparation. The antiquarian skill and taste of the dean (Dr. Merewether), combined with the zealous co-operation he receives from the canons of the cathedral, and from the clergy and gentry of the neighbourhood, give a most encouraging prospect of success, while the professional experience of Mr. Cottingham is a voucher for the restoration of the sacred structure to its pristine beauty and magnificence.

The work is one of more than local interest, it is important to the whole kingdom. Our antique buildings cannot be regarded as an insignificant part of our national wealth. They show that we are not of yesterday and they link us to the past. There is, indeed, a share of sanctity in the feeling that would prompt us to shield from the despoiling hand of time the monuments of those ancestors from whom we have received our being, our social institutions, and many of our sacred privileges.

Let the appeal for the requisite funds, therefore, not be limited to the county or the diocese; let an opportunity of sharing in the work be afforded to the taste and liberality of the country at large, and it will soon be found that these time-honoured structures have friends everywhere throughout the country, from John o'Groat's-house to the Land's-end.

Martyrs' Memorial.—Those of our readers who live at a distance from Oxford, and who take an interest in the completion of the Martyrs' Memorial, will be gratified to learn that great progress has been made in the works during the last three months, notwithstanding occasional impediments from the unfavourable state of the weather. The cross has been raised to about two-thirds of the height of the first stage or division of the shaft, which forms the base of the niches for the statues; and though much of the detail in the ornamental carving is of necessity left for the present in a rough state, till the upper portion of the cross is completed, yet sufficient is expressed to give a very good idea of the rich effect which will be produced when the whole is finished. At one time we were somewhat apprehensive lest the colour of the stone should prove darker than we had been led to expect; but we have been assured by competent authority that this partial discolouring will readily pass off as the stone becomes more exposed to the action of the atmosphere: and this result has already taken place in the lower part of the base, which was first laid down. We believe a similar effect may be observed in the new Houses of Parliament, in which the same description of stone is being used; the upper courses, which have been recently laid, appear for some time discoloured, while those in the lower part of the walls, having been longer exposed to the air, have already nearly assumed their natural tone of colour. The exterior walls of the Martyrs' Aisle, as well as of the east end of the centre aisle, which it was necessary to take down and rebuild, in order to throw open the whole line of the Martyrs' Aisle in the interior of the church, have been sufficiently advanced to enable the workmen to commence laying the slates upon the roof. A considerable portion also of the ornamental parts, the finials, pinnacles, and the pierced parapet, has been set up. The general effect of this aisle, when completed, will be very striking; and we do not hesitate to say that it will be one of the most beautiful specimens of ecclesiastical architecture in this city. The workmanship also appears to us to be very well executed. The rebuilding of the east end of the centre aisle has rendered it necessary to make extensive repairs to other parts of St. Mary Magdalen Church. The gable of the adjoining aisle was found to be in so defective a state that it was necessary to take it down without delay; and it has been rebuilt in a style corresponding in its general character with the other new work, but it is not so much ornamented in detail as the other gables. We understand also that the flat plaster ceiling of this aisle is to be removed, in order to open to view a handsome wooden ceiling in panels, which is above it. But these, as well as some other alterations to improve the general character of the interior of the church, will be effected entirely by separate subscriptions, raised specifically for this purpose, and which are wholly independent of the subscription to the Martyrs' Memorial. We regret to add, that we understand the sum of 700*l.* is still wanting in order to meet the engagements of the committee for the Martyrs' Memorial. We believe that some additional expense has been incurred in sinking the foundation of the cross to a greater depth than was at first thought might be sufficient, in order to obtain a firmer basis, as well as in providing a more durable description of material for the foundation, according to a provision in the contract, as what was to be obtained in this neighbourhood was not deemed sufficiently good by the architect.—*Oxford Herald.*

NEW INVENTIONS AND IMPROVEMENTS.

CALOTYPE.

Abstract of the specification of a patent granted to William Henry Fox Talbot, Esq., of Lilcock Abbey, Wilts, for improvements in obtaining pictures or representations of objects.—Enrolment Office, August 8, 1841.—The best and smoothest writing paper is washed on one side with a camel hair brush dipped in a solution of 100 grains of crystallised nitrate of silver in six ounces of distilled water. The side being marked, to know it again, the paper is dried before a distant fire, or in the dark, after which it is dipped for a minute or two in a solution of 500 grains of iodide of potassium in a pint of water; the paper is then dipped in water and dried. It is now called iodised paper, and kept in a portfolio for use. Immediately before using, this iodised paper is washed on the marked side with the following mixture:—100 grains of nitrate of silver are dissolved in two ounces of distilled water, to which solution one-fourth of its volume of acetic acid is added. A saturated solution of crystallised gallic acid, or the tincture of galls, is mixed with the foregoing in equal volumes, forming gallo-nitrate of silver. After being washed with this mixture, the paper is dipped into water, it is then dried lightly with blotting paper, and finished by a distant fire. These operations should be performed by candle-light. This paper, which the inventor calls "Calotype Paper," is used as follows:—A sheet of the paper is placed in a camera obscura, so as to receive the image formed in the focus of the lens. If the object is very bright, or the paper is exposed a sufficient time, a sensible image will appear on the paper when removed from the camera obscura. But when the object is "invisible or dimly seen," it is brought out in the following manner:—The paper is washed over with gallo-nitrate of silver, and held before a gentle fire until the picture is sufficiently distinct, which is then fixed in the following manner:—The paper is first dipped into water and partly dried with blotting paper, after which it is washed with a solution of 100 grains of bromide of potassium in eight or ten ounces of water; after which the picture is again washed with water and dried. In the picture thus obtained, the lights and shades are reversed, but another being taken from it restores their natural position. For this purpose a second sheet of calotype paper—or the patentee prefers using common photographic paper—is placed in contact with the picture, a board placed beneath and a sheet of glass above them, pressed into close contact by screws. On placing them in the sunshine for a short time, a picture with the lights and shadows in their natural position is produced on the second paper, which is to be fixed as before directed. After frequent copying in this manner, a calotype picture sometimes becomes faint, to prevent which, it is to be washed by candle-light with the gallo-nitrate of silver. A second improvement consists in a mode of obtaining positive calotype pictures, *i. e.*, with the lights and shades in their natural position, by a single operation. For this purpose a sheet of calotype paper is exposed to the daylight until its surface is slightly browned; it is then dipped into the solution of iodide of potassium, by which the browning is apparently removed. On being taken out of this solution, the paper is dipped in water and slightly dried, it is then placed in the camera obscura and pointed at an object for five or ten minutes. The paper is then removed, washed with gallo-nitrate of silver, and warmed, when a positive image will be produced. A third improvement consists in producing photogenic images on copper; a plate of polished copper is exposed to the vapour of iodine, or bromine, or the two combined, or either of them combined with chlorine; or the copper is dipped into a solution of some of these substances in alcohol, ether, &c. On this copper a photogenic image is formed in the usual manner, and exposed to the vapour of sulphuretted hydrogen, when a different colour is produced on those parts of the copper which have been acted upon by the light to that which appears on the parts not so exposed; consequently, a permanent coloured photogenic image is obtained, which is not injured by further exposure to light. A fourth improvement is as follows:—A thin coating of silver is given to a plate of steel or other suitable metal, which is made sensitive to light in the usual way; the plate is then placed horizontally and covered with a solution of acetate of lead, through which a galvanic current being made to pass a coloured film is precipitated on the picture. A fifth improvement consists in a method of obtaining very thin surfaces of silver for photographic processes. A very thin plate of copper is first precipitated on a polished plate of metal by the electrotype process, and a sheet of card is cemented to the back of the layer; when dry, the card and copper are removed, and the copper silvered by immersion in a suitable solution of that metal. A sixth and last improvement is in transferring photogenic pictures from paper to metal. For this purpose, the surface is rendered sensitive to light, and the picture placed upon it with a plate of glass in front, kept in contact by screws, and exposed to the sun's rays, when the required transfer is effected; which is to be afterwards fixed, and otherwise treated according to the effect required.—*Mech. Mag.*

RAILWAY SIGNALS.

Abstract of a patent granted to Charles Hood, of Earl Street, Blackfriars, for improvements in signals. Enrolment Office, August 1, 1841.—A suitable receiver is filled with air condensed to about 45 lb. per square inch, by means of a condensing syringe; this receiver is provided with a tube to which a whistle is attached, similar to the steam whistle of locomotive engines, but rather smaller. A stop-cock is placed upon the tube, between the whistle and the receiver, on turning of which the condensed air passes through, and sounds the whistle. This contrivance enables the guard of a railway train to give a signal to the engine-driver, in case of accident of any kind. It is also applicable to steam boats, or to railway stations, for giving signals at night, or in foggy weather. A second signal apparatus consists of four wedge-shaped leaves or panels, which are centred at their pointed ends, describing an arc of 45°, and spreading out like a fan. These leaves are attached to each other in such a manner, that on pulling a cord, the lowest leaf is drawn up behind the second, the second leaf behind the third, and all three behind the fourth; lastly, the four are drawn up into a case, by which they are concealed. Each leaf is painted a different colour, indicating some arbitrary sign. The raising or lowering of these fan-like leaves may be done by hand, or by means of machinery. For night signals, each leaf has a pane of glass let into it, on which figures, &c., may be painted, to indicate fixed intervals of time, when worked by clock machinery. On an engine-driver approaching one of these signal stations, the colour or number of the leaf that is visible will convey the intelligence desired—to stop, to proceed cautiously, or any other signal. If no leaf is visible, no signal is to be communicated, and he will fearlessly continue his progress. The claim is—1. To the mode of giving signals by applying condensed air in apparatus, in combination with whistles. 2. To the mode of giving telegraphic signals on railways, by means of moveable leaves or panels, worked either by hand or by machinery, or by both means conjointly, and combining therewith clock movements, or other similar machinery, for producing a gradual and ascertained velocity of motion in the leaves or panels of the telegraph, and for the continuous sounding of an alarm bell, as described.—*Ibid.*

RAILWAY TURN TABLE.

Abstract of a patent granted to Elisha Oldham, of Cricklade, Wilts, railroad contractor, for certain improvements in the construction of turning-tables to be used on railways. Petty Bag Office, August 8, 1841.—The upper platform of the table is composed of a strong iron framing, filled in with wood, and supported at its centre upon an upright pin or pivot, lubricated by means of an oil-chamber immediately over it. At the extreme edge, or at a point nearer to the centre, the platform is supported upon eight iron anti-friction rollers, mounted in bearings upon a stationary cast iron framing. The whole weight of the carriage, &c., rests entirely upon the centre pin, when the platform is properly balanced; but if the weight is unequally placed, one side of the platform will be sustained by the anti-friction rollers. The claim is to the arrangement of parts herein described, as applied to the construction of turn-tables; or any other arrangement in which the moveable platform is supported on a pin or pivot at its centre, and assisted by stationary anti-friction rollers at its sides, in the manner described.—*Ibid.*

DREDGING MACHINE.

Abstract of an American patent granted for improvements in the Dredging Machine, for deepening Harbours, Rivers, Canals, &c., to William Easby, City of Washington, D. C. August 25, 1841.

This machine is intended to be worked by horses, that travel on a circular platform, built on the deck of a large scow. The whole machine is made narrow enough to pass through a canal lock, and in order to make the platform, on which the horses travel, of sufficient size, a segment of the circle, called a wing, is hinged on each side to the scow, so that in passing through a canal lock, or any other narrow place, the wings may be turned up. The scoop is to be worked by two barrels, or drums, placed one at the top, and the other at the bottom, of a vertical shaft, in the middle of the platform—these drums are, alternately, thrown in and out of gear by means of a vertical sliding bolt, and a horizontal lever, worked by the attendant. The chain that draws up the scoop passes around a roller at the end of the machine, and thence around the barrel at the top of the shaft, and that which draws it down and back, passes under the platform, and winds on the lower barrel.

The scoop is attached by one of its sides to two long guide poles, that slide in loops made in two collars, turning loosely on the ends of a horizontal windlass, which forms the axis around which the scoop swings, when drawn up or let down. In letting down the scoop, the chain which is attached to its bottom, is drawn in by throwing the lower barrel into gear; this causes the guide poles of the scoop to slide in the loops, which brings it near to the windlass, and after it has passed a vertical line its gravity causes it to sink. The lower barrel is then thrown out of, and the upper into gear; by this the scoop is drawn along the bottom, and filled, and then, with its load, is drawn up out of water. The stuff raised is discharged from it into a scow, or other receptacle, by pulling a rope, or chain, which disengages a spring catch, by which the hinged bottom is fastened. The bottom is closed as the scoop strikes the water, in the operation of being drawn down to be re-filled. The distance to which the scoop descends below the windlass, around which it works, is regulated by a chain, which winds around it, and is attached to a brace connecting the two guide poles together, near the scoop.

Claim—"What I claim as my invention, and desire to secure by letters patent, consists in the arrangement of the barrels on the perpendicular shaft, for winding and unwinding the main chains, in combination with the vertical sliding bolt and lever, for throwing the barrels in, and out of gear, with the shaft, by which the scoop, or bucket, is alternately raised, lowered, and drawn back, whilst the animal, by which the main shaft is turned, continues to travel on the circular tracks without interruption." Also the combination and arrangement of the parallel guide poles, chains, and windlass, for raising the scoop, so as to draw it back to its proper position, as described; and this I also claim in combination with the scoop and the apparatus for "disengaging the drop, or shutter, to discharge the load, as described." I also claim "the arrangement of the wings of the horse track, which can be raised, and thereby reduce the width of the machine, so that it may pass through a canal lock, or any other narrow place, as described."—*Franklin Journal.*

"*Description of Stephenson's Theatre Machinery.*" By J. B. Birch, Grad. Inst. C. E.

In this communication the author describes a system of machinery which was erected for the purpose of avoiding the confusion, mistakes, and noise, consequent upon the number of men usually employed in the stage department of a theatre, and with a reduced number of men to effect more perfectly all the operations required there.

The apparatus provides means for shifting simultaneously and without noise, any number of distinct pieces of scenery, bringing at the same time into view other scenes to replace them. The general arrangement of the machinery for effecting this is fully described.

The interior of the house between the basement and the roof, is divided into four compartments, viz.:

1. A raised platform on which the gearing for working the stage traps is placed. The trap frames are mounted upon rollers: they traverse on the lower platform in every direction; and when brought under the apertures in the stage, allow the traps to sink or rise steadily at any required speed.

2. The stage, with its traps of various dimensions, including a considerable portion formed to rise or fall by suitable machinery, and called the sinking stage.

3. The lower flies or corridor, between which and the stage are placed the wings or side scenes, and the border frames are suspended.

4. The upper flies upon which is placed the machinery to communicate motion to the whole, from the upper horizontal shaft, by means of bevel gear, provided with double clutches to reverse the motion and shafts, on the lower ends of which are the slow-motion wheels and drums, an endless chain is driven horizontally in either direction; to this are attached the borders representing clouds, foliage, arches, &c.

The side scenes or wing frames, the number of which is determined by the depth of the stage, may be either flat, circular, or triangular, and receive a rotary motion, combined with or apart from a forward and backward movement at pleasure, and can be placed at any desired angle to the audience. At every change of the scene they revolve through 120° or ⅓ of a circle, and the scenes when removed from sight are replaced by those which are to succeed them. The traversing frames revolve on a centre, and are suspended from the border frames, or from the upper part of the theatre, for crossing the stage in any direction, and at any given inclination. Several improvements in the mode of lighting the stage and house have been introduced with the machinery; they are more fully referred to in the detailed description which accompanies the ten elaborate drawings sent with this communication.

"*On the Combustion of Anthracite, and its value as a Fuel for Steam Engine and other Furnaces.*" By Andrew Fyfe, M.D.

Anthracite, although known as a valuable fuel for particular purposes, is so difficult of combustion, that it has hitherto been very partially brought into use; it has, however, become desirable to introduce it more generally, and the author having been engaged in testing the value of Mr. Bell's patent furnace, was induced to make some experiments on the use of anthracite in conjunction with that system.

The objects sought to be obtained by the apparatus are, to insure a larger amount of evaporation, by passing heated air, unmixed with the products of combustion, through tubes in the boiler and surrounded by the water, thus increasing the evaporating surface; and that the surplus caloric taken originally from the fuel, and not given out in its passage through the water, should be beneficially used in aiding the combustion beneath the boiler.

It has been found in the manufacture of iron that anthracite could be advantageously used by means of heated air; the author therefore considered that the experiments upon this apparatus (the intrinsic merits of which he does not at all discuss in this communication), afforded an advantageous opportunity for ascertaining in what manner this fuel could be successfully employed under steam boilers.

The anthracite supplied to the author was unfortunately of inferior quality, analysis giving only of fixed carbon 71·1, and of volatile inflammable matter 13·3; the setting of the boiler required much alteration before sufficient draught could be procured. The fuel was thrown on to the bars by hand, which is the worst manner of using it, as from its density, and its being a bad conductor of heat, it decrepitates when it first inflames, unless it is previously warmed—this was found to occur for a short time, but on the application of the heated air the decrepitation ceased, and combustion went on steadily. In ascertaining the amount of evaporation, the water at a temperature of 45° was injected by hand from a vessel, the content of which was measured, and the level in the boiler regulated by the float and index. The fire was brought up to a certain intensity before commencing, and was left in the same state at the end of the experiment; this mode of proceeding, although objectionable with bituminous coal, is not so with anthracite, as it does not swell during combustion so as to alter the bulk of the fire.

Results of the experiment.—The results of an experiment extending over [illegible] hours without interruption, are then shown in a tabular form. In this trial, 448 lb. of anthracite were thrown on the fire in four equal portions, at intervals of two hours; 3560 lb. of water at 45° were pumped into the boiler and evaporated under a pressure of 17 lb. per square inch. After deducting 40½ lb. of unconsumed coal which fell through the bars, the amount of evaporation was found to be 8·73 lb. of water for each pound of coal consumed. If the feed water had been at a temperature of 212° the evaporation would have amounted to 10·03 lb. During this trial the air in the tubes of the boiler never exceeded 139°, but on subsequent occasions it was raised as high as 700°.

This product of evaporation is below that obtained by other persons, which the author attributes to the inferior quality of the specimens of anthracite, and the admission of cold air above the furnace bars when throwing on the fuel. His opinion is, that when anthracite is completely burned, the practical evaporative power will be found directly in proportion to the amount of fixed carbon contained by it—that with the exception of the loss of heat which is always transmitted to the brick-work of the furnace, and of that which is carried up the chimney to keep up the draught, the whole of that evolved by the fixed carbon will be retained by the water; because from good fuel there is little or no escape of gaseous matter, and hence the superior efficacy of anthracite. From the analysis of a number of specimens of anthracite, the author found the quantity of fixed carbon to amount to 90 per cent. The evaporative power of these fuels, as fixed by Berthier's process (la voie sèche), would amount to 12·3 lb. of water for each pound of coal consumed. He calculates that 6 lb. of anthracite will evaporate one cubic foot of water under the ordinary circumstances of a steam engine boiler, and taking the average specific gravity of bituminous fuel at 1280, while that of anthracite is 1410, there is a difference of nearly 10 per cent. in favour of the latter, considering the space in which it can be stowed. This is an important consideration for its use on board steam vessels, but it is essential that its rate of combustion should be such as to raise steam rapidly, its capabilities for which the author then proceeds to examine, and deduces from the experiments that the combustion of the anthracite was carried on so as to produce a greater amount of evaporation in a given time, than could be obtained from bituminous coal. This result is attributed in some degree to the use of heated air.

The author recommends that the anthracite should be supplied to the furnace by a hopper through the boiler,* wherein it is warmed before reaching the fire bars, which obviates the inconvenience of decrepitation, and insures regularity in the supply of steam.

Mr. Lowe saw no reason to doubt the results recorded by so accurate an experimenter as Dr. Fyfe, which proved that anthracite was efficient just in the proportion of the carbon it contained, but he was at a loss to reconcile this with the opinion of Mr. C. W. Williams, who recommended the addition of bituminous substances to pure carbon, as a means of increasing the calorific power of fuel. He must repeat the opinion expressed by him on a former occasion, that the coal most free from elementary oxygen, would in practice be found the most effective fuel. Neither could any fuel be used too dry or too hot. At the gas works under his charge, a considerable economy had been effected by Mr. Croll's patent process of using the coke as it was drawn from the retorts, and thrown in an incandescent state into the furnaces.

"*Description of the new Sewer in the Valley of the Cowgate, Edinburgh.*" By George Smith.

In this communication the author first gives an account of a complete system of drainage, designed by him as architect to the Commissioners for improving the City of Edinburgh, and then describes the mode of constructing the first sewer, which begins at the south back of the Canongate, passes along the Cowgate, and through the Grass-market to the foot of the Bow. This principal sewer is 950 feet long; it was built in several sections; the upper portion was 4 feet high by 2 feet 6 inches wide, and increased at the lower extremity to 5 feet high by 3 feet wide; it was constructed of stone with vertical sides, and large flat stones for both the sills and the covers—the dimensions of the branch drains varied in proportion to the quantity of matter passing through them; they were situated opposite the cross streets, and had a cesspool to each, with a malleable iron grating hinged to afford access for cleansing them. The average depth of the excavations was 9 feet; a great portion of the work demanded great precaution in executing, on account of the narrowness of the streets, the frequent floods, the local impediments from the gas pipes, &c., and the soft character of the ground, as in some places the foundation stones sunk deep into the mossy soil by their own weight; it has, however, proved very successful, and will doubtless induce an extension of the sewage of the City of Edinburgh, which has been too long neglected.

The paper was accompanied by two drawings of the construction of the sewers, and the plan of the general system proposed, with the report to the Commissioners and other explanatory documents.

* Player's Patent.

"*On an uniform System of Screw Thread.*" By Joseph Whitworth, Assoc. Inst. C. E.

The subject considered in this paper, is the importance of having a constant thread for a given diameter in all screws used in fitting up steam engines and other machinery. It is argued, that uniformity of thread would be productive of economy, both in the use of screwing apparatus, and in the consumption of bolts and nuts. The refitting shop of a railway or steam packet company affords a striking instance of the advantage to be derived from the application of this principle. If the same system of screw threads were common to the different engines, a single set of screwing tackle would suffice for any repairs. No attempt appears to have been hitherto made to attain this important object. Engineers have adopted their threads without reference to a common standard. Any such standard must be in a great measure arbitrary, and hence its absence may be accounted for.

The author enters at some length into the consideration of the circumstances affecting the choice of a thread, with a view to show that it cannot be determined by precise rules. The essential characters of the screw thread are—pitch, depth, and form. The required conditions are—power, strength, and durability. But the exact degree or proportion in which these conditions are required, cannot be ascertained, and consequently the characters on which they depend cannot be fixed by calculation. An approximation may be made, but within a certain limit the decision is arbitrary. The mutual dependence of the several conditions, and the relation subsisting between the constituent characters, are noticed as having a tendency to perplex in the choice of a thread. From the vagueness of the principles involved in the subject, a corresponding latitude was naturally to be expected in the practical application of them, and accordingly, instead of that uniformity which is so desirable, there prevails a diversity so great as almost to discourage any hope of its removal. The only mode in which this could be effected, would be by a compromise; all parties consenting to adopt a medium for the sake of common advantage. The average pitch and depth of the various threads used by the leading engineers, would thus become the common standard, which would not only have the advantage of conciliating general concurrence, but would in all probability approach very nearly to the true standard for practical purposes.

The author then proceeds to describe the mode adopted by Messrs. Whitworth and Co., some years since, in selecting their threads upon this principle. An extensive collection was made of screw-bolts from the principal workshops throughout England, and the average thread was carefully observed for different diameters. The $\frac{1}{4}$ inch, $\frac{1}{2}$ inch, and $1\frac{1}{2}$ inch, were particularly selected, and taken as the fixed points of a scale by which the intermediate sizes were regulated, avoiding small fractional parts in the number of threads to the inch. The scale was afterwards extended to 6 inches. The pitches thus obtained for angular threads were the following:—

Diameter in inches.	$\frac{1}{4}$	$\frac{5}{16}$	$\frac{3}{8}$	$\frac{7}{16}$	$\frac{1}{2}$	$\frac{5}{8}$	$\frac{3}{4}$	$\frac{7}{8}$	1″	$1\frac{1}{8}$	$1\frac{1}{4}$	$1\frac{3}{8}$	$1\frac{1}{2}$	$1\frac{5}{8}$	$1\frac{3}{4}$	$1\frac{7}{8}$	2″
No. of threads to the inch.	20	18	16	14	12	11	10	9	8	7	7	6	6	5	5	$4\frac{1}{2}$	$4\frac{1}{2}$

Diameter in inches.	$2\frac{1}{4}$	$2\frac{1}{2}$	$2\frac{3}{4}$	3″	$3\frac{1}{4}$	$3\frac{1}{2}$	$3\frac{3}{4}$	4″	$4\frac{1}{4}$	$4\frac{1}{2}$	$4\frac{3}{4}$	5″	$5\frac{1}{4}$	$5\frac{1}{2}$	$5\frac{3}{4}$	6″
No. of threads to the inch.	4	4	$3\frac{1}{2}$	$3\frac{1}{2}$	$3\frac{1}{4}$	$3\frac{1}{4}$	3	3	$2\frac{7}{8}$	$2\frac{7}{8}$	$2\frac{3}{4}$	$2\frac{3}{4}$	$2\frac{5}{8}$	$2\frac{5}{8}$	$2\frac{1}{2}$	$2\frac{1}{2}$

Above the diameter of 1 inch the same pitch is used for two sizes, to avoid small fractional parts. The proportion between the pitch and the diameter varies throughout the entire scale. Thus the pitch of the $\frac{1}{4}$ inch screw is $\frac{1}{5}$ of the diameter; that of the $\frac{1}{2}$ inch $\frac{1}{6}$, of the 1 inch $\frac{1}{8}$, of the 4 inches $\frac{1}{12}$, and of the 6 inches $\frac{1}{15}$. The depth of the thread in the various specimens is then alluded to. In this respect the variation was greater than in the pitch. The angle made by the sides of the thread being taken as an expression for the depth, the mean of the angle in 1 inch screws was found to be about 55°, which was also nearly the mean in screws of different diameter. Hence it was adopted throughout the scale, and a constant proportion was thus established between the depth and the pitch of the thread. In calculating the former a deduction must be made for the quantity rounded off, amounting to $\frac{1}{3}$ of the whole depth, *i. e.* $\frac{1}{6}$ from the top, and $\frac{1}{6}$ from the bottom of the thread. Making this deduction, the angle of 55° gives for the actual depth rather more than $\frac{3}{5}$, and less than $\frac{2}{3}$ of the pitch.

It is observed that the system of threads thus selected has already been widely extended, demonstrating the practicability and advantage of the proposed plan. The author then notices the obstacles to general uniformity arising from the inconvenience which any change would occasion, in existing establishments, and also from the imperfect screwing tackle in general use. He anticipates as an important result of a combined effort to introduce uniformity, that screwing tackle generally would be much improved, and the efficiency and economy of bolts and nuts be thereby increased.

He recommends also standard gauges of the diameters and threads, as they would form a convenient adjunct to the screwing apparatus, and would be applicable to other useful purposes.

Mr. Field claimed for the late Mr. Maudslay the credit of the first attempt to introduce uniformity of thread—it was well known how incessantly his attention and skill had been devoted to this object, and with what success his efforts had been attended. He would at the same time accord great merit to Mr. Whitworth, not only for his present effort to introduce a very desirable measure, but also for the general excellency of the screwing tackle made under his directions.

Mr. Seaward corroborated all that Mr. Field had advanced; he had always considered that to Mr. Maudslay the mechanical world was indebted for the accuracy with which screws were now made. He considered the plan proposed by Mr. Whitworth to be good, but difficult of attainment in old-established manufactories, where very extensive assortments of screwing tackle already existed.

The President concurred in the opinion, that it was to Mr. Maudslay's well-known talent and skill that the mechanical world was indebted for the great improvements in the form of the screw, and the mode of its manufacture; but it was to Mr. Whitworth that the Institution was indebted for having brought the subject before the meeting; he trusted that this example would not be lost upon the numerous members, who could contribute so largely to the interests of the meetings, by recording the facts which came under their notice in the course of their diurnal employments.

"*Account of the original construction and present state of the Plymouth Breakwater.*" By William Stuart, M. Inst. C. E.

In the year 1806, the Lords Commissioners of the Admiralty instructed the late Mr. John Rennie, C. E., and Mr. Whidby, then Master-Attendant at Woolwich Dock, to make a survey of Plymouth Sound, with a view to the construction of a breakwater for sheltering vessels.

Their report was favourably received, but it was not until 1812 that the works were commenced.

Their plan consisted of a pier or breakwater 1700 yards in length, the centre part of which, 1000 yards long, was straight, with an extension at each end 350 yards in length, placed at an angle of 20° with the main body. The top to be 30 feet wide at the level of 10 feet above the low water of an ordinary spring tide:—the slope towards the sea to be 3 feet horizontal to 1 foot perpendicular, and on the land side 1 foot 6 inches horizontal to 1 foot perpendicular.

By the middle of March, 1813, the work had been brought up in parts to within 5 feet of low-water mark of spring tides—at this period 43,789 tons of stone had been deposited—and in the month of March of the following year sufficient shelter was afforded for ships of war to anchor in the Sound instead of in Cawsand Bay.

It was then determined to raise the whole structure to the height of 20 feet above low-water spring tides; great exertions were made to complete it rapidly, and during the week ending on the 24th of May, 1816, the quantity of stone deposited amounted to 15,329 tons, which was the largest quantity ever conveyed within the same space of time.

Slight injury had frequently been received by the works whilst in progress, but the storm of the night of the 19th of January, 1817, was the first which materially affected them. The most destructive effects were, however, produced by the storm of the 22nd and 23rd of November, 1824. On that occasion the spring-tide rose 7 feet higher than usual; and so great was its power, that a length of 795 yards of finished work was completely overturned, and the remaining parts slightly injured.

It was observed, that the effects of this storm left the slope from low-water mark upward at about 5 feet horizontal to 1 foot vertical. It was therefore determined to adopt that angle of inclination for the exterior or sea side, and a slope of 2 to 1 for the inside. The centre line of the breakwater was also removed 19 feet 6 inches towards the north, and the top width was increased to 45 feet.

The works continued upon this scale until 1830, when a fore-shore was added of a width of 50 feet at the toe of the south slope at the west end, and of 30 feet at the east end of the main arm: for this purpose 600,000 tons of stone were deposited.

The extreme western end of the breakwater was then, after more alterations and extensions, terminated by a circular head, with an inverted arch as a foundation for a light-house, now constructing under the direction of Messrs. Walker and Burges.

In consequence of further injuries from storms in 1838, when large quantities of stones of 16 or 20 tons' weight each were torn from below low water, and carried completely over the top of the Breakwater, a further extension of the fore-shore was made, and a projecting buttress built to secure the foot of the south slope, to afford additional security to the light-house, and to prevent the stones from the fore-shore being carried over to the north side.

From the time of its commencement in August, 1812, until the 31st of March, 1841, there had been deposited upon this work 3,369,261 tons of stone.

Cost.—The expenditure upon the whole work, when completed, will, it is estimated, be within one million and a half sterling. The main body of the work is composed of blocks of limestone from the quarries of Oreston, adjoining the harbour of Catwater. They were deposited from vessels constructed for the purpose. In certain portions of the work the blocks have been subsequently ranged from a diving bell. The buttress and the works now in progress round the west end are composed of granite masonry, dove-tailed horizontally, and fixed vertically by iron levis cramps.

Subsequently to the reception of the plan of Messrs. Rennie and Whidby, most of the leading engineers of the day were consulted, under whose directions the author has superintended the execution of the work.

The communication is accompanied by six elaborate drawings by Mr. Dobson, illustrating in detail the various stages of the work, and the mode of construction.

Mr. Rendel could have wished that the account of this interesting work, the most extensive of the kind in Great Britain, had entered more fully into details, not only of the difficulties met with and overcome, but of the peculiarities of the construction; there were many points connected with it of great importance to engineers. He would allude to one only upon which no information was given; the amount of interstice in the whole cubic content as compared with the mass of materials employed; an accurate account had been kept of the quantity of stone deposited, and knowing the cube of the mass at a given period, he had ascertained the amount of interstice or vacant space in the old part of the works to be at one time 37 per cent. This great deficiency of solidity had arisen from the employment of an excess of large stone, or rather from a deficiency of small stone to fill the interstices between the large stones.

June 22.—The PRESIDENT in the Chair.

"*On the Construction and Use of Geological Models in connexion with Civil Engineering.*" By Thomas Sopwith, F. G. S., M. Inst. C. E.

The author commences this paper with a review of the various methods adopted for the representation of objects required in carrying out the designs of engineers, architects, and mechanics—whether as the means whereby such designs are first studied, and afterwards matured—as guides for the resident superintendents and workmen—or for being preserved as records of what has been executed, and studies for those who may be engaged in similar undertakings.

He then proceeds to elucidate the advantages peculiarly possessed by models for demonstrating practical results in Geology and Mining, dividing the subject into six heads, as follows:

1. On the application of modelling to geological and mining purposes.
2. On the materials to be employed.
3. On the mode of construction.
4. On the scales to be employed.
5. On the objects to be represented.
6. On the use of geological models, and the connexion of the subject with civil engineering.

1. A large number of plans and sections is usually required to elucidate with clearness the geology of a district, and the nature and extent of mining operations; and few departments of practical science admit of greater improvement than the art of delineating mining plans in connexion with geological features.

Much ingenuity has been exercised in representing the undulating surface of countries either by the process called "relief-engraving, (procédé Collas) or as in the Ordnance Maps of England and Wales, and Mr. Greenough's recent edition of his Geological Map: but even in comparison with these a model affords a more correct idea. Hence models in relief are more peculiarly applicable in all cases where it is desirable to comprehend at once the relations of the several parts, and it is evidently still better adapted to explain the geological conditions; especially when it is required to show the relative position of various rocks, their inclination, thickness, extent, and the disturbances to which they have been subjected, which could only be understood by comparing together a number of drawings.

To those interested in mining, therefore, the easiest mode of conveying ideas is by modelling. This was illustrated by two models of the Forest of Dean, and by reference to Mr. Jordan's model of the Dolcoath mine, now in the Museum of Economic Geology.

Materials for models.—2. The first material for forming a model which naturally occurs to the mind is clay, pins and wires being used to define the principal elevations. Plaster of Paris has occasionally been used, and is well adapted for solid forms, where the edges are not exposed to injury; but its brittleness and contraction in drying are objectionable. Papier Mâché is a more elegant and durable material, but the expense of the requisite moulds prevents its general use. Coloured wax is adapted for small models not subject to be handled. Pottery appears to possess more requisites, but many corresponding disadvantages. Of all the materials which the author has employed, he found none so generally useful as well-seasoned wood, whether for the facility with which the requisite forms are attained, for durability, for portraying different strata by various-coloured woods, or for comparative economy.

Mode of construction.—3. The mode of constructing geological models had been briefly alluded to by the author on a preceding occasion.* It is more fully described in the present communication, and was illustrated by complete models, and the detached parts for forming them purposely made on a large scale.

The plan of the district being divided by lines at given distances apart, into a certain number of squares, a series of thin slips of wood are made to intersect each other, corresponding to the lines so drawn—upon these slips the profile of the surface and the positions of the strata are delineated, when it is intended that the model when complete shall be dissected; the compartments are then filled in with wood, and carved down to the lines upon the slips, the several strata thus rest upon the subordinate beds, and can be detached in a mass or in compartments; these being geologically coloured, convey an accurate idea of the relative positions of the strata, and display with the utmost clearness the mining operations in each. This system is applicable to any extent: and the operation of forming the model is so simple, that a skilful workman at once comprehends and executes unerringly the instructions given him by the engineer or surveyor, as the accuracy entirely depends upon the profile which is drawn upon the slips. The author considers lime-tree or plane to be the most suitable wood for the purpose; but in the construction of small models for showing peculiar geological features or disturbances of strata, he uses various coloured woods: as an illustration of which he showed a series of twelve models, which (with a printed description*) are now in the Museum of the Institution. These contain 579 pieces of wood, one of them consisting of 130 pieces. By fitting the parallel layers of wood together, and arranging them in conformity with sections of strata of the carboniferous limestones and coal measures of the north of England, he illustrates the formation of that district, and the nature of its dislocations, &c. better than can be done by any number of plans and sections.

4. *Scales to be employed.*—Attention is drawn at some length to the proportion to be observed between the horizontal and vertical scales, and the relative merits of corresponding and dissimilar horizontal and vertical scales fully examined, illustrating the positions by two models of the Forest of Dean, in one of which the vertical is enlarged to three times that of the horizontal scale; while the other has the scales exactly alike. For the conventional purpose of giving an idea of a country such as would be formed by a general observer passing through it, the former model appeared best adapted; but in a scientific point of view the latter had a decided advantage, being based on geometrical truth, and conveying an exact knowledge of the real, but not of the apparent relations of the surfaces, and other objects represented.

5. *Objects to be represented.*—Models had hitherto been chiefly used for conveying impressions of tracts of the surfaces of countries, or for displaying the minute tracery and proportions of buildings. The author's views have been more especially directed to introducing the construction of models for geological and mining purposes, for which he considers them peculiarly adapted.

The series of models now presented to the Institution, contains examples of various geological phenomena of regular stratification—interruption by slips, faults, and dykes—the effects of denudations in exposing to view the various strata—the deceptive appearance of the course of mineral veins on the surface—the intersection of veins—and many other details which are intimately connected with practical mining.

6. *Models used in civil engineering.*—The author then proceeds to describe his view of the uses of such models, and the connexion of the subject with civil engineering.

He considers that by them a practical knowledge of geology may be attained by the civil engineer, and that such knowledge is indispensable for his guidance in many of the works he is called upon to undertake in the exercise of his profession. It is to an engineer that the merit is justly due of having, by efficiently labouring to establish English geology on a firm basis, acquired the title of "Father of Geology," which has been generally conceded to the late Mr. William Smith.

The avocations of the civil engineer peculiarly qualify him for an observant geologist; and being called upon to visit so many different districts, the remarks he might make would be replete with instruction. These observations might be illustrated more efficiently by models than by any other means; at the same time they might be made to answer another purpose—that of demonstrating to the owners of mineral property the advantage or the futility of commencing researches or mining speculations.

Plans do not admit of such certainty of definition as modelling, and no regular system of planning mining districts has yet been generally practised, by which the engineer can judge of the probable results of the operations which he is often called upon to direct. As a record of mining operations, models of this kind are pre-eminently valuable; the exact position not only of the mineral veins and the strata are clearly shown, but the quantities extracted are registered, and a guide for future proceedings is established. The author contends that it is a duty to secure, while it is in our power, such records of mining operations as may enable us and our successors really to exhaust whatever minerals can be worked with advantage.

As being in some degree connected with the subject under discussion, Dr. Buckland described a mode used by Sir John Robison, for obtaining moulds for plaster casts. The object, of which the mould was required, was immersed in a mixture of common glue, dissolved in brewers' sweet wort of about the consistency of thick cream, and allowed to remain until the mass became

* Journal, Vol. III., page 347.

* Description of a series of Geological Models, &c. By Thos. Sopwith, F.G.S., &c. 12mo. Newcastle, 1841.

stiff: it was then released by cutting the mould open, when it would be found to resume its original form like Indian rubber: holes were made in it for pouring in the plaster of Paris, and for carrying off the air; from such moulds, casts of the most delicate objects could be taken.

He entirely concurred in the praise of the beauty and the utility of the models which had been described, and he hailed with much pleasure the co-operation of engineers in the study of geology; by their researches in the science of dynamics, and their knowledge of the power of elastic vapours, light might be thrown upon the upheavings of the great mountain ranges; whether that had been the work of time, or by the sudden development of a mighty force, it was peculiarly the province of the civil engineer and the mathematician to consider and to explain. The observation of the effects of torrents, the causes of removal of masses of material, the disturbance of strata in certain localities, and numerous other instances of the utmost interest to the geologist, were even more important to engineers.

Mining models.—In mining operations, where for want of accurate records of previous workings, much expense was frequently incurred, accompanied with loss of human life, the adoption of the models proposed by Mr. Sopwith was of the utmost importance; he trusted that the keeping of such records of present operations would be rendered compulsory by legislative enactment, that proprietors of collieries would not be permitted by inattention to do irremediable injury to the mineral and coal basins, which were the vital riches of the country. If accurate models of all the coal districts were prepared, similar to that of the Forest of Dean, a close estimate of the duration of the supply of mineral fuel could be made: present expense would also be avoided, by the best positions for sinking pits and erecting engines for draining being fixed upon with greater certainty, the positions and extent of the beds or veins of coal or minerals, the faults, dykes, slips, &c., would be shown for the guidance of speculators; in fact, these models would do much towards giving a degree of precision to a branch of engineering, in which the greatest uncertainty prevailed at present.

Thames Tunnel borings.—As an instance of the utility of a knowledge of geology to the engineer, he might mention, that after the Thames Tunnel had been commenced by Sir Isambard Brunel, upon an assurance from those who made the borings that they had reached the London clay, it was found that they were actually traversing the sands of the plastic clay; hence arose nearly all the difficulties which the engineer had displayed so much skill and perseverance in overcoming.

Artesian well at Paris.—It was the adaptation of the science of geology to engineering, which enabled Monsieur Arago to inspire the contractor for the Artesian Well of the Abattoir de Grenelle, with the confidence that he should eventually obtain the abundant supply of water which had from the commencement been foretold—and which had now been realised.

In short, whether viewed in connexion with the labours of the mining engineer as directing his proceedings with greater certainty, or giving a correct knowledge of the properties of materials employed in the works of the civil engineer, and for numerous other self-evident reasons, he considered the study of geology to be indispensable for every member of the profession.

The Council of the Institution of Civil Engineers have awarded the following Telford and Walker premiums for 1841:—

A Telford Medal in Silver to John Frederick Bateman, M. Inst. C. E., for his "Account of the Bann Reservoirs, County Down, Ireland."

A Telford Premium of Books, suitably bound and inscribed, to William La Trobe Bateman, for the Drawings illustrating the "Account of the Bann Reservoirs."

A Telford Medal in Silver to Samuel Seaward, M. Inst. C. E., for his Paper "On the application of Auxiliary Steam Power to Sailing Vessels upon long voyages."

A Telford Medal in Silver to Benjamin Green, for his "Description of the Arched Timber Viaducts on the Newcastle and North Shields Railway, &c."

A Telford Medal in Silver to Thomas Sopwith, M. Inst. C. E., for his Paper upon "The construction and use of Geological Models in connexion with Civil Engineering."

A Telford Medal in Silver to Dr. Charles Schafhaeutl for his two Papers on "A new Universal Photometer," of his invention, and "On the circumstances under which the Explosions of Steam Boilers frequently occur."

A Telford Premium of Books, suitably bound and inscribed, to David Stevenson (Edinburgh), for his "Description of a Coffer Dam, designed by him for Excavating Rock in the Navigable Channel of the River Ribble."

A Walker Premium of Books, suitably bound and inscribed, to George Clarisse Dobson, Assoc. Inst. C. E., for the execution of the Drawings illustrating the "Account of the Plymouth Breakwater, by William Stuart, M. Inst. C. E."

A Walker Premium of Books, suitably bound and inscribed, to Robert Mallet, Assoc. Inst. C. E., for his "Description of the methods designed by him for raising and sustaining the Sunken Roof of St. George's Church, Dublin."

A Walker Premium of Books, suitably bound and inscribed, to Joseph Colthurst, Grad. Inst. C. E., for his two Papers "On the Position of the Neutral Axis in Rectangular Beams of Cast and Wrought Iron and Wood," and "Experiments on the Force necessary to Punch Holes in Wrought Iron and Copper Plates of various thickness."

A Walker Premium of Books, suitably bound and inscribed, to George Thomas Page, Assoc. Inst. C. E., for the Drawings illustrating the "Memoir of the Montrose Suspension Bridge, by James Meadows Rendel, M. Inst. C.E."

A Walker Premium of Books, suitably bound and inscribed, to Samuel Clegg, jun., for his "Description and Drawings of the Great Aqueduct at Lisbon, over the Valley of Alcantara."

A Walker Premium of Books, suitably bound and inscribed, to John Brannis Birch, Grad. Inst. C. E., for the "Description and Drawings of Stephenson's Theatrical Machinery."

The Council invite communications on the following as well as other subjects for Telford and Walker premiums:—

1. The alterations and improvements in Blackfriars Bridge.
2. A Description of the Katwyk Dykes; the Canal of the Helder; or of any similar Foreign Engineering works of equal importance.
3. The modes of Drainage adopted in the Lowlands of the United Kingdom, or works of a similar nature in Holland or in other countries.
4. On any of the principal Rivers of the United Kingdom: describing their Physical Characteristics, and the Engineering works upon them.
5. The various kinds of Limes and Cements employed in Engineering Works.
6. The resistance to Aeriform Fluids in their passage through Pipes or Conduits at different velocities.
7. The conveyance of Fluids in Pipes, under Pressure, and the circumstances which usually affect the velocity of their currents.
8. The means of rendering large Supplies of Water available for the purpose of extinguishing Fires.
9. The construction of large Chimneys, as affecting their Draught; with examples and drawings.
10. The comparative advantages of Wire and Hempen Ropes.
11. The relative merits of Granite and Wood Pavements, derived from actual experience.
12. The ascertained effects of any method for preserving Timber from decay.
13. The Smelting and Manufacture of Iron, either with Hot or Cold Blast.
14. The Smelting and Manufacture of Copper.
15. The comparative advantages of Iron and Wood, or of both materials combined, as employed in the construction of Steam Vessels: with drawings and descriptions.
16. The sizes of Steam Vessels of all classes, whether River or Sea-going, in comparison with their Engine Power: giving the principal dimensions of the engines and vessels, draught of water, tonnage, speed, consumption of fuel, &c.
17. The various mechanism for propelling Vessels, in actual or past use.
18. The causes, means of preventing, and methods of determining the amount of priming in Steam Boilers.
19. The description of any Meter in practical use for accurately registering the quantity of Water for supplying Steam Boilers, or for other purposes.
20. The explosion of Steam Boilers; especially a record of facts and evidence connected with any well-authenticated cases; also a description, drawings, and details of the Boilers, both before and after the explosion.
21. The various modes adopted for moving Earth in Railway Tunnels, Cuttings, or Embankments, with the cost thereof.
22. On Stone Blocks and Timber Sleepers or Sills, with or without continuous Bearings, for Railways.
23. The results of experience as regards the consumption of Power for a given effect, on Railways having different widths of Gauge with the advantages or disadvantages attributable to any established width of Gauge.
24. Memoirs, and Accounts of the Works and Inventions of any of the following Engineers:—Sir Hugh Middleton; Arthur Woolf; Jonathan Hornblower; Richard Trevithick; and William Murdoch (of Soho).

The communications must be forwarded to the Secretary on or before the 31st of May, 1842.

UNIVERSITY COLLEGE—CIVIL ENGINEERING.

The introductory lecture to this course was delivered by Professor Vignoles, at University College, on Wednesday last. The attendance of engineers and students in the large lecture-room was numerous. The learned lecturer stated that it had recently become his duty to attempt to form a distinct class in the college, for the purpose of elucidating, to those desirous of embracing the profession, the elementary principles of civil engineering; and it was mainly with that end in view that the present course of lectures had been undertaken. After a few introductory remarks upon the the nature of civil engineering, which he defined as a combination of practical skill, in conjunction with a well-grounded education on scientific principles, the learned lecturer proceeded to observe, that the use and signification of the term engineer was somewhat indefinite and obscure. In the middle ages, and long after the commencement of the last century, it was used exclusively as a military term. It was likewise applied to architecture and hydraulics; and even the term engineering, in the present day, was not less equally multiform in its application and meaning; for even from the turncock of a water company to the conductor of an engine, or the stoker of a steam-boat, all included themselves under the denomination of engineers. Very different, however, was the province and the line of study which was requisite to qualify the young engineering graduate for this noble profession. Amongst the more immediate branches of study for this purpose were to be enumerated those of mechanical, topographical, and mineral engineering. An intimate acquaintance with mathematics, a knowledge of natural and mechanical philosophy, of chemistry and economic geology, were likewise necessary in pursuing the business of civil engineering.

The stupendous aqueducts, constructed by the Romans, have been commonly stigmatized as but immense monuments of their ignorance of the simplest principles of science, inasmuch as they seem constructed in utter disregard of the now universally familiar fact, that water, if left to itself, will find its level; but the learned Professor showed that the defect in their construction were much more probably owing to the low state of the metallurgic arts in ancient times, and the difficulty if not responsibility, of their providing pumps, pipes, &c., of strength and capacity enough for sustaining the pressure of large bodies of water. Modern engineers had, he thought, but little superiority to boast of, in point either of scientific knowledge, or engineering skill. There was, however, scarcely any one branch of the arts and sciences from which an engineer might not draw important aids in the exercise of his profession. How chemistry might lend her helping hand, was strongly exemplified by the highly philosophical researches of Mr. C. W. Williams into the process of combustion, by which the long standing nuisance of smoke seemed likely to be for ever extinguished, and a saving effected of not less than 30 per cent. in the consumption of all fuel employed for engineering purposes. How a knowledge of pneumatics might be turned to good account was evidenced in the various contrivances for storing and distributing the gas with which our cities and towns are lighted, and would, he believed, be soon still more strikingly manifested in the atmospheric railway; for which we are indebted to the same ingenious individual Mr. Clegg, who invented the greater part of our gas machinery. The Professor stated that he had himself not only investigated with great care the principles of this new system of railway transit, but witnessed several most successful trials made of it, and had no doubt whatever of its coming, ere long, into most extensive and profitable use. He cited these "modern instances," (besides others which we have not space here to notice,) not so much because they were among the most remarkable of their kind, as because they were among the most recent. Although true it was that civil engineering was not made, as it ought to be, a matter of regular study by all embarking in the practice of it, and true also, that it had been hitherto almost wholly neglected as a distinct branch of education in our universities and colleges, yet he felt bound to acknowledge, and did so with great pleasure, that there were other means and other channels of acquiring information on engineering subjects, peculiar to the present day, of which engineers did avail themselves to an extent which went a great way to make up—though they could never do so entirely—for the want of early and systematic instruction. He referred particularly, and in terms of great commendation, to the establishment of the Civil Engineers, to its interesting and edifying weekly conversational meetings, and to the liberal and extensive circulation of its Transactions. Of the value of such an institution as a sort of storehouse for the communications of engineers on all subjects of interest to their profession, it was impossible to speak too highly. He might cite as an appropriate example of this, the account lately furnished to the institution by Mr. Clegg, jun., of the Portuguese viaduct of Alcantara—a work as extraordinary for its magnitude as its expense, having cost no less than about 120,000*l.* a mile. The scientific periodical press had also rendered most important service to the engineering profession; in particular the Mechanics' Magazine, and Civil Engineer and Architect's Journal. Much valuable information was to be gleaned from the periodical literature of the day, and from such works as those of Smeaton, Tredgold, Rennie, the "Transactions of Civil Engineering," and other productions. Many were the striking results which might be mentioned of the power of knowledge, where science was combined with skill, as might be illustrated in the labours of the Earl of Ross, better known in the scientific world as Lord Oxenstown, who, following in the steps of Herschell, had constructed the wonderful reflecting telescope. It was the business, he conceived, of a civil engineer, to be economical in his works, and to keep down every branch of expenditure as much as possible.

THE LEVELLING STAFF.

Sir—Observing in this month's number of your excellent Journal, a notice of some "improvements" made in levelling instruments, by Mr. T. Stevenson —I cannot refrain from a few remarks on the too great disposition now prevalent to "improve" by complication, many instruments which we have already had much improved by being simplified. I allude more particularly to the levelling staff, which has been made almost perfect by the ingenious method of "self-reading," and which when properly used, in my humble judgment renders any adjusting apparatus worse than useless.

Inventive minds when impressed with improving ideas are, in their anxiety to bring them forth, prone to overlook many attendant circumstances which more than neutralize the presupposed advantages, and such, I conceive, is the case with Mr. Stevenson, for in the attempt to attain such superlative accuracy by means of his adjusting screw and clamp, in the reading of the staff, a certain portion of both the observer's and holder's attention is absorbed, which should be entirely devoted to obtaining the exact reading when the staff is in the perpendicular position. A method which I have adopted in practice, and which may not generally be known, ensures, I may say, perfect accuracy, and allows the observer to be quite independent of his assistant—is expeditious in the extreme—and may be practised in moderately windy weather still ensuring the same accuracy of observation. It consists in instructing the staffholder to firmly and slowly move the staff to and fro in the plane of the observer, the base of the staff acting in its seat as a hinge,—during this motion, the cross wire of the telescope is seen to travel up and down, and up again on the face of the self-reading staff—the sequence of these being reversed in its return motion. The *least* reading should be always taken down as it is at this point the staff is perfectly perpendicular. I have found this plan most satisfactory and easy in practice, and I trust the judgment of any practical man will convince him of the superiority of it over any complicated adjusting screws which may be applied, and which tend greatly to increase the expense of a most simple and cheap instrument when properly made.

I am, Sir,

Your very obedient servant

Dublin, 13th Nov. William Bewley.

W. B.'s IMPROVED RAIL AND CHAIR.

Sir—Surely your correspondent W. B. must be one of those who walk through the world with their eyes shut; it would be difficult otherwise to reconcile the fact of his being "practically engaged in the construction of railways for some years," and his calling the attention of your readers to such an extremely impracticable thing as his "improved rail and chair."

W. B. starts with the astounding observation No. 1, "that the greatest strength of the rails is not in the direction of the force they are intended to bear." I can only say, if W. B. has really seen this to be the case, it can but have been on the lines on which he has been "practically engaged." Subsequently, he admits indeed that "this is assisted a little by placing the chairs declining a little inwards; but which is entirely at the mercy of the workmen employed to lay the rails." Were this true, it would be a sweeping denunciation of the whole profession; but fortunately for engineers, it is not so; the observation reflects only on W. B. himself. This important point is no more left to "the mercy of workmen," than is the gauge itself of the line; both are with the same accuracy adjusted with a template, and receive the careful attention of engineers and inspectors.

Template.

Chairs and Rails inclined.

Had W. B. known what was done on all lines but his own, he would surely in very fairness have placed the rails under his barrel in their true position, however much, giving them a vertical direction might help out the argument of his offspring.

In observations 2 and 3, W. B. complains "that there is invariably considerable attrition between the rail and chair, and between the joints of the rails," and "that the fixing of the rails is subject to failure from the loosening of the key or wedge;" which said observations lead me to suppose that his practical engagement on railways must be of rather ancient date; I shall therefore take the liberty of informing him, that in most, if not all, the later methods of laying rails, these inconveniences have been very nearly obviated; so perfect indeed, in most cases is the connection between the rail and chair, that in instances of partial subsidence, the pins are much more frequently seen drawn from the sleepers and blocks, or these lifted from their beds, than the rails parted company with, or loose even in the chairs. The latter part of W. B.'s third observation is rather a sly hit at himself. He complains of "a wooden wedge having greater force to sustain than it is able without being compressed," and yet he not only uses a wooden wedge himself, but actually compresses it until it fills a series of notches in the chair!

It is not a little singular that with all W. B.'s acute perception of the difficulties and dangers of rolling the usual "irregular forms of the present rails," as evinced in observation No. 4, and with all his practical experience, it did not occur to him that there might be some slight practical reasons to induce the whole world to battle with these difficulties, and adopt a flatheaded rail in spite of them, instead of contenting themselves with the simpler form of 'ead that could be had without them.

Having disposed of the observations, let us examine a few of the practical advantages of his "improved rail and chair;" and it will materially assist in the enquiry, if W. B., who has "practically proved the rail himself," will favour us in your next with further information on the following trivial points. As, on W. B.'s lines of railway, the position of the rails is "left entirely to the mercy of the workmen," has he not found that the "improved" may possibly cut as sorry a figure by the chair not being placed perfectly straight, as the present bungling methods may, by not being sufficiently declined? Most things, I imagine, "left to the mercy of workmen," would have as good a chance of being placed crooked as straight; and then what might not be the fatal consequence of the one-tenth less metal?

There is one point however on which the "improved" decidedly bears away the palm from all the present disadvantageous methods that I have ever seen; which is, the next to impossibility of ever unfixing the line that has once been laid with it. From the method of joining the rails, one faulty one cannot possibly be removed without two others being also taken up, and some fifteen chairs being removed from the sleepers; just increasing the work in the proportion of three to one of the present disadvantageous methods. I say fifteen chairs removed from the sleepers, for assuredly W. B. would not attempt to remove the keys and the wooden wedges he has so neatly compressed into the notches of the chairs; these could not possibly be drawn to release the rails without destruction.

Are W. B.'s lines of railway in an unknown country of equable temperature, or has the "improved" the additional practical advantage of being of metal unaffected by such sublunary causes? If not, what becomes in the winter time, of the "piece of thin cast lead," so carefully inserted between the joints? What service it would do in any season, what noise it would deaden where no noise occurs except from a loose joint, of which, no one, would accuse the "improved," I leave to W. B. to explain with the rest.

Your obedient servant,

H. A.

Sir—In the engraving of the improved chair, the ratchets are shown acute, and on enquiry I find the draftsman sketched them thus, although my directions were for the same to be drawn as shown in the models, or more obtuse, and they should have been like a wave, as I distinctly state there are no internal angles in the chairs, which would be futile if the ratchet or wave was as shewn in diagrams, figs. 3 and 4, and in fact would prevent the withdrawal of the wedge, whereas that shewn in the models I have repeatedly proved will not prevent the wood wedge being drawn or driven out after removing the iron key even without prejudice to its being re-used. My reason for having used the term ratchet was the attaining equal security as given by common ratchets

The preceding correction may seem unnecessary as it would of course be seen by a practical man, and it requires but little penetration to see it is not intended as shewn in diagrams Nos. 3 and 4, but for the benefit of those who may not have seen the models I respectfully request your insertion of the above explanation.

I am, Sir,

Your obedient servant,

W. B.

ON REVERSING ENGINES.

Sir—Seeing a plan for reversing engines in your pages, signed Geo. Coe, civil engineer, I take the liberty of sending you a few remarks, which I trust you will give a place in your Journal.

The plan which Mr. Coe has given is similar to one of which I consider myself the inventor, only that I have but one-half the work which he has shown, to answer the same purpose. He is silent on some of the most essential points; the lead of the eccentric for instance, if it be set right for going ahead, would be far from being right for going astern; the engine would be what we call too late and not be able to pass its centres, which every practical man is quite aware would not move in a contrary direction.

He further states that one man would be able to manage any of the largest marine engines that ever navigated the ocean, better than 4 or 6 or even 10 men on the present system. Now let alone what I have stated above, I will take two engines of 100 horse power, which is far from being the largest which we have navigating the seas. The steam ways that would be required for cylinders of this power should contain 55 superficial inches, 16 inches by 3½ inches nearly; the valve that would be required to cover sufficiently, would be 18 inches long and 19 inches broad, containing 112 superficial inches working together. For two engines it will be double the area, excepting one bar less will do, as the centre one acts for both engines, so that will make it equal to 217 superficial inches working together. The pressure which is on a valve of this description will be immense, taking it at the lowest figure, say 15 lb. on each square inch, 12 lb. by a vacuum being formed in the condenser, and 3 lb. of steam in the valve box or on the back of the valve, making it equal to a weight of one ton nine cwt. to be moved by one individual, which is quite impossible, unless multiplied by a long lever, which never can be done to any advantage.

I have by me a working model which I exhibited at the Hull Mechanics' Institution, on the 25th of February, 1841, and at that time I entered it at the Patent Office, London; I have since then made working sections. All the different points which I consider in the sketch given in the Journal, as deficient, I have adopted in full perfection, and proved by the working model which answers instantaneously forward, backward and stop, with the greatest ease, and can be attached to any engine at a trifling expense. An engine of 45 horse power is at the present time being made by Messrs. Overton and Wilson, engineers, Hull, in which will be introduced my improvements. I hope in a few weeks to see it in full play on the river Humber, where any one will have an opportunity of judging of its importance.

I will send you a sketch of it as soon as time will allow me.

I am, &c.,

Thomas Stather,

Foreman to Messrs. Overton & Wilson, Hull,

And an Old Subscriber.

Hull, November 17, 1841.

Sir—Page 336 of your Journal for October last, contains an article professing to be a new and advantageous plan to facilitate the reversing of steam engines. Although the plan is to me perfectly new, and will I have no doubt be found to change the action of steam very effectually, I do not conceive its peculiar advantage, either as to friction, weight, or cost in construction. On the contrary, it would in the first place cause a very considerable amount of friction, in consequence of the additional slide-valves on the opposite side of the cylinder. Secondly, the boxes for these additional slide-valves, together with the regulating valve-box and those massive pipes which form the communications between it and the other valve-boxes, would add very largely to the weight of our marine engines. Thirdly, these additional pipes, valve-boxes, the moveable joints, levers, &c., necessary to connect the two pair of double-faced slide-valves, and also those necessary to facilitate the changing and adjusting of the reversing valve, all combined, would add very materially to the cost of an engine.

However far the above inconveniences may oppose the practical application of Mr. Coe's system, it has an objection of still greater importance; which objection I trust will apologise for my thus intruding upon your pages.

It is in practice found advantageous (and is now almost universally attended to), to give the slide-valves of all reciprocating steam engines what engineers term lead and cover; the importance of which is very clearly explained in one of your late preceding numbers. Now the valves of Mr. Coe's present system could not be adjusted to produce this effect for one direction without destroying it when reversed. If then we are obliged to neglect the lead and cover, why use the reversing valve and additional double-faced slide-valves proposed by Mr. Coe, when we can obtain exactly the same result from one common single-faced slide-valve, with the addition of one simple lever merely to change the direction of the motion produced by the fixed eccentric?

With great respect, I am, &c.,

Vesper.

P.S. Should Mr. Coe, or any other of your able correspondents, think it worth their trouble to lay before the readers of your Journal a description of a complete apparatus for working steam engines expansively, that is, capable of cutting off the steam at any point between the commencement and termination of the stroke; such an article would, I presume, be at the present very acceptable.

Leeds, November 1, 1841.

ON THE THEORY OF BARS.

Sir—Mr. Brooks' letter in your Journal for the present month purports to be a reply to mine of July last; in my opinion it is not so. He accuses me of an attempt "to go off on another tack," although he has no authority for such an accusation; but he flies off, not at a tangent, but in an eccentric movement, and seizes with avidity the bonum magnum found in the Nautical Magazine for 1837. So far from abandoning the law there by me propounded, I adhere to it without qualification or reservation, *i. e.* to the fact that the *right angle* course of egress water charged with matter in suspension, and causing a conflicting action with that water into which it falls, is the cause of a bar.

He calls on me to adduce proofs of my proposition; the columns of your Journal and of others already contain a number of facts, demonstrating the accuracy of my thesis. He threatens, if I fail in "duty," to supply the omission by giving proofs "that many rivers are free from bar, notwithstanding their rectangular direction, and of numerous rivers which have bars, although their discharge is at an acute angle." It has been very properly observed that "those who discuss important subjects should be cautious in their choice of facts."

To the first of these, the rectangular course of river water not causing a bar, the exceptions are explained in my Treatise, page 5. As to the second I promptly admit that if a river do pass out in an acute angle, and be charged with matter, and have velocity adequate to cause a conflicting action with the water of the ocean, then in that case a deposit or bar would ensue. But in all my extensive and practical observations, I know of no river, nor is there *an instance* to be found in our globe, where a river at its disembogning *point* and where it *meets* the tidal water of the ocean, and commences the conflicting *action*, does pass out or meet the tide at an acute, but *invariably* at a right angle. Surely no scientific or practical man can be so uninformed as not to know that however meandering may be the interior course of a river, ere it arrives at the ocean, *naturally* and *necessarily*, it must take a perpendicular course into the sea, and *continue* that course till influenced by the ocean's tide. In some places this perpendicular or right angle course into the sea is by a long, in others by a short *sea-reach*.

Mr. Brooks has mistaken the fact, the important distinction between that course or direction of the river water at its fall into, and until it absolutely gets in contact with the tidal water; and that direction which it takes subsequent to the joining of the two waters. It is the *pressure* of the larger and heavier power of the sea tide, passing parallel with a coast, and consequently crossing the mouth of a river at right angles, which forces the water from a river to incline to the direction of the more powerful stream; and thus the river water takes an oblique or an acute angle of direction from its uninfluenced course—but for this cause, a river would continue to advance seaward in its perpendicular direction until it was exhausted, and disappeared in the vast ocean.

We see then the cause why all bars are formed on the lee-side of the entrance to a harbour, if the ebb tide come from the right, the bar invariably inclines towards the left, and *vice versa*.

In making these observations I beg it may be understood that they relate *only* to a coast where there are regular passing *tides*.

I remain, Sir, your obedient servant,

HENRY BARRETT.

72, Broughton Street, Edinburgh, November 17, 1841.

DREDGE'S SUSPENSION BRIDGE.

SIR—An entire description of my patent suspension bridge would occupy too much space in your Journal, and employ more time than I can at present spare, and as an abridgment, would perhaps produce more cavilling than would be interesting to your readers, or necessary for the investigation of truth, I will refer Mr. Fordham to a full mathematical description, which will be published in a few days, by Mr. Weale, to four foot bridges in the vicinity of the Regent's Park, and similar works in various parts of the kingdom, so that as a mathematician, and man of science, he may be able to read, see, and judge for himself, and from these evidences, form what opinion he thinks fit, and I shall be most happy to see that opinion publicly expressed through the medium of your pages.

I remain, Sir,
Your obedient servant
J. DREDGE.

METHOD OF PREPARING AND APPLYING A COMPOSITION FOR PAINTING IN IMITATION OF THE ANCIENT GRECIAN MANNER.

BY EMMA JANE HOOKER.

PUT into a glazed earthen vessel, four ounces and a half of gum-arabic, and eight ounces, or half a pint (wine measure) of cold spring water: when the gum is dissolved, stir in seven ounces of gum-mastich, which has been washed, dried, picked, and beaten fine. Set the earthen vessel containing the gum-water and gum-mastich over a slow fire, continually stirring and beating them out with a spoon, in order to dissolve the gum-mastich: when sufficiently boiled, it will no longer appear transparent, but will become opaque, and stiff, like a paste. As soon as this is the case, and that the gum water and mastich are quite boiling, without taking them off the fire, add five ounces of white wax, broken into small pieces, stirring and heating the different ingredients together, till the wax is perfectly melted and has boiled. Then take the composition off the fire, as boiling it longer than necessary would only harden the wax, and prevent its mixing so well afterwards with water. When the composition is taken off the fire and in the glazed earthen vessel, it should be beaten hard, and whilst hot (but not boiling) mix with it by degrees a pint (wine measure) or sixteen ounces more of cold spring water; then strain the composition, as some dirt will boil out of the gum-mastich, and put it into the bottles: the composition, if properly made, should be like a cream, and the colours, when mixed with it, as smooth as with oil. The method of using it is to mix with the composition, upon an earthen pallet, such colours in powder as are used in painting with oil, and such a quantity of the composition to be mixed with the colour as to render them of the usual consistency of oil colour; then paint with fair water. The colours, when mixed with the composition, may be laid on, either thick or thin, as may best suit your subject, on which account this composition is very advantageous, where any particular transparency of colouring is required; but in most cases, it answers best if the colours be laid on thick, and they require the same use of the brush, as if painting with body colours, and the same brushes as used in oil painting. The colours, if grown dry, when mixed with the composition, may be used by putting a little fair water over them; but it is less trouble to put some water when the colours are observed to be getting dry. In painting with this composition, the colours blend without difficulty when wet, and even when dry the tints may easily be united, by means of a brush and a very small quantity of fair water. When the painting is finished, put some white wax into a glazed earthen vessel over a slow fire, and when melted, but not boiling, with a hard brush cover the painting with the wax, and when cold take a moderate hot iron, such as is used for ironing of linen, and so cold as not to hiss if touched with anything wet, and draw it lightly over the wax. The painting will appear as if under a cloud till the wax is perfectly cold, as also, whatever the picture is painted upon is quite cold; but if, when so, the painting should not appear sufficiently clear, it may be held before the fire, so far from it as to melt the wax but slowly; or the wax may be melted by holding a hot poker at such a distance as to melt it gently, especially such parts of the picture as should not appear sufficiently transparent or brilliant; for the oftener heat is applied to the picture, the greater will be the transparency and brilliancy of colouring; but the contrary effects would be produced if too sudden or too great a degree of heat were applied, or for too long a time, as it would draw the wax too much to the surface, and might likewise crack the paint. Should the coat of wax put over the painting when finished appear in any part uneven, it may be remedied by drawing a moderately hot iron over it again as before mentioned, or even by scraping the wax with a knife; and should the wax, by too great or too long an application of heat, form into bubbles at particular places, by applying a poker heated, or even a tobacco-pipe made hot, the bubble will subside; or such defects may be removed by drawing anything hard over the wax, which will close any small cavities.

When the picture is cold, rub it with a fine linen cloth. Paintings may be executed in this manner upon wood, (having, first, pieces of wood let in behind, across the grain of the wood to prevent its warping), canvas, card, or plaster of Paris. The plaster of Paris would require no other preparation than mixing some fine plaster of Paris in powder with cold water the thickness of a cream; then put it on a looking-glass, having first made a frame of bees-wax on the looking-glass, the form and thickness you would wish the plaster of Paris to be of, and when dry take it off, and there will be a very smooth surface to paint upon. Wood and canvass are best covered with some grey tint mixed with the same composition of gum-arabic, gum-mastich, and wax, and of the same sort of colours as before mentioned, before the design is begun, in order to cover the grain of the wood or the threads of the canvas. Paintings may also be done in the same manner with only gum water and gum-mastich, and wax; but instead of putting seven ounces of mastich, and when boiling, adding five ounces of wax, mix twelve ounces of gum-mastich with the gum water, prepared as mentioned in the first part of this receipt; before it is put on the fire, and when sufficiently boiled and beaten, and is a little cold, stir in by degrees twelve ounces or three-quarters of a pint (wine measure) of cold spring water, and afterwards strain it. It would be equally practicable, painting with wax alone, dissolved in gum water in the following manner. Take twelve ounces or three-quarters of a pint (wine measure) of cold spring water and four ounces and a half of gum-arabic, put them into a glazed earthen vessel, and when the gum is dissolved, add eight ounces of white wax. Put the earthen vessel with the gum-water and wax upon a slow fire, and stir them till the wax is dissolved and has boiled a few minutes; then take them off the fire and throw them into a basin, as by remaining in the hot earthen vessel the wax would become rather hard; beat the gum-water and wax till quite cold. As there is but a small proportion of water in comparison to the quantity of gum and wax, it would be necessary, in mixing the composition with the colours, to put also some fair water. Should the composition be so made as to occasion the ingredients to separate in the bottle, it will become equally serviceable if shaken before used to mix with the colours.

I had lately an opportunity of discovering that the composition which had remained in a bottle since the year 1792, in which time it had grown dry and become as solid a substance as wax, returned to a cream-like consistence, and became again in as proper a state to mix with colours, as when it was first made, by putting a little cold water upon it, and suffering it to remain a short time. I also lately found some of the mixture composed of only gum-arabic water and gum-mastich, of which I sent a specimen to the Society of Arts in 1792; it was become dry, and had much the appearance and consistency of horn. I found, on letting some cold water remain over it, that it became as fit for painting with as when the composition was first prepared.—*The Art Union.*

An elegant painted window, designed and executed by Mr. Willement, of London has just been erected in St. George's Chapel, Edgbaston, by the subscriptions of the congregation.

ROADS AND CANALS IN INDIA.

The progress of internal communication in Bengal is developed at great length in a report made in the month of August last to the Government authorities by the military board, which, besides containing an account of what has been done during the official year ending April, 1841, gives a general review for the past twenty years. In this review we find the Grand Turk-road from Calcutta, described as the main artery of communication throughout Bengal and Hindostan, extending to a length of 770 miles, with a general breadth of thirty feet, increased in some places to forty. It has already 1,102 bridges of various extent of opening, has cost, exclusively of convict labour, 1,228,000 rupees, and is likely to cost 10 lacs more during the three years required for its completion. The road from Pooree to Bissenpore, which connects Orissa with Bengal, and which is commonly known as the Juggernauth road, is held to be of the next importance, and has cost about 15 lacs, or at the rate of 5,415r. the mile. The expense of the road from Calcutta to Kishnagur is estimated at 2,700,000r., or 4,756r. the mile for the seventy miles. The road from Sylhet to Gowhatty, the capital of Assam, across the Cassia hills, was in active preparation, and in this line of communication the two torrents of the Bur-panee and the Boga-panee are to be spanned with suspension-bridges. The Deccan road from Mirzapore to Jubbulpore, a distance of 239 miles and commenced in 1824, had been completed lately; its cost in the 15 years, exclusive of the labour of convicts, had been 8 lacs of rupees. Another road, small in point of expence, but of great importance, was also in progress from the eastern frontier of Bengal, through Cachar, and across the Munipore hills to the limits of the Burmese empire. Besides these roads, which are stated to be the most prominent, a variety of districts roads have added greatly to the local conveniences of the people, and have proportionately occupied attention. The total outlay for all the roads to which allusion is made has been 57,34,225r., and from which there is no return. A toll on a road is unknown.

The canals which fringe the eastern part of the city of Calcutta, and connected with the Isamuttee river, are of the highest importance to the welfare of the city, as the produce of all the eastern districts is thus brought to it with little or no risk. These have cost in the whole about 16½ lacs of rupees, which now includes the erection of five suspension bridges. To improve Tolly's Nullah, seven suspension bridges have been thrown across it at a cost of 179,381r. The canals west of the Jumna have been repaired at an expense of 1,566,500r., which, with a further outlay on the Dooab Canal, west of the Jumna, of 579,164r., makes, with other expenditure, a total outlay of 4,063,288r. in constructing and repairing canals in the presidency. The canals are very productive of revenue, for the tolls on those in the vicinity of Calcutta are said to yield on an average 121,800r. a year, while the annual average charge for their maintenance appears to be about 15,000 rupees. Hence it is argued, that the Government cannot do better than lay out funds for their extension and improvement. In reference to these canals it is remarked, that while the toll remained at the rate of one rupee the 100 maunds, the proceeds were 125,000r., but when the Government liberally reduced the levy by one-half, they fell in the succeeding year to about 60,000r. This fall, it was ultimately discovered, arose mainly from the corruption of the native collectors, which had been so far remedied by close observance, that in the last year (1840) the collection again rose to 122,000r., showing that the state receives the same return as when the import was double its present amount. The canals east and west of the Jumna exhibit the most gratifying results, not only in respect of the means they supply to the agricultural community for the irrigation of upwards of 100,000 acres of land, but indirect money returns. The sum expended on the canals west of the Jumna by the British Government has been 1,566,500r., and the annual amount levied as water rent is 258,826r., or more than 16½ per cent. While the outlay has therefore been in the whole 15½ lacs of rupees, the returns up to the end of the year 1840 had been 21½ lacs. In restoring the Dooab Canal, the cost to the government was 5 lacs and 80,000r. The direct return in rupees up to the end of 1840 has been 5 lacs and 13,000r. At the end of the official year, the whole sum expended by the Government had been reimbursed to the public coffers, and an annual income of 6,000r. might be expended for the future. The tolls on the Nuddea river produce a clear annual surplus of one lac and 12,000r. And now adverting more particularly to what has been done during the official year of 1840, we find that in the department of canals the Government has sanctioned an outlay of 23,000r. for deepening a canal in the Hedgelee district for the express object of facilitating the transportation of salt. The other expenses in connexion with canals have been incurred partly in reference to those near Calcutta, and partly to those on the east and west of the Jumna. The former appear to have cost in necessary repairs a sum of about 14,000r. independently of an iron suspension bridge at Ooltadanga, over the Circular Canal, amounting to 12,000r. On the Dooab Canal has been expended 71,500r. in the construction of aqueducts, with the view to the further extension of the benefits of irrigation. The total amount of money expended in canals during the year under consideration was 2,57,813r.; the returns 4,69,197r., being a clear profit of 2,11,384r. The new roads were progressing steadily. The road from Burdwar to Benares is completed, as far as regards earth work, to its full height and width. On this undertaking there had been an outlay of 6,00,000r., and it will require an equal outlay to complete it. The road from Patna to Gya would have the benefit of a grant of 70,000r., and for the road to Darjeeling a revised estimate of 28,000r. would be appropriated. The proposed road from Agra to Bombay had been negatived from the fact of the enormous expense it would entail. The total outlay in public works for that period was 9,69,686r., which produced a return of 4,69,197r., thus leaving 5,00,489r. as the difference between expenditure and return. On this the India journals remark that it is an expenditure of less than one per cent. on the land revenues of these provinces, and that however much the public may be grateful for these improvements, it exhibits much niggardness as compared with the revenue the Government authorities derives from the territory of which they are the useful and necessary embellishment.—*Times.*

COMMUNICATION FROM THE ATLANTIC TO THE PACIFIC OCEAN, ACROSS THE ISTHMUS OF DARIEN, OR PANAMA.

A project has been started for forming a road or railway communication from Chagres to Panama, which probably will not exceed in length 42 miles, and over a gross ascent between the two oceans of about 500 feet. It is proposed to be constructed on the surface, (that is, without a tunnel) thereby the danger arising from earthquakes will be much lessened.

It is stated that by this route, and using steam navigation across the Atlantic and Pacific oceans, the passage from England to the colonies of New Zealand, Van Dieman's Land, and to Australia generally, may be reduced from five months to ten weeks, and also that the passage from England to the coast of Chili and Peru, would be reduced to 35 or 40 days. The advantages of a road or way across the isthmus will be very great, not only to England but to the whole of Europe and America. Steam packets will shortly be established between England and the Atlantic shore of the Isthmus; steam boats are already working along the coast of Chili and Peru, and there is little doubt that a complete steam navigation will be effected within a short time from Panama to New Zealand and other British colonies in New South Wales.

It only remains, therefore, (to render this route perfect) to construct a road or railway across the neck of land, and to show that every facility would be afforded by the government of New Granada, in the execution of such a work, that Congress is willing to grant extensive privileges on those parties undertaking the project.

Pile-driving Machine.—An ingenious machine for driving a double row of piles, has recently been imported from the United States. It was built at Utica, and has the national name "Brother Jonathan" inscribed on it. It is now in operation at Smith's timber wharf, Pedlar's Acre, where it can be seen driving the piles for the causeway and abutment on the Surrey side of the New Hungerford Market Bridge, now in progress. The rams or "monkeys" are elevated to a height of 35 feet or thereabouts, along grooves in perpendicular ladders, similar to the ordinary machine, by means of a locomotive steam engine of 10-horse power, fixed on a platform, on which the whole of the machinery is placed. The power of the blow given by each of these hammers exceeds 600 tons, and drives a pile of 27 feet long, and as thick as the thickest piles used in embankments and for coffer-dams, nearly its whole length into the earth in about eight minutes, or perhaps less. It drives two piles at the same time. A circular horizontal saw is worked by the engine, which, in a few seconds, cuts the tops of the piles even, and enables the trucks, or small wheels on which the platform is supported, to come forward as fast as the piles are driven, and cut them even at the top; The power of this machine is astounding, and requires to be seen to be fully estimated. It is an important application of steam power, likely to produce very beneficial results in public works, in the formation of sea banks, and in all operations on a large scale where rapidity of execution and precision are required. The machine was used in America for driving piles for railways; and travelled by its own power upwards of 200 miles, driving piles, and making its own road through swamps and districts heretofore impervious. It is patented in this country, and also in the United States. The machine has, moreover, the power of drawing piles out of the earth as quickly as it drives them in, and can be applied to the raising of blocks of stones, and all heavy weights that require an extraordinary power. It is almost indispensable for all persons immediately connected with engineering and science to see it. We hope next month to be able to give drawings and a description of the machine.

REPORT FROM THE SELECT COMMITTEE ON FINE ARTS.

The report of the above committee, together with the minutes of evidence taken by them, have been printed by order of the late House of Commons. Amongst the witnesses examined were Mr. C. Barry and Sir Martin A. Shee. We shall now proceed to give an abstract.

The committee commence by stating, that although the then approaching dissolution compelled them to conclude their inquiry somewhat abruptly, still they have obtained the opinions of some distinguished professors and admirers of art, who are unanimously of opinion that so important and national a work as the erection of the two Houses of Parliament affords an opportunity which ought not to be neglected of encouraging not only the higher but every subordinate branch of fine art in this country. In this opinion the committee state their entire concurrence, supported as it is by witnesses of extensive information, and by artists of the highest ability. The committee, however, in recommending that measures should be taken without delay to encourage the fine arts, by employing them in the decoration of the new Houses of Parliament, desire to express their decided opinion, that, to accomplish this object successfully, it is absolutely requisite that a plan should previously be determined upon, and that as soon as practicable, in order that the ar[illegible] they may [illegible] with [illegible].

The committee are not, in the present stage of the inquiry, prepared to suggest the details of a plan; but they think that a commission might most usefully be appointed [illegible] depart[illegible] of the Government [illegible] consideration, should be solely [illegible] the execution of the plan [illegible] to realize the objects of the committee.

Whether, however, a commission be appointed or not, the committee think that it is most desirable that the advice and assistance of persons should be sought, who are competent, from their knowledge of art, and their acquaintance with great public works, both at home and abroad, to give, in conjunction with the architect, the most effectual means of [illegible] of [illegible] the appointment of the committee [illegible] at the fine arts of this country. By taking this course, the [illegible] and the other artists will be enabled to understand and assist each other's views; and thus the abilities of both would be exerted for the decoration of so eminently national a building, and, at the same time, encouragement, beyond the means of private patronage, would be afforded, not only to the higher walks, but to all branches of art.

The committee state that their attention has been called to one branch of the fine arts hardly known in this country—namely, fresco painting, which has lately been revived on the continent, and employed in the decoration of public buildings, especially at Munich. The space which it demands for its free development, and the subjects which it is peculiarly fitted to illustrate, combine to point out national buildings as almost the only proper sphere for the display of its peculiar characteristics—grandeur, breadth, and simplicity. The committee, after a careful consideration of the evidence, are disposed to recommend that this style or mode of painting should be adopted. They fully concur in the opinion of Mr. Eastlake, that England possesses artists equal to the occasion, whose genius only wants that exercise and encouragement which this great opportunity may be made to afford. But the committee suggest, that if fresco painting should be employed in the decoration of certain portions of the new buildings, it would be a safe and judicious plan to give the artists an opportunity of making some experimental efforts in the first instance.

The committee then quote a passage from a valuable paper on fresco painting, written by Mr. Eastlake, given in the Journal of last month.

With reference to another branch of the inquiry—the cost incident to an extensive and well-devised plan for the public patronage and encouragement of art—the committee, notwithstanding that they are aware that objections are entertained by many to a large expenditure of the public money for such a purpose, are of opinion, independently of the beneficial and elevating influence of the fine arts upon a people, and every pecuniary outlay, either for the purpose of forming or extending collections of works of art in this country, has been directly instrumental in creating new objects of industry and of enjoyment, and therefore in adding at the same time to the wealth of the country.

The committee state, that the collection of vases made by Sir W. Hamilton led to the introduction of a new branch of manufacture in this country by Mr. Wedgwood, which not only employed artists and artizans, but tended to improve every branch of a great staple trade, and in its results elicited from the hands of comparatively ordinary workmen works almost rivalling their originals in texture, form, and beauty. The committee further remark, that the collection of Sir W. Hamilton's ancient Greek vases (for the purchase of which a sum of £8,400 was granted by Parliament) was a great acquisition to the country, and ought to have opened the eyes of the Government to the utility arising from similar acquisitions. "The discovery of these vases (the committee observe), and their communication to the public by engravings, coinciding with the discoveries of Herculaneum and Pompeii, may be considered an essential epoch in the history of the arts, and which contributed greatly to their revival."

The committee observe that the beneficial influence of art upon the character of the people may, it is hoped, be inferred from the gradually increasing numbers, of late years, who take an interest in the national collections. This fact has been fully proved by the report of the select committee on "national monuments and works of art," of which we, some time ago, laid an abstract before our readers. "The habit," says Reynolds, "of contemplating and brooding over the ideas of great geniuses till you find yourself warmed by the contrast, is the true method of forming an artist-like mind. It is impossible, in the presence of those great men, to think or to invent in a mean manner; a state of mind is acquired that receives ideas only which relish of grandeur and simplicity."

As then the collection and exhibition of works of art have not only tended to the moral elevation of the people, but have also given a fresh stimulus and direction to their industry, so the committee is of opinion that a direct encouragement of the higher branches of art on this occasion will have a similar effect in a still higher degree.

The committee then refer at some length to the evidence given by Mr. T. Wyse, the late M.P. for the city of Waterford, and one of the Lords of the Treasury. We regret that our space will not allow us to enter into a detail of it; the evidence of Mr. Wyse goes to show the effect produced upon a nation and its industry by the public patronage of the fine arts, which he illustrated by the example of Bavaria, &c.

The committee, after referring to the evidence of Mr. Dyce, thus conclude their report:—

"Your committee, from the abrupt termination of the session, and consequently of their inquiry, have not had the opportunity to form any fair estimate of the expense of carrying out the views here stated; but they are, however, of opinion, that judging from the manner in which great works have been effected on the continent, and by the adoption in the outset of a well-considered plan for the employment of artists, and the application of the arts, a moderate annual expenditure would accomplish very important results, if not all that can be desired. They think that the very fact of a [illegible] by the [illegible] of the opportunity of encouraging the arts, by associating them with our public architecture, our legislation, our [illegible], and our history, would alone stimulate and raise their character and quality, and extend their beneficial influence over a still wider circle. "I consider it," says Sir M. A. Shee, "a most favourable opportunity for calling forth the genius of our country, and promoting the fine arts to the utmost extent of which they are capable; it is the only opportunity that has occurred for many years, and if it be suffered to pass unheeded, I should say that there is no hope in this country for artists in the higher departments of the arts."

"Whilst your committee, in conclusion, regret that they could not investigate the whole subject so fully as they desired, and as its importance demanded, they unanimously recommend the evidence herewith presented to the house to its favourable consideration, with a view to its receiving the immediate attention of the Government, and in the hope that our new Houses of Parliament may hand down to posterity a memorial, as well as the genius of our artists, as of the importance attached by the country to the nobler productions of art; and that the subjects embodied in such representations, whether by painting or sculpture, may serve to perpetuate the events of the past history, and the persons of our public benefactors, in the grateful remembrance of the people."

Whitehall, November 22, 1841.—The Queen has been pleased to appoint His Royal Highness Prince Albert, K.G., the Right Honourable Lord Lyndhurst, his Grace the Duke of Sutherland, K.G., the most Honourable the Marquess of Lansdowne, K.G., the Right Honourables the Earl of Lincoln, the Earl of Shrewsbury, the Earl of Aberdeen, K.T., Lord John Russell, Lord Francis Egerton, Viscount Palmerston, G.C.B., Viscount Melbourne, Lord Ashburton, Lord Colborne, Charles Shaw Lefevre, Sir Robert Peel, Bart., Sir James Robert George Graham, Bart.; Sir Robert Harry Inglis, Bart., Henry Gally Knight, Esq., Benjamin Hawes, jun., Esq., Henry Hallam, Esq., Samuel Rogers, Esq., George Vivian, Esq., and Thomas Wyse, Esq., Her Majesty's Commissioners for inquiring into the best mode of promoting the Fine Arts in the United Kingdom.

ON INCREASING THE EVAPORATING POWER OF BOILERS.

At the general monthly meeting of the Polytechnic Society, Liverpool, Mr. Williams read a paper on increasing the evaporating power of boilers who was provided with a number of working models wherewith to illustrate his views, addressed the meeting in a very clear and scientific manner on this important subject, developing a most interesting discovery of his own, which (already practically tested) will be extremely valuable as effecting a more rapid generation of steam, without increasing the size of the vessel, or the requirement of additional fuel. The question, he said, involved the improvement of our boilers by a very simple contrivance, whether as applied to land engines, or to the advancement of steam navigation. There were two leading considerations in the application of fuel, which were, unhappily, confounded; one the generation of heat; and the other, its application. The first appertained more peculiarly to chemical science; and the second, to mechanical appliance. The object in view was, to transmit the greatest possible amount of heat for the generation of steam, with a given quantity of fuel. Heat was imparted by two distinct media, namely, radiation and conduction. By radiation, heat was conveyed to bodies not placed in contact, as was evinced by placing the hand pretty close to the flame of a candle. By conduction, heat was conveyed by metal or other substances not consumable. In the heating of boilers, both modes were necessarily operative. In radiation, the evolved proceeded in direct lines, or radii, from the combustion to the boiler or other body exposed to it. If a thermometer were placed with the ball near the candle, the mercury would rise by radiation; but if placed immediately over the flame, the heat would be greater, but different in the mode; for, in this case, it was not fairly radiation, but a compound medium, radiation and the heated and ascending gas being combined. The speaker then exhibited the model of a boiler, with its tortuous flues, through which the several gases passed; and expressed his conviction, that nine-tenths of the heat in marine and land engine boilers was immediately received from the furnace and flame-bed, and not from the gases, which might be made available to the same end by an improved construction of boiler. The general opinion of parties working steam engines was, that to increase the size of the furnace would add to the heating of the whole boiler; but this, he considered, was treating the boiler with great neglect, for the object could be accomplished without such increase of the furnace. The means of conducting heat to water in boilers had been much neglected, reliance being almost solely placed on increasing the length of the flues. His plan was to insert a number of iron pins through the plates of the boiler, one end of them projecting into the flue and the other into the water in the boiler. These pins, exposed at one end to the heat in the flue, acted as powerful conductors, through the boiler-plates, of the heat into the water. Hitherto, the question of the mere surface of plate exposed to the flues had been alone considered; and the only remedy for defective generation of steam was conceived to be an increase of that surface. The conducting pins, however, were found to arrest the heating gases in their progress along the plates of the boiler, and greatly to hasten the generation of steam. A pin of half-an-inch in diameter projecting three inches into the flue, gave a heating surface of $1\frac{1}{2}$ inches, and by its conducting power and interior projection (as we understood the speaker) that half-inch gave as much heat as $9\frac{1}{2}$ inches on the outer surface of the plate. Air was a good conveyor, but a bad conductor of heat; for it carried most of it out of the chimney. His object was to arrest the heat in its progress, and give it out at the right place. The current of heat passing along the plates of the boiler rendered them only traverse conductors; but the heated pins were longitudinal conductors. He also showed several iron pins that had long been experimentally in use in the boiler of a steam vessel with great success. He had endeavoured to ascertain the proper lengths of which they should be, so as to remain as durable conductors of heat. One of seven inches in length had become slightly oxidized. Another, of 4 inches long, was so little affected that the smallest mark of the hammer, which it ordinarily bore, was distinctly visible. He, therefore, considered about 4 inches to be the proper length. He further illustrated his invention by three evaporating pans, one of them with pins projecting into the boiler and also into the flues, which he called double conductors; another with pins projecting into the flue only, called single conductors; and the third, a plain boiler, on the usual plan without any such conductor. The first he had found the more powerful in producing speedy evaporation; though the second was scarcely inferior. The third, or plain boiler, was greatly behind either in evaporating power. A gas lamp was affixed at one end of the double conducting pan, containing 22 lb. of water, and the evaporation appeared to be rapid. With 30 feet of gas the evaporation was as follows:

	Evaporation.		Waste Heat.
Common Pan	1 lb.	14 oz.	408
Single Conductors	7	13	320
Double Ditto	8	5	284

Here we see the quantity evaporated is in an inverse ratio to the waste heat by the chimney. He had tried them often with precisely the same results, so that there could be no error.

He then combated, in a clear and comprehensive manner, an opinion expressed by Dr. Fyfe, of Scotland, in a tract published by him, that anthracite was the best fuel or coal for engine boilers. That opinion was founded solely on the fact that anthracite contained the greatest quantity of fixed carbon or, in other words, left the greatest residue of coke. He differed from the deduction of the doctor, with whom he had corresponded on the subject. That gentleman had begun at the wrong end; he should have considered not the fuel alone, but the vessel in which it was consumed. He (Dr. F.) had taken no means to ascertain the quantity of heat that escaped in the gases or by the chimney. He had set down the hydrogen at nought, because he had not had the power of consuming it by the common furnace and boiler. He (Mr. W.) felt certain that the common Scotch coal was superior, if properly employed.

Mr. Williams's communication was listened to with great attention, and he was frequently greeted by bursts of applause. Shortly before he concluded, Mr. Dunance, engineer of the Liverpool and Manchester Railway, stated that he had tried the pins on the lecturer's principle in the boiler of one of their stationary engines with great success. He had only 105 pins driven into the boiler, and the steam, which could not before be kept up, was now abundant.

The Chairman then invited discussion on the subject, and some doubts were expressed and questions put as to the advantages of the invention, all of which were ably replied to by Mr. Williams, and ended in the complimentary acknowledgment of all who demurred, and the concurrence of all who were present, that the invention constituted a valuable and immense practical improvement in the construction of engine boilers.—*Liverpool Albion.*

FINAL TRIAL OF THE DEVASTATION STEAM FRIGATE

Commander Hastings Reginald Henry, and all the officers of this fine vessel attended on Tuesday Nov. 2 on board, to make a final trial of her capabilities previous to the engines being reported upon to the Lords Commissioners of the Admiralty. At 11 o'clock in the forenoon Captain the Hon. J. F. F. De Ros, R.N. and F.R.S.; Captain the Hon. Edward Plunkett, R.N., and several scientific gentlemen; Messrs. Maudslay and Field, engineers; and Mr Ewart, chief engineer of the Woolwich Dockyard, went on board, and shortly afterwards the vessel was loosed from her moorings, off Woolwich, proceeded down the river to Long Reach, to the measured ground, where the speed of steam-vessels is ascertained with the greatest correctness.

On this occasion the Devastation, for the purpose of giving her a fair trial, and testing her powers, had a cargo of 320 tons of coal put on board, and 61 tons of water in casks. Her draught of water was 13 feet 4 inches forward, and 14 feet aft, which afforded her paddle-wheels a depth of water sufficient to propel her with greater velocity than on the former occasion, although the strokes of the engine were only the same number, about 18 to 19 per minute. She accomplished the measured mile against the tide in 5 minutes and 48 seconds, and with the tide and against the wind in 4 minutes and 42 seconds, being nearly at the rate of 12 and 1-5th statute miles on the average per hour. Mr. Ewart, the chief engineer, whose duty it will be to report as to the efficiency of the engine, and the speed of the vessel, expressed himself in the highest terms relative to the ease and smoothness of her motion, and added, that "he never timed any that could approach her in speed before, and he was of opinion she was decidedly the fastest vessel in Her Majesty's navy."

The result of this trial is one of great importance to the country, and of which it has reason to be proud, as the engines are the simplest, as they have proved to be the most efficient, of any yet introduced to public notice, and on that account our steam navy will be far superior to the steam navy of any other country. Messrs. Maudslay and Field have done themselves great credit by the liberality with which they undertook to fit this vessel, as a specimen of the advantages of their invention, and are deserving of the complete success they have met with, and there can now be no doubt their engineer will be introduced into all the new powerful vessels built for Her Majesty's service in future. The disconnecting roller was tried during this trip, and in one minute and a quarter one of the powerful paddle-wheels, 25 feet in diameter, was detached from the engines, and the whole of their power applied to the other wheel. In three quarters of a minute the stupendous lever of the wheel was again attached, and the vessel sped through the water with the greatest velocity. On returning up the river, she overtook the Manchester and Duchess of Kent large steam vessels, and their crews appeared astonished that the Devastation had got so far a-head of them before they arrived opposite Woolwich.

The Lords Commissioners of the Admiralty have very judiciously complied with the application of Commander Henry, and ordered one of Porter's anchors, of 28 cwt., for the Devastation, and it was delivered at the dockyard yesterday, for the purpose of being tested. Commander Henry Boye, of the Vixen steam frigate, of the same mould as the Devastation, has obtained an order to be supplied with one of Porter's anchors of the same weight, to be delivered in about a fortnight.

MISCELLANEA.

Kent.—The ceremony of laying the first stone of a new church at Platt, in the parish of Wrotham, was performed on the 8th ult., in the presence of a large concourse of spectators, by the daughter of the rector of Wrotham, the Rev. Geo. Moore. The architects are Messrs. Whitehead and Walker, of Maidstone. The church about to be erected is on a site, the gift of — Lombard, Esq., being part of three acres of land which it is contemplated to lay out in a picturesque and advantageous manner, in building a parsonage house, school rooms, and alms-houses. The church will be built of Kentish rag stone, in the early pointed style, and is cruciform on plan. The dimensions within the walls (exclusive of the tower) are 78 feet from east to west, and 60 ft. 6 in. from north to south, by 25 ft. 6 in. in width. It has a tower at the west end 70 ft. in height and 21 feet square, with an octangular turret at the north-eastern angle, in which is a stone staircase, leading to the various floors, and roof, of the tower. The organ gallery (the only one in the church) is situate in the tower, and is lighted by a large 3-light window in the western wall. The chancel has a corresponding window, under which is a series of small pointed arches, and on either side a niche to serve as a seat for the officiating minister. The roof is an ornamental open timber-framed roof, with hammer beams and moulded ribs running down, and resting on stone moulded corbels. At the intersection of the transepts, the trusses are placed diagonally. The church will contain sittings for 500 persons, 120 in pews, 210 in free seats, and 170 for children. The pews are placed in the transepts, the free seats in the nave, and the children on raised seats, at the west end of nave, and in the organ gallery. The ends of all the seats next the aisles, are moulded and finished with a carved finial. The pulpit and reader's desk are placed at the south-east angle of the intersection of the nave and transepts. The total cost of the church will not exceed £2500.

Tracing Paper.—We have received from Mr. Dixon a sample of drawing paper made perfectly transparent for the purpose of tracing off drawings, which will be a great acquisition to the profession, that was much wanted, the ordinary tracing paper being too flimsy for general use.

Sir Francis Chantrey.—We regret to announce that this highly talented sculptor, died suddenly on the 26th ult.

The following is a summary of a comparative statement of houses inhabited, &c., in Great Britain and islands in the British seas in 1801, 1811, 1821, 1831, 1841:—

	Houses Inhabited.	Uninhabited.	Building.
1801.			
England	1,467,870	53,965	
Wales	108,053	3,511	
Scotland	299,553	9,537	
1811.			
England	1,678,006	47,925	15,189
Wales	119,398	3,095	1,019
Scotland	304,093	11,329	2,341
1821.			
England	1,951,973	66,055	18,289
Wales	136,183	3,652	985
Scotland	341,474	12,657	2,405
Islands in British Seas	13,763	427	98
1831.			
England	2,326,022	113,885	23,462
Wales	155,522	6,030	1,297
Scotland	369,393	12,719	2,568
Islands in British Seas	15,658	697	226
1841.			
England	2,753,295	162,756	25,882
Wales	188,196	10,133	1,769
Scotland	503,357	24,307	2,760
Islands in British Seas	19,159	865	220

The Foundation Stone of a New Church at Manchester.—The committee of the Ten Churches Association have commenced, on Pin Mill Brow, the erection of ... [illegible] ... the Church St. S... [illegible] ... built in the Norman ... architecture ... are towers surmounted by octagonal spires ... the windows ... and ... columns. Messrs. Stark and Co. are the architects. The dimensions of the church are 56 feet by 90, and it is calculated to accommodate about 1,100 persons. One-half of the sittings are to be free.

Opening of the Sheffield and Manchester Railway.—On the 17th ult. a portion of this line of railway extending from Manchester to Godley, a distance of seven miles, was opened to the public. At present but a single line of rails is laid, so that the train at one end leaves immediately after the arrival of the train from the other, by which all danger of accident from collision is avoided. The line, so far as it is yet open, after the first embankment and the viaducts, is chiefly in cuttings. It was inspected by Sir Frederick Smith last week, who certified to the perfect stability of the works and its fitness for opening. There are three engines at present on the line with their tenders, and three first-class, five second-class, and six third-class carriages. The engines were manufactured by Messrs. Kirtley and Co., of Warrington, and the carriages are from the manufactories of Messrs. Dunn and Son, Lancaster, Messrs. Allcard and Co., Warrington, and Mr. Bradley, of Sheffield.

Thames Tunnel.—A thoroughfare was effected in this work on the 14th ult., and made use of for the first time by the whole of the directors and some of the original subscribers, who had assembled upon the occasion. The shield having been advanced to the shaft at Wapping, a considerable opening was cut in the brickwork, and it was through this the party who had met at Rotherhithe were enabled to pass, thus opening the first subterranean communication between the opposite shores of the river. Upon their arrival at the shaft the party was greeted by the workmen with most hearty cheers. The engineer, Sir J. Brunel, appeared highly gratified at the happy result of all his past anxiety and arduous labour. The shield will continue its advance until it has afforded space for the formation of the remainder of the tunnel, which is expected to be completed in about three weeks.

LIST OF NEW PATENTS.

GRANTED IN ENGLAND FROM 2ND NOVEMBER, TO 28TH NOVEMBER, 1841.

Six Months allowed for Enrolment.

William Golden, of Huddersfield, gun-maker, and John Hanson, of the same place, lead-pipe manufacturer, for "*certain improvements in fire-arms, and in the bullets or other projectiles to be used therewith.*"—November 2.

Thomas Macauley, of Curtain-road, upholsterer, for "*certain improvements in bedsteps, which are convertible into other useful forms or articles of furniture.*"—November 2.

Robert Logan, of Blackheath, Esq., for "*improvements in obtaining and preparing the fibres and other products of the cocoa nut and its husk.*"—November 2.

Robert Holt, of Manchester, cotton-spinner, and Robinson Jackson, of Manchester, aforesaid, engineer, for "*certain improvements in machinery or apparatus for the production of rotary motion, for obtaining mechanical power, which said improvements are also applicable for raising and impelling fluids.*"—November 2.

Moses Poole, of Lincoln's-inn, gentleman, for "*improvements in machinery, used in the manufacture of bobbin-net or twist lace.*" (Being a communication.)—November 2.

Henry Kirk, of Tavistock-square, gentleman, for "*a substitute for ice for skating and sliding purposes.*"—November 2.

William Brunton, of Neath, Glamorganshire, engineer, for "*an improved method or means of dressing ores and separating metals or minerals from other substances.*"—November 2.

Jeremiah Bynner, of Birmingham, lamp-maker, for "*improvements in gas burners.*"—November 2.

Edward Robert Simmons, of Croydon, Esq., for "*improvements in apparatus for preventing splashing in walking.*"—November 2.

Henry King, of Webber-row, Westminster-road, engineer, for "*certain improvements in steam engines and boilers.*"—November 4.

Jules Lejeune, of North-place, Cumberland-market, manufacturing chemist, for "*a means of condensing and collecting the sulphurous and metallic vapours which are evolved in the treatment by heat of all kinds of ores.*"—November 4.

Job Cutler, of Ladypool-lane, Birmingham, gentleman, for "*improvements in the construction of the tubular flues of steam-boilers.*"—November 6.

John Carr, of North Shields, earthenware manufacturer, and Aaron Ryles, of the same place, agent, for "*an improved mode of operating in certain processes for ornamenting glass.*"—November 9.

Jesse Ross, of Leicester, manufacturer, for "*a new wool-combing apparatus.*"—November 9.

Henry Davies, of Birmingham, engineer, for "*certain improved machinery suitable for applying power to communicate locomotion to bodies requiring to be moved on land or water.*"—November 9.

Jesse Smith, of Wolverhampton, lock-maker, for "*improvements in the construction of locks and latches, applicable for doors and other purposes.*"—November 9.

William Edward Newton, of Chancery-lane, civil engineer, for "*certain improvements in the production of ammonia.*" (Being a communication.)—November 9.

William Palmer, of Sutton-street, Clerkenwell, manufacturer, for "*improvements in the manufacture of candles.*" (Being partly a communication.)—November 9.

John Garnett, of Liverpool, merchant, and Joseph Williams, of Liverpool, aforesaid, manufacturing chemist, for "*an improved method of manufacturing salt from brine.*"—November 9.

John Burnell, the younger, of Whitechapel, manufacturer, for "*improvements in the manufacture of leaves or sheets of horn, commonly called lantern leaves, and in the construction of horn lanterns.*"—November 9.

John Edwards, of Cow Cross-street, gentleman, for "*an improved strap or band, for driving machinery, and for other purposes.*"—November 9.

James Stewart, of Osnaburgh-street, St. Pancras, pianoforte maker, for "*certain improvements in the action of horizontal pianofortes.*"—November 11.

George Allarton, of West Bromwich, Stafford, surgeon, for "*certain improvements in the method of balling and blooming iron.*"—November 11.

John Peter Booth, of Hatton-garden, feather-merchant, for "*certain improvements in the manufacture of a substance, or compound fabric, which will be applicable to the making of quilts, coverlets, and wadding, for purposes of clothing or furniture.*"—November 11.

Isaac Davis, of New Bond-street, optician, for "*improvements in the manufacture of sealing wax, which compounds are applicable to other useful purposes.*"—November 11.

Edward Joseph Francois Duclos de Boussois, of Clyne Wood, Metallurgical-works, Swansea, for "*improvements in the manufacture of copper.*"—November 11.

John Onions, of Field-lane, Barlaston, Stafford, engineer, for "*improvements in the manufacture of certain descriptions of nails, screws and chains.*"—November 11.

James Young, of Newton-le-Willows, chemist, for "*certain improvements in the manufacture of ammonia and the salts of ammonia, and in apparatus for combining ammonia, carbonic acid, and other gases with liquids.*"—November 11.

Isaac Dodds, of Sheffield, engineer, for "*certain improvements in the modes or methods of supplying gas for the purpose of illuminating towns and other places.*"—November 13.

Henry Mortimer, of Frith-street, Soho, gentleman, for "*improvements in covering ways and surfaces, and in constructing arches.*"—November 16.

John Squire, of Albany-place, Regent's-park, engineer, for "*certain improvements in the construction of steam boilers or generators.*"—November 16.

Robert Stirling Newall, of Gateshead, Durham, wire-rope manufacturer, for "*improvements in the manufacture of flat bands.*"—November 16.

John Venables, of Burslem, in the county of Stafford, earthenware manufacturer, and John Tunnicliff, of the same place, bricklayer, for "*a new and improved method of building and constructing ovens used by potters and china-manufacturers in the firing of their wares.*"—November 20; two months.

William Manwaring, of York-street, Lambeth, engineer, for "*certain improvements in the manufacture of sugar.*"—November 23.

Richard Gurney, of Trevinnion-house, Cornwall, for "*a method of cutting wood and incrusting the same in order to present a sure footing for horses and other purposes.*"—November 25.

TO CORRESPONDENTS.

Communications on the Tractive Power of Paddle Wheels—On Atlantic Steam Navigation—and on Steam Locomotion on Common Roads, will appear next month.

The Fourth Report on both banks of the River Hull, and also Mr. Denton's suggestions for a Bill for Drainage of Land, will be noticed in the next Journal.

A Constant Reader.—*The First Volume of Bruff's Engineering Field Work has been published.*

E. *If we can be furnished with Lists of Iron Steamers built by the various Builders, similar to the one of Messrs. Fairbairn & Co., inserted some time back in our Journal, we shall be happy to publish them.*

A Correspondent who wishes to know what is the qualification requisite to be admitted into the Institution of Civil Engineers, had better apply to the Secretary in George Street, Westminster.

Communications are requested to be addressed to "The Editor of the Civil Engineer and Architect's Journal," No. 11, *Parliament Street, Westminster.*

Books for Review must be sent early in the month, communications on or before the 20th (if with drawings, earlier), and advertisements on or before the 25th instant.

The present Number completes the Fourth Volume: the Index, Title-page, &c., will be given with the next Number.

Vols. I, II, III, and IV, may be had, bound in cloth, price £1 each Volume.

INDEX.

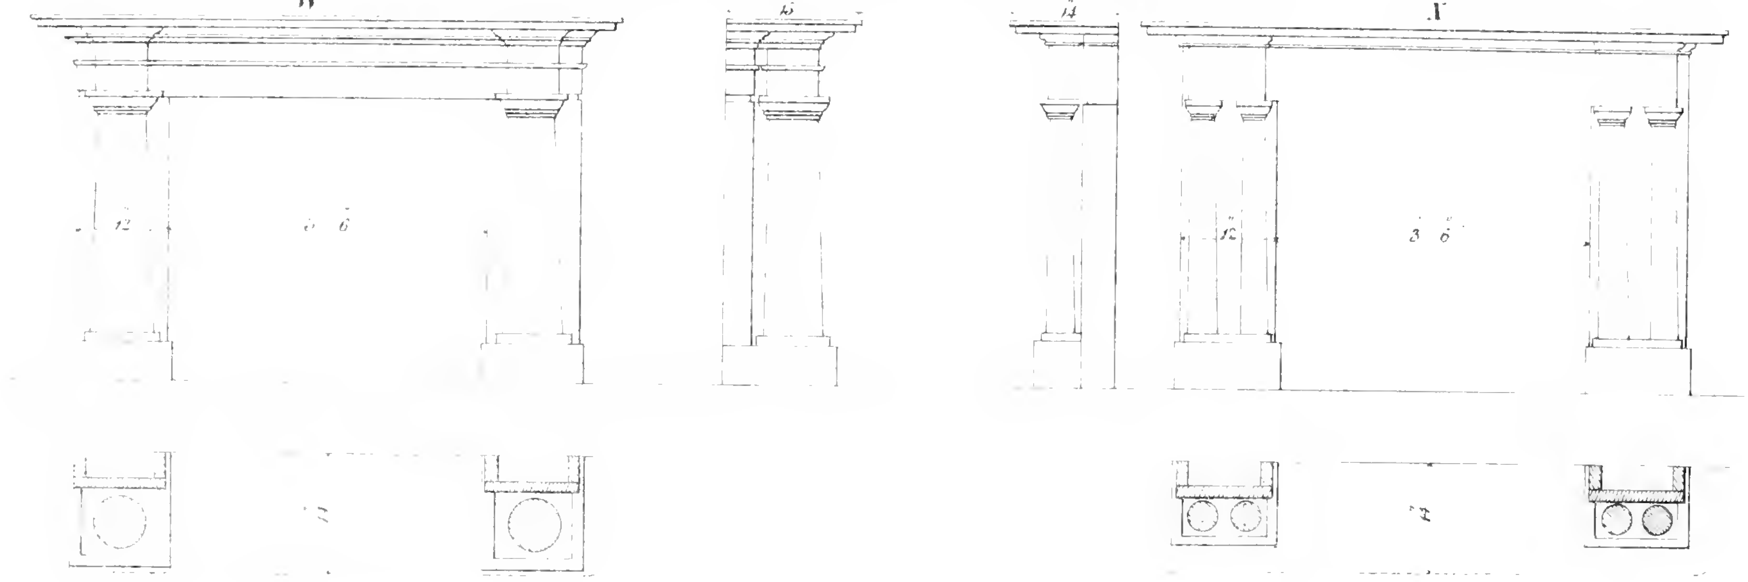
INDEX TO PLATES AND ENGRAVINGS.

DIRECTIONS TO BINDER.

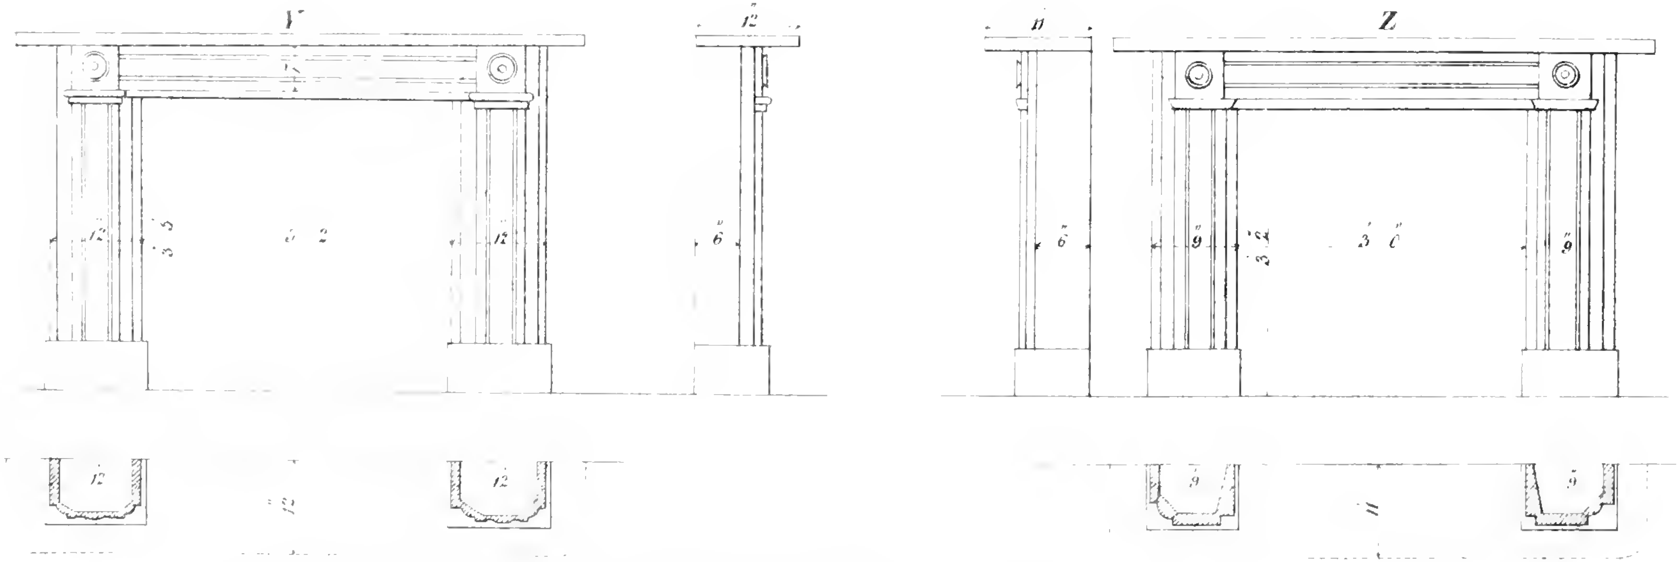
Grundy & Compy.

Foreign & British Marble Factory,

1, EARL STREET, HORSEFERRY ROAD, WESTMINSTER



The Patterns run Alphabetically from A to Z. by directing to the Factory parties may be supplied with all particulars as to Prices



The Proprietors of the above Factory have made extensive arrangements in supplying Chimney Pieces Manufactured by Machinery in a superior manner at reduced Prices.
